THE absorption and dispersion of liquid water in the radio-frequency and far-infra-red regions have been the subjects of numerous investigations over the past 20 years. The position in 1948 was reviewed by Magat[1], who was of the opinion that the dispersion could be divided into two parts; the first, occurring at wave-lengths greater than 1 mm, was associated with the non-resonant viscously damped reorientation of dipoles (the Debye process), and the second, occurring at wave-lengths less than 1 mm, was due to resonant absorption by the intramolecular modes of the liquid lattice. However, experimental observations in the region from 10 cm^{-1} to 100 cm^{-1} were few and of unknown reliability. Since much higher power sources are now available[2] measurements of greater accuracy can be made and there is an incentive to have these results in that they are needed in making improved calculations of atmospheric attenuation.

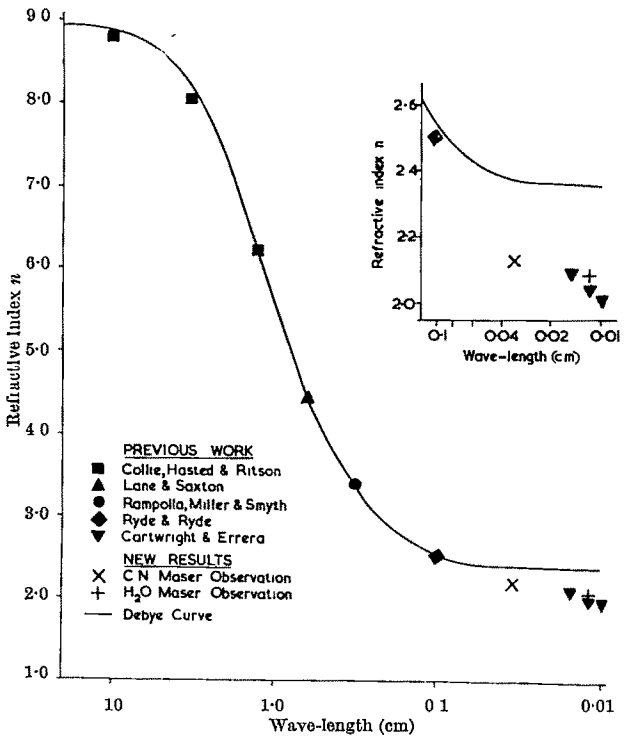

Fig. 1. Dispersion of liquid water at 20° C. The Debye curve is calculated from the parameters given in ref. 3 The inset shows an enlarged section of the lower portion of the graph

Refractive Index

Measurements have been made with a CN maser (frequency 29·7 cm^{-1}) and with a water vapour maser (frequency 84·6 cm^{-1}) using the method of determination of the absolute reflectivity at normal incidence. The results for water at 20° C are $n^2 = 4{\cdot}55 \pm 0{\cdot}08$ and $4{\cdot}30 \pm 0{\cdot}08$, respectively; and for heavy water at 20° C $n^2 = 4{\cdot}07 \pm 0{\cdot}09$ at 29·7 cm^{-1}. The data for water are plotted in Fig. 1 together with earlier microwave and far-infra-red values[4–7]. In Fig. 1 is also shown a Debye curve determined from the microwave points of Collie, Hasted and Ritson[3]. The increasing departure from Debye behaviour is clearly seen at high frequencies. If the parameter ε_∞ which Collie, Hasted and Ritson determine from their microwave data is chosen to agree with n^2 at 84·6 cm^{-1} then poor agreement is obtained at the intermediate frequencies. In fact, a good fit to the microwave and submillimetre data cannot be obtained with a Debye function.

The temperature dependence of the refractive index at 29·7 cm^{-1} has been measured over the range from 20° C to 85° C. The results are shown in Fig. 2 and it will be seen that the index rises by about 8 per cent for a 50° C increase in temperature.

Absorption Coefficient

The absorption coefficient α for liquid H_2O at 29·7 cm^{-1} and 20° C is found to be 200 ± 10 nepers/cm. The absorption due to the Debye process should reach an asymptotic value at high frequencies given by:

$$\alpha_\infty = \frac{(\varepsilon_0 - \varepsilon_\infty)\, 2\pi}{\sqrt{\varepsilon_\infty}\, \lambda_c}$$

where ε_0, ε_∞ are the dielectric constants at zero and very high frequency, respectively, and λ_c is the critical wave-length. For water, with the parameters of Collie, Hasted and Ritson this asymptotic value should be 111 nepers/cm, that is about half the observed value. We have determined the absorption spectrum of liquid water from 10 cm^{-1} to 100 cm^{-1} using an interferometer. Very thin samples had to be used (approximately 50μ thick) and the thickness of these was determined by measuring the attenuation at 29·7 cm^{-1} using the CN maser. Our results are shown in Fig. 3 together with those of other workers[8,9]. The steeply rising absorption has been found[9] to reach a maximum at 193 cm^{-1} as a shoulder on a still stronger band the central frequency of which is 685 cm^{-1}. Both these features are to be attributed to the vibrations

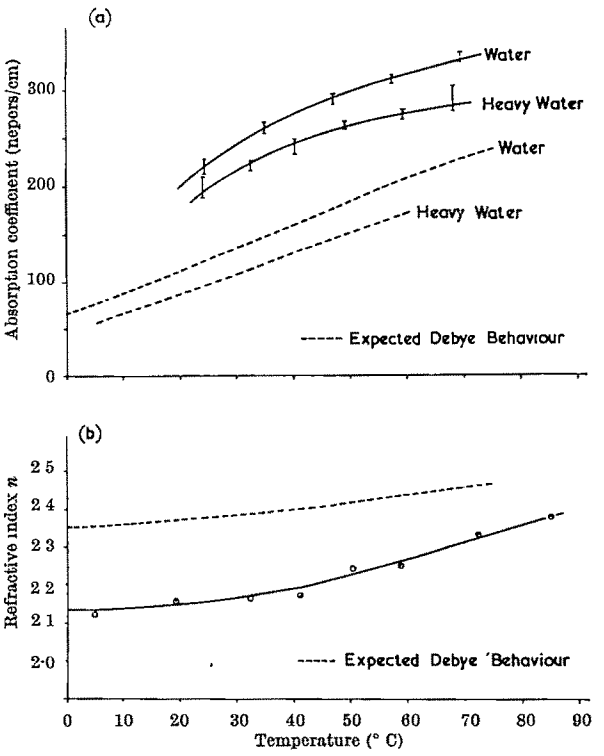

Fig 2. *a*, Variation with temperature of the absorption coefficients of water and heavy water at 337μ; *b*, variation with temperature of the refractive index of water at 337μ. In both *a* and *b* the expected Debye behaviour is calculated from the parameters given in ref 3

* Guest worker—permanent address, University of Glasgow.

of the hydrogen bonded liquid lattice[9,10]. Magat[1] has suggested an additional absorption band at 50 cm^{-1} but no distinct feature corresponding to this could be observed. Similar measurements for deuterium oxide are shown in Fig. 4.

The temperature dependence of the absorption coefficient has also been measured at 29·7 cm^{-1} using the CN maser. The results are shown in Fig. 2. The results show a considerable increase of absorption with temperature. If it is assumed that the Debye relaxation mechanism makes a distinguishable contribution to α at 29·7 cm^{-1}, the amount of this may be calculated and this is also shown in Fig 2. It will be seen that nearly all the temperature variation of the absorption can be attributed to the Debye process. Similar behaviour is shown by deuterium oxide.

Conclusions

The division of the liquid water dispersion into two regions has been confirmed by our work. At wave-lengths below 1 mm the Debye process is dominant but at shorter wave-lengths the "liquid lattice" modes[11] become more and more important so that at 29·7 cm^{-1} they already account for half the total absorption. This is also reflected in the behaviour of the refractive index where the departures from the Debye type of behaviour become marked at the higher frequencies. The temperature dependence of n is more rapid than would be expected from the Debye functions and is probably to be ascribed to the shift of the lattice bands to lower frequencies on heating.

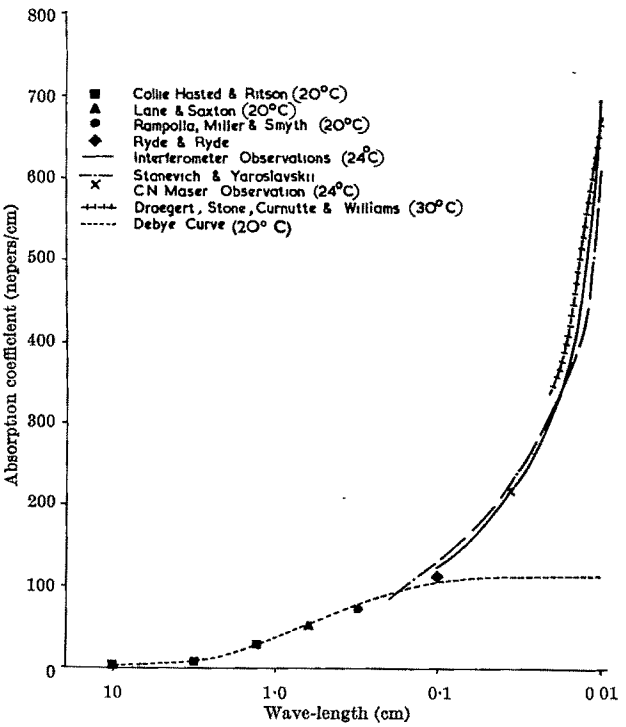

Fig. 3. Dielectric absorption of liquid water The Debye curve is calculated from the parameters given by Collie, Hasted and Ritson (ref. 3) for 20° C

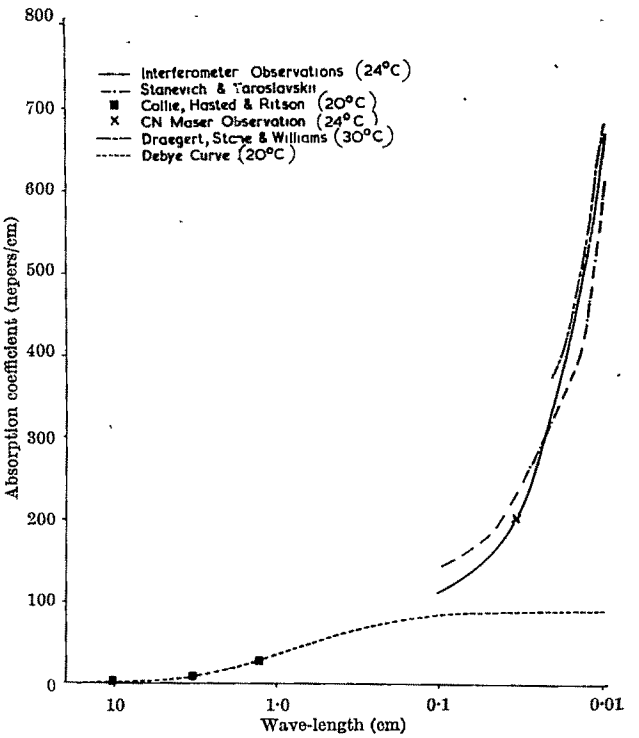

Fig 4. Dielectric absorption of liquid heavy water. The Debye curve is calculated from the parameters given by Collie, Hasted and Ritson (ref. 3) for 20° C

In spite of the reported peaks in Raman scattering[10] at 60 cm^{-1} and the well-known peak observed in slow neutron scattering at 56 cm^{-1}, no distinct peak in the infrared absorption can be detected below 193 cm^{-1}. This discrepancy indicates the presence of a significant group of low-frequency oscillations with surprisingly little infrared activity.

CALCIUM METABOLISM IN A FRESHWATER MOLLUSC: QUANTITATIVE IMPORTANCE OF WATER AND FOOD AS SUPPLY FOR CALCIUM DURING GROWTH

By Dr. O. VAN DER BORGHT and S. VAN PUYMBROECK

Department of Radiobiology, Studiecentrum voor Kernenergie, Mol-Donk, Belgium

ATTENTION has repeatedly been directed to molluscs as indicator organisms for radiocontamination in fresh-water for strontium-90 (refs. 1–3), radium-226 (ref. 4), carbon-14 (ref. 5) and other radionuclides[6], as well as in sea-water for zinc-65 (refs. 7, 8), cobalt-60 and other radioisotopes[9,10].

Since only a small isotopic dilution is possible in fresh water, higher concentration ratios $\frac{(^{90}\text{Sr/g body-weight})}{^{90}\text{Sr/g water}}$ are observed for ^{90}Sr in freshwater than in marine molluscs: values of 1 or 2 in the latter animals[11,12], as compared with

60–5,000 in the former[1,6]. This higher concentration ratio makes these freshwater animals particularly useful as indicator-organisms, since measurements on these animals are relatively more accurate and simpler to perform.

Nothing is yet known about the quantitative relations in freshwater molluscs between the amount of calcium taken up directly from the water[3,13] and that extracted from the food. These data would also be of importance for the interpretation of radiocontamination results.

We therefore set up a long-term experiment, keeping young freshwater gastropods in water with a trace of ^{45}Ca, while their food (lettuce) contained no tracer. The proportion of the calcium intake which the animals took up from the water would thus be reflected in the proportion of ^{45}Ca in the body. Thus, the ratio of the specific activity of the increase of calcium in the animals during the experiment to the specific activity of calcium in the water will give the percentage of the calcium taken up from the water.

Lymnaea stagnalis (L), from a laboratory culture kept in tap-water, were used. This water contains 35 mg/l. $Ca^{\cdot\cdot}$, 8 mg/l. $Na^{\cdot}$, 4 mg/l. $K^{\cdot}$, 4 mg/l. $Mg^{\cdot\cdot}$, 25 mg/l. $C^{\cdot\cdot}$ and 12 mg/l. HCO'_3, and allows a normal development. It approximates fairly closely to the composition of the natural habitat of these animals in the neighbourhood of the laboratory. The animals used for the present investigations had a shell-length of 1·88 ± 0·04 cm, at the start of the experiment. This corresponds to about 4 mg organic nitrogen as determined by a micro-Kjeldahl method.

They were placed in groups of ten in four high-pressure polyethylene beakers filled with 1 l. tap-water, and containing 3·6 μc. ^{45}Ca/l. at a specific activity of 0·08 μc./mg calcium. In a fifth beaker, snails were kept in the same conditions but without radioisotope, in order to determine eventual effects of irradiation on the growth of the animals. Corrections for evaporation were determined in a sixth beaker without animals or food.

The lettuce is renewed daily and fed *ad lib.* This food has no influence on the concentration or specific activity of calcium in the water in the experimental conditions used.

Excrements were evacuated weekly and prepared for determination of total calcium and calcium-45. The water is changed every week to maintain its total concentration of calcium above 10 mg/l., because below this level the direct uptake of calcium could be reduced[3].

The concentrations of calcium were measured in a spectrophotometer with an acetylene-air flame (Unicam '*SP*-900'). The calcium-45 was determined by liquid scintillation counting (Packard 'Tri-Carb'). The calcium content at the beginning of the experiment was determined by analysing three groups of ten animals each of the same size as the experimental animals. Afterwards, the animals were ashed (500° C), the ash dissolved in hydrochloric acid and the mixture diluted to about 15 mg calcium/l. The experiments were stopped after 74 days. The calcium content and radioactivity of each group of ten animals from each beaker were measured as described previously.

The statistical limits indicated throughout this paper are the fiducial limits of the mean at a probability of 95 per cent[14] ($=\bar{x} \pm ts_{\bar{x}}$).

At the start of the experiment, the animals contained 16·1 ± 0·7 mg calcium each; they reached 53·1 ± 3·2 mg at the end. The mean gain was thus 36·6 ± 3·8 mg calcium per animal.

The specific activity of this gain of calcium was = 106·700 ± 7·200 c.p.m./mg (c.p.m. = counts per minute) and of the calcium in the water = 129·000 ± 6·400 c.p.m./mg. Mean ratio of these two specific activities is 0·82 ± 0·05. This indicates that about 80 per cent of the calcium originated from the calcium in the water: about 30 mg was thus supplied directly by the water, and 7 mg came from the food.

The radioactivity had no measurable effect on the uptake. The gain of calcium in the non-radioactive beaker was 38·7 mg/animal, while the highest value observed in the radioactive animals was 39·7 mg/animal.

No bacterial or algal growth that could serve as an intermediate between water and snails for calcium fixation was found. When a colloidal dye such as Evans blue was added to the water, no pigmentation in the intestine was seen and drinking by the snails can therefore be neglected.

Estimation of intestinal efficiency for absorption of calcium.

We can estimate the efficiency of the intestinal absorption of calcium using these results, the specific activity and the total calcium content in the excrements. Indeed, if we put:

c = total calcium content of the excrements,

g = non-radioactive calcium not absorbed from the food by the gut, and remaining in the excrements,

e^* = (calcium + ^{45}Ca), excreted by the gut (Intestinal excretion of calcium is real, as shown by the fact that ^{45}Ca-loaded animals which are kept in non-radioactive solutions and fed non-radioactive food excrete radioactivity in the excrements),

a^* = (Ca + ^{45}Ca) from the water and contaminating the excrements by adsorption or exchange,

then

$c = g + e^* + a^*$, or

$g = c - e^* - a^*$.

If F = calcium extracted from the food during the whole experiment, as estimated by the ratio of specific activities, then the efficiency (E) of intestinal absorption (as percentage of calcium extracted from the food) will be

$$E = 1 - \frac{F + g}{g}$$

The following results are obtained:

Total calcium content of the excrements = 4·6 ± 0·6 mg/beaker (added over a period of 10·5 weeks).

^{45}Ca-content of the same excrements: 138·000 ± 14·000 c.p.m.

Specific activity of the excrements: 29·000 ± 2·500 c.p.m./mg.

Specific activity of the water: 129·000 (= 5·170·000 c.p.m. for 44 mg/l).

The value of 138·000 c.p.m. in all the excrements of the ten snails in one beaker therefore represents $44 \times \frac{138}{5 \cdot 170}$ = 1·1 mg (calcium + ^{45}Ca) coming: (*a*) from the water by intestinal excretion of ^{45}Ca that was previously directly absorbed from the water by the animals (= e^*) and (*b*) from radiocontamination of the excrements by adsorption (= a^*).

The residue of non-radioactive calcium not absorbed from the food by the intestine and thus left in the excrements ($g = c - e^* - a^*$) amounts to 4·8 mg − 1·1 mg = 3·7 mg.

Since the ten animals in one beaker extracted about 70 mg calcium from the food, the efficiency will be given by $1 - \frac{3 \cdot 7}{70 + 3 \cdot 7} = 0 \cdot 95$, which indicates that nearly all the calcium obtainable from the food was extracted by the animals.

This estimation could possibly be affected by two errors which act in opposite direction:

(*a*) diffusion of calcium from the excrements to the water, and (*b*) intestinal excretion of non-radioactive calcium coming from the part of the shell and other calcium reserves formed before the experiment began. However, adding radioactive excrements to non-radioactive water shows only a small and slow loss of calcium from the excrements which are included in mucus.

The approximation made here is therefore only the best obtainable for the time being, since estimations based on consumption of food and its calcium content are difficult, as a result of the variations in the content of calcium and water from leaf to leaf or even within the same leaf[15].

Transport over the food chain is usually considered responsible for radiocontamination in non-planktonic aquatic animals[16–18], although direct uptake of fission products has also been observed in different animals[18,20].

In molluscs living in sea-water, such direct uptake of soluble or particulate calcium and probably also of strontium occurs[21–24]. Diffusion of calcium ions from the water to the animals could explain this uptake[23,25]. In freshwater molluscs, on the other hand, the diffusible calcium in the animal is 5 to 10 times higher than in the surrounding medium[31] and diffusion alone could thus not lead to a significant uptake of calcium ions from the water. Fromming[26] denies that direct uptake of calcium from the water is possible here, but the observations of De Vorges[27], Schoffeniels[13] and Van der Borght[3,28] have shown direct uptake of calcium from the water, occurring against an electrochemical potential gradient in *L. stagnalis*[29].

The present results confirm the quantitative importance of this uptake of calcium. Even when food is offered *ad libitum* and when the period of observation is relatively long (2·5 months versus the life-cycle of 4 months from egg to egg in laboratory conditions), about 80 per cent of the calcium fixed by the animals is derived directly from the water. As pointed out previously[3,29], an analogy exists between the uptake of calcium and that of strontium in *L. stagnalis*. It may be thus supposed that the radiocontamination by ^{90}Sr in these animals also reflects the soluble radiocontamination of the water in which they live. This may also show that food is not a necessary link in this chain. Since the whole shell does not exchange calcium or strontium with the water to an appreciable extent, assimilation of these soluble radionuclides from the water is an integrative process for a period of about one year. Absorption of soluble calcium from the gut after drinking is not a likely pathway, as is shown by the experiment with the colloidal dye. Furthermore, drinking in general is limited in freshwater animals, since they have rather to excrete water than to take it up[30].

The estimated high efficiency of calcium extraction from the food is in good agreement with the data given by Wagge[15] for the land snails *Helix aspersa*, and indicates that the strontium content of the food can also contribute to the total radiocontamination of the animals, particularly when the food has a high strontium content and is more radiocontaminated than the water.

The importance of absorption of ions such as Ca^{++} emphasizes the role of ionic regulations for radiocontamination of aquatic organisms.

We thank Dr. G. Gerber for correcting the manuscript and Ir. R. Kirchmann for his stimulating interest. This investigation was supported by the Belgian Fund for Joint Fundamental Research.

INCORPORATION OF INORGANIC PHOSPHATE INTO SUGAR PHOSPHATES DURING CARBON DIOXIDE FIXATION BY ILLUMINATED CHLOROPLASTS

By C. W. BALDRY, C. BUCKE and D. A. WALKER
Department of Botany, Imperial College of Science and Technology London, S.W.7

PHOTOPHOSPHORYLATION has been widely studied since its discovery in 1954[1,2]. When supplied with inorganic phosphate and a co-factor such as phenazine methosulphate (PMS), illuminated chloroplasts will carry out 'cyclic' photophosphorylation (reaction 1) of exogenous adenosine diphosphate (ADP) at rates as high as 2,000 μmoles phosphate esterified/mg chlorophyll/h.

$$\text{ADP} + \text{inorganic phosphate} \xrightarrow{\text{light}} \text{adenosine triphosphate (ATP)} \quad (1)$$

If the co-factor is omitted and the illuminated chloroplasts are supplied with nicotinamide adenine dinucleotide phosphate (NADP) as well as ADP and inorganic phosphate, 'non-cyclic' photophosphorylation[3] occurs (reaction 2).

$$\text{NADP} + \text{H}_2\text{O} + \text{ADP} + \text{inorganic phosphate} \xrightarrow{\text{light}} \text{NADPH}_2 + \text{ATP} + \tfrac{1}{2}\text{O}_2 \quad (2)$$

Ferredoxin, a non-haem iron-containing protein, which is readily lost from chloroplast fragments, has been shown to participate in reaction 2 and must be added back to 'broken' chloroplasts to obtain the best rates of phosphate esterification.

The discovery of photophosphorylation was of the utmost importance because it showed that there was a mechanism within the chloroplast which could produce ATP in a reaction which was driven by light rather than by the consumption of a food material. Considerable attention was therefore given to the actual rates. According to present views[4], nine molecules of ATP and six molecules of $NADPH_2$ are required in photosynthesis for every three molecules of carbon dioxide converted to triose phosphate. The intact leaf can reduce carbon dioxide to sugar at rates as high as 180–200 μmoles/mg chlorophyll/h (ref. 5). This would require a photophosphorylation rate of about 600 μmoles/mg chlorophyll/h. When rates of this magnitude were actually demonstrated, it became clear that the chloroplast might be self-sufficient in the sense that it could be induced to form ATP at a rate which was more than ample for whole-cell photosynthesis.

In 1954, Arnon, Allen and Whatley[1] also showed that in addition to their ability to catalyse photophosphorylation, isolated chloroplasts could reduce carbon dioxide to carbohydrate. Since this first demonstration, the actual rates of carbon dioxide fixation have been improved by a factor of ten but the best[6–8] are still only 10–20 per cent of those attained by the intact leaf. There has been some tendency to argue that carbon dioxide fixation is unlikely to be limited by photophosphorylation since the actual phosphorylation mechanism must clearly retain its ability to function effectively in the isolated chloroplast. As Gibbs[9] has pointed out, such arguments should be regarded with caution and the fact that the highest rates of photophosphorylation have been obtained in the presence of added ADP and 'non-physiological' co-factors, such as PMS and pyocyanine, must not be overlooked. Also, maximal rates are only obtained with disrupted chloroplasts and there are some grounds for supposing that the chloroplast with an intact envelope may be impermeable to ADP and therefore incapable of supporting photophosphorylation of exogenous ADP[7].

For these and other reasons it would be of value if endogenous photosynthetic phosphorylation could be studied in chloroplasts which still retain some ability to fix carbon dioxide. This article reports a first attempt to measure such light-induced incorporation of inorganic phosphate into sugar phosphates by intact chloroplasts. Reactions were carried out in the absence of added ADP, NADP, ferredoxin or co-factors of cyclic photophosphorylation. The method used was one in which chloroplasts were incubated with inorganic phosphate containing phosphorus-32. After illumination in saturating red light at 20° C the inorganic phosphate was precipitated by one of two methods[10,11] and the radioactivity in organic phosphates remaining in solution measured by placing samples on planchettes in a Geiger–Müller counter. Other samples were chromatographed in two dimensions in butanol–acetic acid and water saturated phenol on paper previously washed with oxalic acid[12].

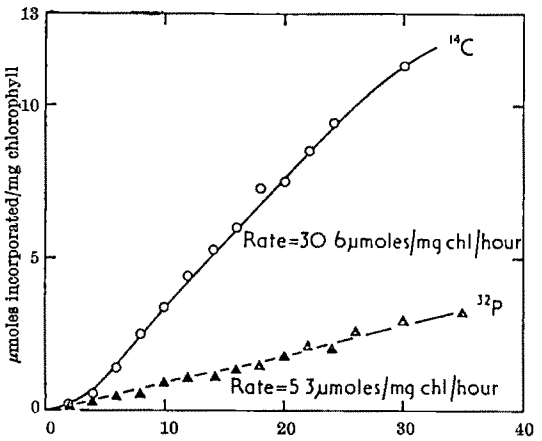

Fig. 1

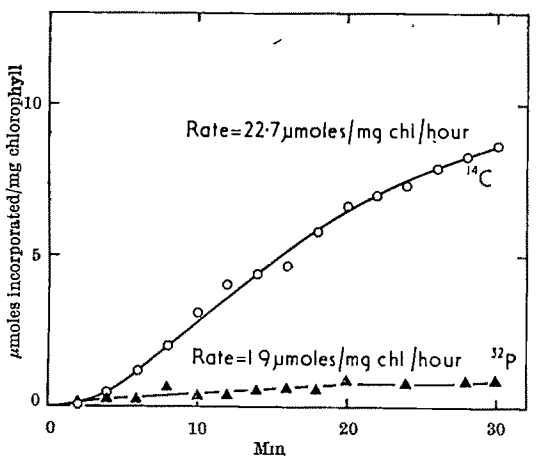

Fig. 2

Figs. 1 and 2. Simultaneous measurements of carbon dioxide fixation and phosphate incorporation by intact chloroplasts. In Fig. 1 ribose-5-phosphate was added to both reaction mixtures to promote carbon-dioxide fixation and in Fig. 2 this was replaced by a mixture of fructose-1, 6-diphosphate and dihydroxyacetone phosphate (see text). In Fig. 1 each reaction mixture contained 0·05 mg chlorophyll and in Fig. 2, 0·55 mg

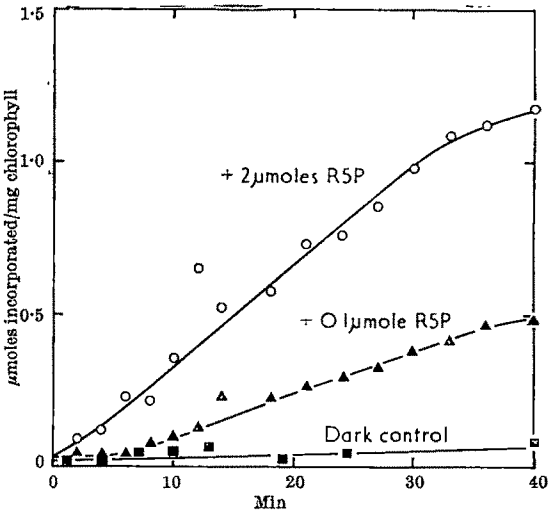

Fig. 3. Incorporation of inorganic phosphate as a light-induced reaction. The middle curve shows the effect of lowering the level of added sugar phosphate to a 'catalytic' level. Chlorophyll, 0·096 mg

Chloroplasts were isolated from 14-day-old pea seedlings in 0·33 M sucrose, 0·1 M phosphate (*p*H 6·8) containing small amounts of magnesium chloride, sodium chloride and sodium isoascorbate[6,7,13] and resuspended in a similar medium from which the phosphate had been omitted and the sucrose increased to 0·45 M. Normally, between 50 per cent and 80 per cent of the chloroplasts in such preparations have intact envelopes[13]. These retain their stroma and in suitable reaction mixtures will fix carbon dioxide at rates between 20 and 40 μmoles/mg chlorophyll/h[13]. Chloroplasts (0·1 ml.) in suspending medium were illuminated in reaction mixtures (0·3 ml.) containing (in addition to the sugar phosphates noted elsewhere in the text) reduced glutathione, 1·0 μmole; manganese chloride, 0·5 μmoles; magnesium chloride, 0·25 μmoles; EDTA, 0·5 μmoles; inorganic phosphate, 0·5 μmoles; tricine[14] buffer, 7·5 μmoles, *p*H 7·5; carbonate–bicarbonate, 2·95 μmoles; sucrose, 30·0 μmoles. Reaction mixtures used to follow carbon dioxide fixation contained a proportion of the carbonate as carbon-14 (50 μc.) and those for phosphate determinations phosphorus-32 (30 μc.). In the former, any $^{14}CO_2$ not fixed after illumination was driven off when samples were acidified with four parts of 0·2 N hydrochloric acid. In the latter, sampling was followed by neutralization with ammonium hydroxide and the addition of 5·8 parts of a mixture of magnesium chloride, ammonium chloride and ammonium hydroxide to precipitate inorganic phosphate[10]. Precipitation was allowed to proceed overnight and a small additional quantity of cold inorganic phosphate was then added to give a suitably bulky precipitate. Alternatively[11], samples were acidified with four volumes of 1 N perchloric acid followed by 8 vols of 0·1 M ammonium molybdate and 2 vols of 0·1 M triethylamine HCl (containing a trace of bromine). Finally, the precipitates were compacted by centrifugation at 2,000*g* for 10 min and samples of the supernatant (the organic phosphate fraction) withdrawn with a micro-syringe.

Figs. 1 and 2 show the results of experiments in which carbon dioxide fixation and organic phosphate were measured simultaneously in similar reaction mixtures.

In Fig. 1 carbon dioxide fixation was promoted[6,13] by the addition of 2 μmoles of ribose-5-phosphate, and in Fig. 2 this was replaced by a mixture of fructose-1,6-diphosphate (2 μmoles) and dihydroxyacetone phosphate (0·1 μmole). These sugar phosphates were added in amounts sufficient to give maximal rates of carbon dioxide fixation though it has been demonstrated that such fixation will occur at slower rates in the presence of catalytic quantities of sugar phosphates and even in their complete absence[8,13]. In the experiments illustrated in Figs. 1 and 2 it was not possible to determine the organic phosphate level sufficiently accurately to be certain that the characteristic initial lag in carbon dioxide fixation[13]

Figs. 6, 7 and 8. Incorporation of phosphorus-32 and carbon-14 into sugar phosphates by illuminated chloroplasts. Fig. 6 shows an autoradiograph obtained after co-chromatography of samples from two reaction mixtures containing carbon-14 and phosphorus-32, respectively (from which the inorganic phosphate had not been precipitated). Fig. 7 is an autoradiograph of the same chromatogram in which a sheet of cardboard was interposed between the chromatogram and the film so that the latter was largely exposed by phosphorus-32 rather than carbon-14. Fig. 8 is an autoradiograph prepared after chromatography of a similar reaction mixture which contained phosphorus-32 but not carbon-14. In this experiment, added ribose-5-phosphate was replaced by a mixture of fructose-1,6-diphosphate and dihydroxy-acetone phosphate (see text) and though the products were much the same there was rather less radioactivity in *A*. The major product, *F*, is dihydroxyacetone phosphate, *A* is thought to be largely ribulose diphosphate and *B*, *C*, *D* and *E* mostly hexose and pentose monophosphates. Solvents (→) water-saturated phenol followed by (↑) butanol (222)-acetic acid (57)-water (150)

was paralleled by a similar lag in organic phosphate formation, though in subsequent experiments an initial lag in esterification became more evident (Figs. 3 and 5). However, the overall increase of phosphorus-32 in the organic fraction, though small, was quite unambiguous and occurred only in the light (Fig. 3). Radioactivity was detected in the organic fraction in the dark but did not increase with time and is thought to be largely a consequence of incomplete precipitation of inorganic phosphate. After 40-min illumination, the radioactivity in the organic fraction was often as much as 10–20 times that of reaction mixtures kept in the dark.

The extent to which phosphorylation and carbon dioxide fixation were linked is also shown in Figs. 4 and 5. When carbon dioxide was omitted (Fig. 4) there was a marked decrease in the amount of phosphorus-32 incorporated into the organic fraction. Similarly, omission of the sugar phosphate normally added to promote carbon dioxide fixation[13] caused a corresponding decrease in esterification (Fig. 5). When sugar phosphate was added in a catalytic quantity[13] the rate of esterification was diminished (Fig. 3).

Chromatography showed that carbon-14 and phosphorus-32 were largely incorporated into the same products. Fig. 6 shows an autoradiograph of a two-dimensional chromatogram which was prepared by co-chromatography of two reaction mixtures, one containing carbon-14 and the other phosphorus-32. Fig. 7 shows an autoradiograph of the same chromatogram except that a sheet of cardboard was interposed between the chromatogram and the film so that the latter has been largely exposed by phosphorus-32. Fig. 8 shows a chromatogram from a similar experiment in which only phosphorus-32 was used (and in which, incidentally, fructose-1,6-diphosphate rather than ribose-5-phosphate was added to promote carbon dioxide fixation). These results are consistent with our previous experience[6,7,13] that the products of carbon dioxide fixation under these conditions are largely sugar phosphates. The major product, *F*, has been identified (by its chromatographic behaviour in a number of different solvents) as dihydroxyacetone phosphate. Product *A* is believed to be largely ribulose diphosphate and most of the radioactivity in *B*, *C*, *D* and *E* (which also contain both carbon and phosphorus) is present in compounds whose chromatographic characteristics are similar to those of pentose and hexose monophosphates.

In the photosynthetic carbon dioxide fixation cycle there are two reactions in which ATP, produced by photosynthetic phosphorylation, is thought to be consumed[4]. In one, 1,3-diphosphoglycerate is formed from 3-phosphoglycerate, but this is immediately followed by the reduction to glyceraldehyde-3-phosphate in which the newly introduced phosphate group is released as inorganic phosphate. The only step leading to an incorporation of phosphate is therefore the reaction in which ribulose-5-phosphate is converted to ribulose-1,5-diphosphate prior to the carboxylation leading to 3-phosphoglycerate. In addition, in the complete cycle, there are two reactions in which sugar diphosphates are hydrolysed to the corresponding monophosphates[4]. These also contribute to the release of newly introduced phosphate so that for every nine molecules of ATP consumed only one molecule of phosphate is incorporated into triose phosphate according to the overall equation:

$$3CO_2 + 3H_2O + H_3PO_4 \rightarrow \text{triose phosphate} + 3O_2 + H_2O \quad (3)$$

If the photosynthetic cycle occurs in chloroplasts in the presence of phosphorus-32 the radioactivity of the sugar phosphate fraction should increase until it eventually reaches a steady-state level which should be the same as that of the inorganic phosphate. The specific activity of the latter should decrease as it is diluted by non-radioactive phosphate released by hydrolysis of non-radioactive sugar phosphates added to the reaction mixture, or already present in the chloroplasts.

In the experiments carried out so far (in which ribose-5-phosphate was added to reaction mixtures to promote carbon dioxide fixation), the overall rate of phosphate esterification was about one-sixth of the rate of carbon dioxide fixation (see, for example, Fig. 1). Such a rate is consistent with the appearance of phosphorus-32 in triose phosphate according to equation 3 and the subsequent conversion of the triose phosphate to other compounds (for example, hexose and pentose monophosphates) in which the ratio of carbon : phosphorus is less than 3 : 1. With added fructose-1,6-diphosphate the ratio was nearer 11 : 1 (see, for example, Fig. 2) and this may in part be attributable to dilution of the labelled inorganic phosphate by enzymatic hydrolysis of the added diphosphate. It should be noted, however, that in the experiments in which ribose-5-phosphate was added to the reaction mixtures in substrate amounts (for example, Figs. 1 and 4) it still did not apparently act as a phosphate acceptor at a rate which was unrelated to that of carbon dioxide fixation.

The rate of endogenous ATP formation must of course be related to the rate at which the limited quantity of ADP within the chloroplast is again made available for further esterification and this in turn is likely to be dependent on the rate at which ATP is utilized in carbon dioxide fixation (Fig. 9).

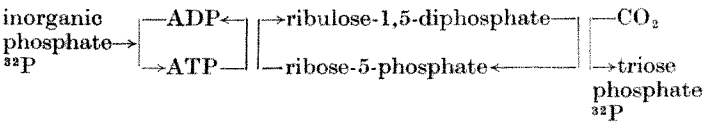

Fig. 9

In such a situation, enhanced carbon dioxide fixation could lead to increased phosphate esterification and increased esterification could in turn bring about enhanced fixation. This could contribute to the autocatalytic acceleration of carbon dioxide uptake in isolated chloroplasts[8,13]. It would also pose the important question of what constitutes the rate-controlling mechanism and to what extent this, rather than any artefact of extraction, limits the rate of fixation by isolated chloroplasts. The present experiments provide no answer to this question but they do show that it is possible to measure the light-induced incorporation of phosphorus-32 into sugar phosphates by isolated chloroplasts and that the rate is affected by factors which promote carbon dioxide fixation. A fuller clarification of this system would undoubtedly enhance our knowledge of regulatory mechanisms in photosynthesis.

We thank Prof. C. P. Whittingham for his advice and criticism. The work was supported by the Science Research Council and special apparatus was provided by the University of London Central Research Fund and the Royal Society.

METHYLATION OF NUCLEIC ACIDS IN KREBS II ASCITES TUMOUR CELLS

By Dr. R. H. BURDON

Department of Biochemistry, University of Glasgow

THE discovery of methylated bases in both ribonucleic acid and deoxyribonucleic acid[1–4] has stimulated the study of nucleic acid methylation at both the enzymatic and cellular levels. Enzymatic methylation of soluble RNA (*s*RNA)[5–8] has been shown to occur at the polynucleotide level with *S*-adenosyl-L-methionine as the methyl group donor in bacterial and animal cell-free systems. In addition, enzymes have been isolated from *Escherichia coli* capable of methylating bases in ribosomal RNA[9] and in DNA[10].

The *in vivo* methylation of ribosomal and soluble RNA, and in some cases DNA, has been investigated using *E. coli*[11,12], sea-urchin embryos[13], *Blastocladiella emersonii*[14] and recently HeLa cells[15]. These investigations were based on the assumption that the methylation of both RNA and DNA bases occurs after synthesis of the primary structure and that the incorporation of label from ^{14}C-[methyl]-L-methionine would be a specific indication of such a process.

The work reported here is an attempt, on similar lines, to investigate the *in vivo* methylation of nucleic acids occurring in Krebs II ascites tumour cells of the mouse and was prompted by the observation of Bergquist and Matthews[16] that *s*RNA from certain tumour cells contains the highest levels of methylated bases in *s*RNA ever recorded, and also that methylation in nucleated cells has been shown to occur primarily in the nucleolus rather than in the chromatin[17,18].

The method described by Martin *et al.*[19] was used for the cultivation of Krebs II ascites tumour cells. After they had been collected, the cells were washed in phosphate-buffered saline and suspended in Hanks's medium supplemented with horse serum as described by McNamara[20]. The cells in this medium were incubated at 37° C at a concentration of 10^7 cells per ml. Such a procedure was found to be necessary by McNamara[20] and by me to maintain RNA synthesis in these cells.

After incubation with appropriate additions the cell suspension was made 1 per cent with respect to sodium dodecyl sulphate (SDS) and 0·5 ml./2·5 per cent bentonite was added. After allowing to stand at room temperature for 5 min the suspension was extracted with 80 per cent phenol with vigorous shaking for 10 min at room temperature. The resulting emulsion was separated by centrifugation at 10,000*g*, the aqueous phase removed, re-extracted with phenol and then with ether to remove traces of phenol. After the removal of ether with a stream of nitrogen, the addition of two volumes of ethanol precipitated the cell DNA and RNA. This preparation of total cell nucleic acids, after further ethanol precipitation, was, in some experiments, submitted to chromatography on methylated albumin kieselguhr (MAK) as described by Comb *et al.*[21].

From this nucleic acid preparation, DNA could be isolated by the method of Marmur[22], after RNase treatment (50 μg/ml. for 30 min at 25° C), and also RNA, by treatment of another portion with DNase (10 μg/ml.) for 5 min at 37° C in the presence of 5 mM magnesium chloride and 3 mg/ml. bentonite, followed by phenol extraction and repeated ethanol precipitation as already outlined.

When the total cell nucleic acids were isolated after incubating Krebs II tumour cells with 2 μc./ml. ^{14}C-[methyl]-L-methionine for 2 h and submitted to chromatography on MAK columns a separation of *s*RNA, DNA and ribosomal RNA was achieved, similar to that described by Comb *et al.*[21]. One disadvantage of the technique when applied to the nucleic acids of mammalian cells is that a good separation of the two ribosomal RNA components cannot be accomplished. However, by measuring the optical density of each fraction and the radioactivity of the precipitate produced by adding trichloroacetic acid (TCA), it was possible to calculate the degree of methylation of each nucleic acid species. The results of this experiment are shown in Table 1, from which it is clear that in Krebs II tumour cells the degree of methylation of the *s*RNA is exceedingly high when compared with the ribosomal RNA.

Table 1. SPECIFIC RADIOACTIVITIES OF DNA, RIBOSOMAL AND SOLUBLE RNA OF KREBS II ASCITES TUMOUR CELLS AFTER INCUBATION OF THESE CELLS WITH ^{14}C-[METHYL]-METHIONINE FOR 2 H

Fraction	c p m /μg nucleic acid
*s*RNA	996
DNA	38
Ribosomal RNA	62

Separation of these fractions was achieved by MAK chromatography as described in the text. Each fraction was assayed for optical density at 260 mμ and TCA-insoluble radioactivity as described in the legend to Fig. 1 for the assay of fractions collected after sucrose-density gradient experiments.

If the DNA labelled in such experiment is isolated and hydrolysed to its component bases with formic acid under the conditions of Vischer and Chargaff[23] and the resulting hydrolysate submitted to paper chromatographic analysis a single radioactive component was found which behaved as 5-methyl cytosine.

Similarly, when RNA isolated from the same experiment was hydrolysed with perchloric acid under the conditions of Marshak and Vogel[24], and following the procedure outlined by Brown and Attardi[15], it was found that, if the black insoluble material formed by the polymerization of ribose moieties during the hydrolysis was assayed for radioactivity, it accounted for 6–7 per cent of the total RNA radioactivity. Thus it would appear that about 93–94 per cent of the methyl groups in Krebs II cell RNA are present as methyl groups on the RNA bases and the remainder as methyl groups on the ribose moieties. Indeed, Brown and Attardi[15] found that up to 80 per cent of the methyl groups in isolated ribosomal RNA of HeLa cells are present as methyl groups on the ribose moieties and they suggest that these methyl groups would be present as 2-*O*-methyl ribose. Paper chromatographic analysis of the bases liberated from the RNA after both formic acid and perchloric acid hydrolysis indicated that no radioactivity derived from the methyl group of L-methionine could be found in any of the four RNA bases. Identification of the methylated bases labelled in these experiments is difficult owing to the low specific

radioactivities involved, but so far the following labelled bases have been tentatively identified: 6-methyl amino purine, 2-methyl adenine, 1-methyl guanine and thymine. However, at least three more methylated bases remain to be identified and work is in progress to achieve this.

In another 2-h labelling experiment with ^{14}C-methionine the RNA was isolated and submitted to sucrose density gradient centrifugation (Fig. 1*A*). Three peaks of optical density at 260 mμ were observed corresponding to 30*S*, 19*S* and 4*S* RNAs[25], and TCA-insoluble radioactivity was detected in positions corresponding to 30*S*, 19*S* and 4*S*. Once again the high specific radioactivity of the *s*RNA (4*S*) was observed. Moreover, the two ribosomal RNA components (30*S* and 19*S*) were not equally methylated. The 19*S* RNA contained about 1·2 times more methyl groups than the 30*S* component. A similar phenomenon was also observed by Brown and Attardi[15] in their studies on HeLa cells. However, in addition to these peaks of radioactivity there is a further peak of activity sedimenting faster than the 30*S* RNA in a position corresponding to about 35*S* as well as some, less well defined, of even higher *S* value (about 45–50*S*). In a similar experiment carried out in the presence of actinomycin *D* (2 μg/ml.), no significant labelling could be detected in the 35*S* and 30*S* regions (Fig. 1*B*), although a very small amount could be detected in the 19*S* region and slightly more in the 4*S* region. This observation that actinomycin inhibits the labelling of the high-molecular-weight RNA indicates that the labelling occurring in the absence of actinomycin is not simply due to a protein contamination of the RNA preparation, since actinomycin *D* does not affect the incorporation of amino-acids into protein by these cells under these conditions.

In order to be certain that the high degree of labelling encountered in the 4*S* region (see Fig. 1*A*) is due to the incorporation of methyl groups into the bases (or ribose moieties) of *s*RNA, the fractions in the 4*S* region were pooled and tested for alkaline stability. An incorporation of methyl groups into some of the bases of *s*RNA would be expected to give a product with the same alkaline stability of ordinary RNA. On the other hand, the ester bond of methionyl-*s*RNA would be expected to show the alkaline lability reported for other types of amino-acyl RNA[8]. The radioactivity occurring in the region of 4*S* RNA isolated from Krebs II cells after incubation with

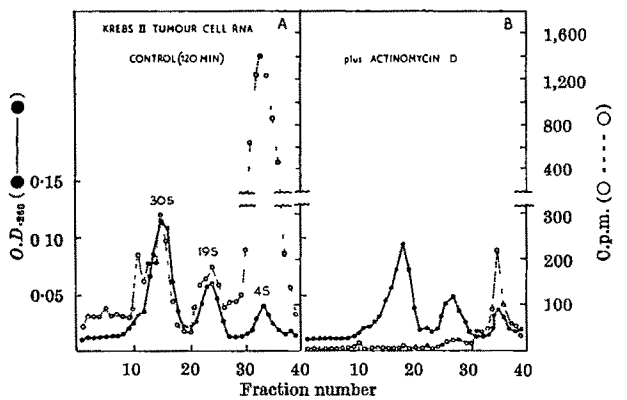

Fig. 1. Sucrose density gradient analysis of RNA from Krebs II ascites tumour cells labelled with ^{14}C-[methyl]-methionine (2 μc /ml.) over a period of 2 h in the presence (*B*) and absence (*A*) of actinomycin *D* (2 μg/ml.)
0·1 ml. of RNA in 0·02 M *tris*-hydrochloric acid buffer, *p*H 7·1, was layered on to 4·6 ml. linear sucrose gradients of from 5 per cent to 20 per cent concentration in 0·02 M *tris*-hydrochloric acid, *p*H 7·1–0·1 mM magnesium chloride and 0·01 per cent with respect to SDS and then centrifuged at 39,000 r.p.m. in the *SW* 39 rotor of the Spinco model *L* ultracentrifuge for 3 h. Fractions were then collected, after puncturing the tube, into 2 ml. portions of 0·02 M *tris*-hydrochloric acid, *p*H 7·2, 0·01 per cent with respect to SDS. Each fraction was first assayed for optical density at 260 mμ and then for acid-insoluble radioactivity by collection of 5 per cent TCA-insoluble material on a 'Millipore' filter and counting these filters, after drying, in 5 ml. of scintillator fluid (5 per cent 2,5 diphenyloxazole plus 0·3 per cent 1,4-*bis*-2-(5-phenyloxazolyl)-benzene in toluene) using a Nuclear Chicago scintillation spectrometer

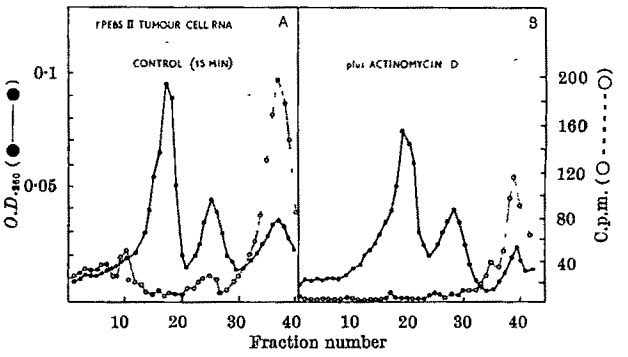

Fig. 2. Sucrose density gradient analysis of RNA from Krebs II ascites tumour cells labelled with ^{14}C-[methyl]-L-methionine (2 μc /ml.) over a period of 15 min in the presence (*B*) and absence (*A*) of actinomycin *D* (2 μg /ml). Remainder of conditions as for Fig. 1

^{14}C-methionine for 2 h was completely resistant to treatment at 37° C at *p*H 8 (or 9) for 30 min under the conditions described by Svensson *et al.*[8], whereas under the same conditions the half-life of methionyl-RNA is about 19 min (ref. 8). Incubation of the Krebs II 4*S* ^{14}C-methyl labelled RNA, on the other hand, at *p*H 13 for 1 h, or with 50 μg/ml. RNase for 30 min at 25° C, renders the radioactivity completely acid-soluble.

If, instead of incubating the Krebs II cells with ^{14}C-methionine for 2 h, a shorter incubation period of 15 min is used, then the pattern of RNA labelling is somewhat different (Fig. 2*A*). Practically no acid-insoluble radioactivity occurs in the 30*S* region although there is already some in the 19*S* region. As was the case with the 2-h incubation period, the 4*S* region is extensively labelled, and again there is a significant amount of activity in the 35*S* region. If the experiment is carried out in the presence of actinomycin *D* no significant label appears in any fraction other than the 4*S* region. Labelling of the 30*S* fraction does not occur until after 1 h of incubation with ^{14}C-methionine.

Although these experiments do not suggest a biological role for the process of methylation in tumour cells, they indicate that the DNA, as well as ribosomal and soluble RNA of Krebs II tumour cells, are methylated *in vivo* with L-methionine as donor of methyl groups presumably by way of *S*-adenosyl-L-methionine as intermediate. The high degree of methylation of tumour *s*RNA first encountered by Bergquist and Matthews[16] is amply demonstrated. Furthermore, because many investigations have been undertaken to determine the function of rapidly labelled high-molecular-weight RNA in rapidly growing, undifferentiated mammalian cells, such as Krebs II ascites tumour[20], HeLa[26] and *FL* cells[27], the methylation of the 35*S* component noted in these experiments is of considerable interest. It has been suggested[20,26,28] that this component together with a 45*S* component are precursors of ribosomal RNA. The experiments reported here suggest that it is the 35*S* component which is methylated at an early stage, possibly in the nucleolus[17,18] after the formation of the high-molecular-weight RNA species on a DNA template. The absence of an extensively methylated RNA component in the 45*S* region, the first type of RNA to be synthesized in HeLa cells[26] and *FL* cells[27], might be reasonable in view of the evidence of Yoshikawa-Fukada *et al.*[27], which suggests that this high-molecular-weight component is a 'messenger' type RNA.

Treatment of the tumour cells with actinomycin *D* considerably depresses the methylation of all RNA components and suggests that RNA methylation is a process which proceeds only in the presence of a continual supply of nascent RNA. The methylation of the 4*S* component occurring even in the presence of actinomycin *D* may only be due to the fact that actinomycin *D* does not completely suppress the synthesis of *s*RNA[25,29].

I thank Prof. J. N. Davidson for providing the necessary facilities for carrying out this work with the aid of a grant from the British Empire Cancer Campaign for Research.

RELATIVE ORIENTATION OF GENE, MESSENGER AND POLYPEPTIDE CHAIN

By DR. J. R. GUEST
Department of Microbiology, University of Sheffield
AND
PROF. C. YANOFSKY
Department of Biological Sciences, Stanford University, Stanford, California

IN studies on the colinearity between the *Escherichia coli* tryptophan synthetase *A*-gene and *A*-protein, two cases were observed in which different amino-acid substitutions occurred at the same position in the *A*-protein[1]. In strains *A*23 and *A*46 a single glycine residue (Gly I) in tryptic peptide TP3 was replaced by arginine and glutamic acid respectively, and in strains *A*58 and *A*78 another glycine residue (Gly II), in the adjacent peptide TP6, was replaced by aspartic acid and cysteine respectively. As a result of subsequent investigations of the amino-acid substitutions associated with primary site reversions at these sites, two families of proteins have been recognized, in which the substituent amino-acids are related to the parent glycine residues by a series of single-step mutational events[2–4]; these are shown in Fig. 1. The probable DNA codons for the different amino-acids are also indicated[5,6]. (Oligonucleotide sequences are expressed according to the accepted convention starting with the 5′-terminus on the left, unless indicated otherwise. Throughout this article codons of the DNA strand possessing the same sequence of nucleotides as the messenger are used.)

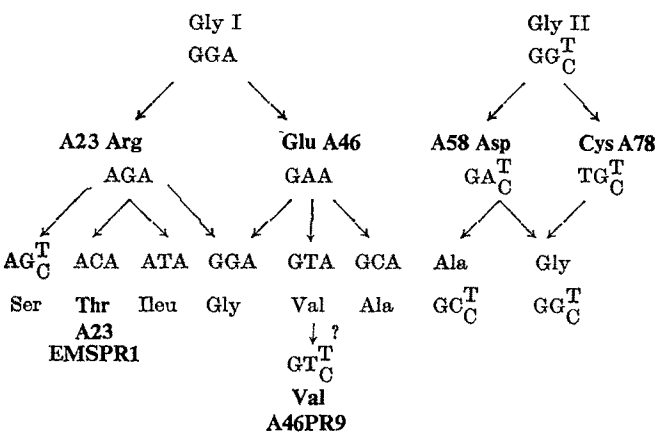

Fig. 1. The amino-acid substitutions observed at the critical sites in TP3(I) and TP6(II) of the tryptophan synthetase *A*-protein. The associated nucleotide sequences represent those of the DNA strand which has the same sequence as the *m*RNA. The strains shown in bold-face type have been used in investigations on intra-codon recombination. DNA codon assignments (refs 5 and 6) are based on the RNA codons determined by *in vitro* investigations (refs. 7 and 8)

The existence of several pairs of mutant strains differing in the composition of only one codon has permitted an investigation of amino-acid substitutions associated with intra-codon recombination[2,4,9]. The purpose of this report is two-fold: (*a*) to summarize the information obtained from intra-codon recombination investigations, and (*b*) to present the results of three-point genetic tests which orient the *A*-gene, its map, the messenger-RNA for the tryptophan operon, and the polypeptide chain of the *A*-protein, relative to one another.

Intra-codon Recombination

Reciprocal crosses were performed by transduction with phage *P1kc* lysates prepared on each donor strain, and a *cys*⁻ derivative of each recipient strain; the details of the method, the precautions taken, and calculation of recombination frequencies have been described previously[4,9]. The results of six crosses between strains having different amino-acids at the same sites are shown in Table 1. Tryptophan independent recombinants were obtained in four of the crosses: Glu × Arg, Val × Arg, Glu × Thr and Cys × Asp. According to the general rules which have been recognized for intra-codon recombination[10], this indicates that the corresponding pairs of codons differ in nucleotide composition at two or three positions within the triplet. Two of the crosses failed to produce tryptophan-independent recombinants (namely, Glu × Val and Arg × Thr) and this can be interpreted as being due to the presence of different nucleotides at only one position in the respective codon. These predictions are readily explained in terms of the ancestry of the strains as illustrated in Fig. 1. The Arg and Glu, and Asp and Cys pairs of mutants are derived from the same parent, presumably by single mutational events; the observed recombination and assigned DNA codons (Fig. 1) indicate that, in each member of a pair, a different nucleotide position in the parent codon was affected. The Val × Arg and Glu × Thr strains are separated by at least three mutational events and, consequently, different nucleotides could occupy one, two or three positions in their respective altered codons. In the Glu × Val, Arg × Thr pairs, one

partner is presumed to be the immediate parent of the other, allowing only a single nucleotide difference between the two codons. Recombination to tryptophan independence was not found here, even though it now appears that the *A46PR9* (Val) strain is separated from its parent *A46* (Glu) by more than one mutational event (see later).

The observed frequencies of intra-codon recombination (0·001–0·003 per cent) are very low. Nevertheless, they are of the order anticipated from calculations based on either (*a*) the length of the *A*-gene (4 per cent, four recombination units)[1], the number of amino-acid residues in the *A*-protein (280), and three nucleotides per codon, which give a value of 0·002 per cent between nucleotide pairs, or (*b*) the average experimental value for the ratio of genetic map distance per amino-acid residue in the *A*-protein of about 0·02[1], which gives a somewhat higher figure, 0·007 per cent per nucleotide pair.

The *A*-proteins of selected recombinants were examined in primary structure investigations. In the cross between mutants *A23* × *A46* only glycine was found at the critical position. Recombination should give a second codon in addition to that of the original wild-type strain. In the *A23* × *A46* cross, this codon would correspond to the amino-acid lysine. It is unlikely that a recombinant with this amino-acid at the *A23–A46* position could be detected, since the protein with the similar amino-acid, arginine, at this position, is inactive. This argument is strengthened by the fact that *A46* never reverts to a strain in which lysine replaces the *A46* glutamic acid[6], although this replacement would involve only a single nucleotide change and therefore would be permissible. Lysine is also the amino-acid that corresponds to the second recombinant codon expected in the *A46* × *A23* *EMSPR1* cross, and the same arguments can be offered for the absence of such recombinants. Analyses of the *A*-protein of recombinants from this cross revealed the presence of alanine at the critical site in the *A*-proteins of three strains. A fourth isolate, bearing a glycine residue, is not compatible with recombination and it has therefore been attributed to a reversion event. In terms of the likely codons (Fig. 1), the results of the cross between *A23* × *A46PR9* (Arg × Val) are also somewhat unusual. The only Val codon that can be derived from GAA (Glu) by a single mutational event is GTA. Crossing AGA × GTA should produce GGA (Gly) and ATA (Ileu) recombinants. Since strains with isoleucine at this position are known to have the partial revertant phenotype, and since the plating medium contained 5-methyl tryptophan which restricts recoverable types to strains with glycine, alanine or serine, only the GGA (Gly) recombinant type was expected. The simplest explanation for the anomalous appearance of recombinants containing Ser as well as the expected recombinants with Gly is that the strain used in the cross, *A46PR9*, is the product of two mutational events GAA (Glu)→GTA (Val) → GT^T_C (Val) (see Fig. 1). The second event, from GTA (Val) → GT^T (Val), could have occurred subsequent to the isolation and characterization of the original revertant strain. The other new codons that would be derived from the *A23* × *A46PR9* cross (see Table 1) corresponding to isoleucine and valine would not be expected to be represented in recombinants because of the 5-methyl tryptophan supplement. The *A46* × *A46PR9* cross could yield Val and Asp codons, but the recombinants with these codons would not be expected to grow on the selective medium used. In the *A78* × *A58* cross, the new codons that are produced correspond to Gly and Tyr. The fact that Gly but no Tyr recombinants were found is understandable as it is unlikely that the *A*-protein with Tyr at the *A58–A78* position is active. If it were active, Tyr revertants of *A78*

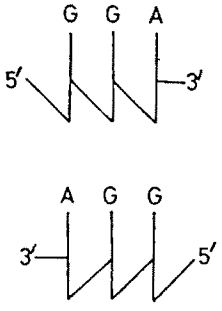
Table 1. RECOMBINATION WITHIN A CODING UNIT

Cross*	Amino-acids at same position in strains crossed	Probable corresponding DNA codons†	Possible recombinant codons	Number of recombinants	Recombination frequency (approx. per cent)	Amino-acid at relevant position of recombinant proteins‡
A46 × *A23*	Glu × Arg	GAA × AGA	GGA(Gly); AAA (Lys)	32	0·001	5 Gly (GGA)
A23 × *A23EMSPR1*	Arg × Thr	AGA × ACA	None	0	<0·0002	—
A46 × *A23EMSPR1*	Glu × Thr	GAA × ACA	GCA(Ala); AAA(Lys)	4	0·003	3 Ala (GCA) + 1 Gly§
A23 × *A46PR9*	Arg × Val	AGA × GT^T_C	$\overset{A}{\underset{C}{GGT}}$(Gly); AG^T_C (Ser); $\overset{A}{\underset{C}{ATT}}$(Ileu); GTA(Val)	5	0·002	3 Gly (GGA)¶ + 2 Ser (AG^T_C)
A46 × *A46PR9*	Glu × Val	GAA × GT^T_C	GA^T_C (Asp); GTA(Val)	0	<0·0002	—
A78 × *A58* (*A90*, *A94*)	Cys × Asp	TG^T_C × GA^T_C	GG^T_C (Gly); TA^T_C (Tyr)	76	0·001	4 Gly (GG^T_C)

* Selfings were performed with all strains but no prototrophs were recovered. *Cys*⁻ recipients were used to reduce interference from reversion and 5-methyltryptophan was included in the plating medium in all crosses involving partial revertants (PR).
† For simplicity, the nucleotide sequences indicated are those of the DNA strand which corresponds to the *m*RNA.
‡ Indicates the number of times the amino-acid shown has been found in a recombinant protein, and the probable corresponding DNA codon (in parentheses).
§ Origin unknown, probably a revertant and not included in the calculation of recombination frequency.
¶ GGA preferred because a double cross-over within the codon would be required to give GGT or GGC.

Table 2. OUTSIDE MARKER DISTRIBUTION IN INTRA-CODON RECOMBINATION

Cross: Donor	Recipient	Non-selective marker distribution* *anth*⁻	*anth*⁺	Suggested order
(1) *cys*⁺ *anth*⁻ *A46*	→ cys⁻ *anth*⁺ *A23*	14	3	*anth-A23-A46*
(2) *cys*⁺ *anth*⁻ *A23*	→ cys⁻ *anth*⁺ *A46*†	4	4	inconclusive
(3) *cys*⁺ *anth*⁻ *A58*	→ *cys*⁻ *anth*⁺ *A78*	8	6	inconclusive
(4) *cys*⁺ *anth*⁻ *A78*	→ *cys*⁻ *anth*⁺ *A58*	4	13	*anth-A78-A58*



* The sum of recombinants from at least three crosses of each type. Selection was for *cys*⁺*A*⁺ recombinants.
† Because the cross performed in this direction yields very few recombinants, lysates were exposed to ultra-violet light to increase recombination frequency.

should have been detected in the extensive reversion investigations with this mutant[4,6].

Orientation of Codons Relative to the Gene and the Polypeptide Chain

Although codons have been designated for the members of the two families of related amino-acids, the orientation of each codon within the gene and relative to the polypeptide chain of the *A*-protein has not been established. For example, in the case of the Gly I residue, situated in the *A*-protein as shown below, the question posed is, which of the following triplets represents the correct orientation of the nucleotides in the GGA codon in the gene or messenger ?

H_2N–Met····· Gly·····Ser–COOH

The investigations on colinearity with the tryptophan synthetase system have established the relative orientation of the *A*-protein and its genetic map. Because it has been shown that the *A*23–*A*46 and *A*58–*A*78 mutational events affect different nucleotide positions within the corresponding glycine codons, an answer to the question posed was sought in an investigation of the relative order of the positions of nucleotide changes within these codons. The standard procedure for intra-codon transductional crosses was adopted except that a closely linked marker, resulting in an anthranilic acid requirement, was introduced into the donor strains as the non-selective marker. The distribution of this non-selective marker in the recombinants obtained in reciprocal crosses is shown in Table 2. Convincing results were obtained in two of the crosses (1 and 4) and these indicate that the relative orders of the altered sites are: *anth* . . . *A*23–*A*46 and *anth* . . . *A*78–*A*58. A comparison of the parent glycine codons with those for the mutant codons (Fig. 1) shows that the *A*46 and *A*58 mutational events lead to substitution of the guanine at the mid-position in the GGA and GG^{T}_{C} codons, whereas the *A*23 and *A*78 mutations effect the replacement of the guanine in the 5′-terminal position. Arranging the codons such that the positions of the *A*23 and *A*78 nucleotide alterations are to the left of the positions of the *A*46 and *A*58 alterations, in accordance with the order derived experimentally, is consistent with only one orientation of the codons within the gene. The details of the two meaningful crosses and the orientation of the codons relative to the order of the mutant sites are illustrated in Fig. 2. Now by definition the DNA codons used here have the same polarity as the functional RNA codons of the messenger, so this strand of DNA and the *m*RNA are analogous. Furthermore, because the relative orientation of the gene and polypeptide chain have been established in previous investigations (as well as the relative positions of the *A*23–*A*46 and *A*58–*A*78 sites)[1], it is now possible to indicate the orientations of the genetic map, gene, messenger and polypeptide chain with respect to each other (Fig. 3). It follows that the 5′- and 3′-termini of the DNA strand with the same nucleotide sequence as the *m*RNA correspond to the amino-terminal and carboxyl-terminal ends of the gene product respectively. In view of the relative orientation of gene and protein and the fact that the process of polypeptide elongation commences at the amino terminus[11], the corresponding *m*RNA must be read in the 5′ → 3′ direction. Similar conclusions regarding the polarity of the genetic message have been reached by Thach *et al.*[12] and Salas *et al.*[13] in recent investigations correlating the structure of the peptides synthesized *in vitro* in response to synthetic *m*RNA having specific terminal sequences. Observations (*in vivo*) on the amino-acid substitutions associated with a reading frame shift involving the codons of five amino-acids in the phage *T*2 lysozyme gene also support these conclusions[14]. However, earlier experiments[15,16] on the effects of specific exonuclease digestion

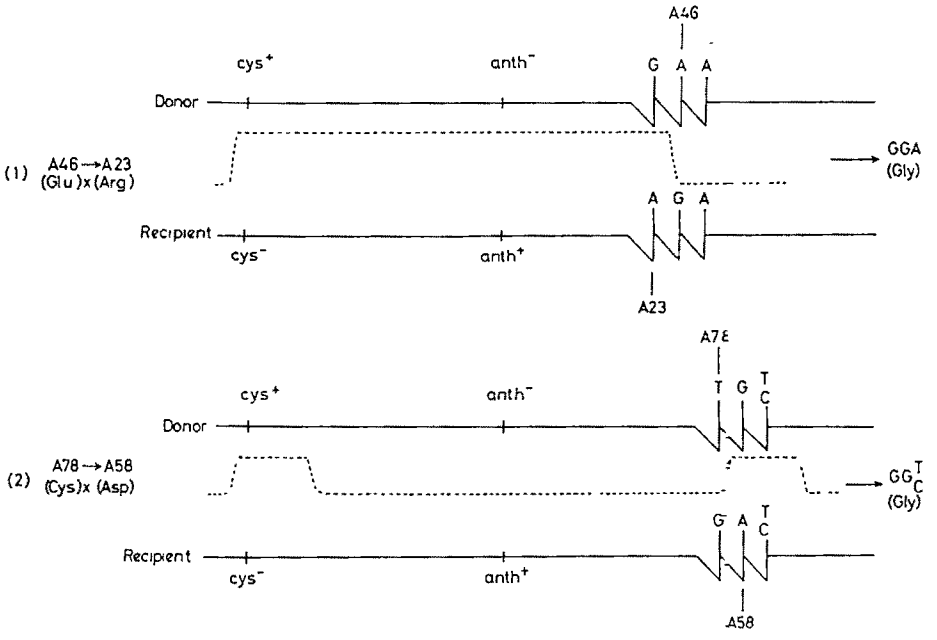


Fig. 2. The ordering of the positions of nucleotide changes within codons, relative to an outside marker

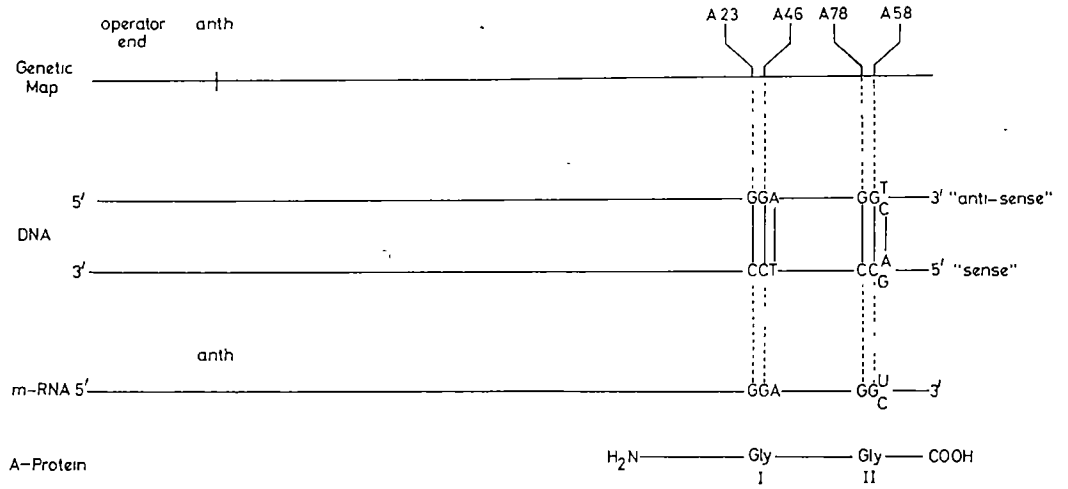

Fig. 3. A diagrammatic representation of the relative orientation of the genetic map of the tryptophan operon, related DNA and RNA nucleotide sequences, and the amino-acid sequence of the *A*-protein. The operator region is believed to be at the anthranilate synthetase end (ref. 21), and transcription appears to start at this end (ref 22)

of reticulocyte polyribosomes led to the opposite conclusion—that is, that the 3′ end of the haemoglobin *m*RNA corresponds to the amino-terminus of the protein.

Further information can be derived from the results presented here, when they are considered in conjunction with recent advances in our understanding of the transcription process. Evidence from both *in vivo*[17] and *in vitro*[18,19] investigations have indicated that during the synthesis of *m*RNA by DNA-dependent RNA polymerase the direction of elongation of the poly-ribonucleotide is from the 5′ to the 3′ end. Accordingly, the polymerase would be expected to transcribe in the 3′ → 5′ direction along the complementary strand of DNA. Therefore, by establishing the orientation of the gene relative to the *m*RNA and the polypeptide chain it can be concluded that, of the two polydeoxynucleotide strands of any operon (Fig. 3), the strand polarized 3′ → 5′ (with respect to the operator) is the 'sense'-strand (that is, the one carrying the genetic information) and the complementary strand with the opposite polarity (relative to the operator), 5′ → 3′, is the 'anti-sense' strand. It also follows that both transcription and translation mechanisms exhibit identical polarities and more important, in both cases, progression along the operon starts at the operator region, thereby confirming present theories on the mechanism of genetic control of protein synthesis[20].

CELLULAR LOCATION OF THE GENES CONTROLLING PENICILLINASE PRODUCTION AND RESISTANCE TO STREPTOMYCIN AND TETRACYCLINE IN A STRAIN OF *Staphylococcus aureus*

By SUSAN M. POSTON

Department of Bacteriology, Guy's Hospital Medical School, London, S.E.1

THE gene controlling high-level resistance to streptomycin in *Staphylococcus aureus* has been shown to be chromosomally located and, since its phenotypic expression is delayed until segregation is complete[1], it seems to be a recessive gene. Studies of transduction of the capacity to produce penicillinase in strains of *S. aureus* have been described[2–4]. In the absence of direct evidence for association of this gene with the chromosome, these workers have described it as a plasmid. Evidence for this included the finding that this gene can sometimes, though not always, be eliminated using acriflavines[3–6]. A high natural mutation rate of loss of penicillinase production[3,7] and the absence of a detectable reverse mutation rate have been reported[8] and have been taken as a further indication of cytoplasmic location for this gene. Furthermore, Novick[3] has reported that the penicillinase marker exhibits no phenotypic lag and that ultra-violet irradiation of the transducing phage lysate fails to enhance the rate of transduction. Ultra-violet irradiation of transducing phage has been shown to enhance transduction of some staphylococcal markers including streptomycin resistance[9], and in *Escherichia coli* was found to increase the frequency

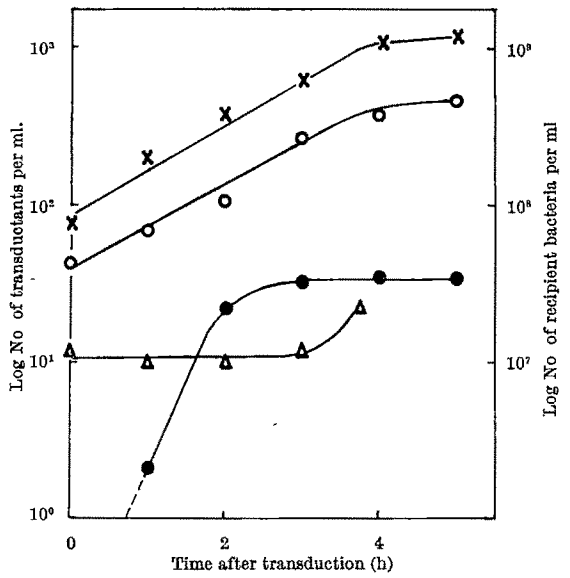

Fig 1. The phenotypic expression of markers. The log of the number of transductants and recipient bacteria per ml is plotted against the time of incubation in broth before selection. Recipient strain *S26 P⁻ SS TS* was treated with phage obtained by ultra-violet induction of donor strain *S26 P⁺ SR TR*. Transductants were selected on antibiotic-containing solid media at intervals of time after transduction. △, Penicillinase-producing transductants (*P⁺*); ●, streptomycin-resistant transductants (*SR*), ○, tetracycline-resistant transductants (*TR*); ×, recipient *S26 P⁻ SS TS*

of transduction of chromosomal markers whereas the rate of episomal transfer was not affected[10]. This increase in the number of stable chromosomal transductants is probably due to increased recombination between the transduced marker and host DNA[10].

In this work the kinetic development of phenotypic expression and the effect of ultra-violet irradiation on the frequency of transduction were used as criteria to judge the location of markers responsible for high-level resistance to streptomycin, resistance to tetracycline and production of penicillinase. All recipient and donor strains were derivatives of a penicillinase-producing strain of *S. aureus S26 P⁺*, that is, N.C.T.C. 8511, lysogenized with phage 53 (N.C.T.C. 8406) kindly supplied by Dr. M. L. Morse. The use of this type of system, with the homologous lysogenic strain as the recipient, has been reported[9,11] and has the advantage of removing the possibility of loss of transductants due to lysis. The recipient *S26 P⁻* was a spontaneously occurring penicillinase-negative mutant of *S26 P⁺* which was obtained when 2×10^4 cells were screened on cellulose acetate membranes by the method of Knox and Smith[12]. No penicillinase was detected in *S26 P⁻* using a modification of the hydroxylamine assay method[13] nor with a modification of the iodometric assay method[3]. Donor phage was obtained by ultra-violet induction of a streptomycin-resistant, tetracycline-resistant mutant of *S26 P⁺*. This strain (*S26 P⁺SRTR*) was prepared from *S26 P⁺* by selection of a naturally occurring streptomycin-resistant mutant on 500 μg/ml. streptomycin agar, followed by transduction to tetracycline resistance using phage 53 propagated on a tetracycline-resistant strain of *S. aureus* 13136 (ref. 14). In transduction experiments, cocci were grown in brain heart infusion broth to a count of about 3×10^8 per ml., concentrated two-fold in nutrient broth (Difco) and mixed with an equal volume of transducing phage at a multiplicity of infection of 0·5–1·5 with a final concentration of 400 μg/ml. calcium chloride: after 45 min at 37° C when about 95 per cent phage was adsorbed, the culture was spun down and resuspended in ten times the original volume of brain heart infusion broth. Throughout this work this time was regarded as time zero. Transductants for tetracycline resistance were selected on 5 μg/ml. tetracycline agar, for penicillinase production on 0·06 μg/ml. benzylpenicillin agar and for streptomycin resistance on 500 μg/ml. streptomycin agar. The kinetics of phenotypic expression were followed by removing aliquots at timed intervals, sampling on to the selective media and making viable counts on non-selective media. Ultra-violet-irradiated transducing phage was obtained by exposing 5-ml. amounts of undiluted phage preparation to a source of ultra-violet light emitting $5{\cdot}4 \times 10^4$ ergs/cm²/min; 0·2 ml. samples were removed at timed intervals, 0·1 ml. assayed for surviving phage and 0·1 ml. diluted 10^{-1} in Difco nutrient broth, stored overnight at 4° C and then used for transduction. Phage assay plates were kept away from bright light in order to avoid photoreactivation[15] of adsorbed phage. A control sample was treated in the same way before irradiation was commenced. Transductants were identified after three to four single colony isolations by lysogenic typing using the supernatant fluid of a broth culture and by antibiotic sensitivity pattern using Oxoid multodisks (11–14*C*) on digest agar. *CY* agar[3] was used for selection of transductants and viable counts. Digest agar (Southern Group Laboratories) containing 400 μg/ml. calcium chloride was used for phage assay plates.

Different patterns of phenotypic expression were shown by the three markers (Fig. 1). Streptomycin-resistant transductants exhibited a typical phenotypic expression lag. Between 1 and 2 h the number of these transductants showed a ten-fold increase, while the total recipient population only increased two-fold. This seems to represent the outcome of the expression of a recessive gene rather than growth. Using hetero-diploids of *E. coli* which carried streptomycin-resistant and streptomycin-sensitive alleles, Lederberg[16] found that such bacteria were streptomycin-sensitive and therefore concluded that streptomycin resistance is recessive. The penicillinase marker showed no lag in phenotypic expression but the number of transductants failed to increase over the next 3 h although the recipient itself multiplied exponentially in the same period. These

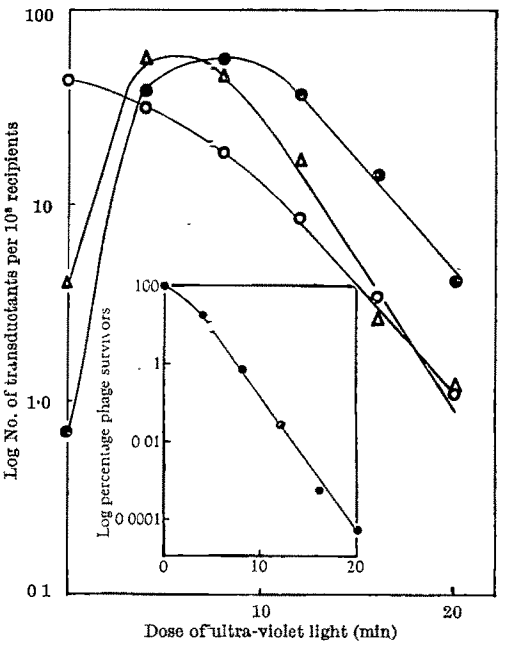

Fig. 2. Effect of ultra-violet irradiation of phage on transduction frequency and phage survival (plaque formation) A donor phage preparation from strain *S26 P⁺ SR TR* was treated with various doses of ultra-violet irradiation and tested for transduction of the recipient strain *S26 P⁻ SS TS*. Transductants were selected on antibiotic-containing solid media immediately after transduction for the *P⁺* and *TR* markers and after 2-h incubation for the *SR* marker. Transduction frequencies are given as the number of transductant colonies per 10^8 recipients, and plotted against the dose of ultra-violet light (minutes). The inset shows the percentage of phage particles surviving (plaque formation) after ultra-violet treatment. △, *P⁺*; ●, *SR*; ○, *TR*; •, donor phage (inset)

findings probably reflect segregation of a dominant gene. In the case of tetracycline-resistant transductants, both phenotypic lag and segregation lag were absent and the transductants grew at a rate similar to that of the recipient culture. The absence of any lag can be explained by the replication of the gene immediately on entering the cell, before the onset of cell division, so that all progeny received the determinant controlling tetracycline resistance. This type of behaviour occurs in non-chromosomally located genes (for example, episomes and plasmids).

Reconstruction experiments have shown that cells carrying any one of these three markers are able to grow at a rate similar to that of the antibiotic-sensitive recipient culture when present at a ratio of 1 in 10^6 and thus the foregoing findings must reflect the establishment of the markers into the recipient genome.

The effect of using ultra-violet-irradiated transducing phage on the frequency of transduction was studied and the results shown in Fig. 2. The frequency of transduction of streptomycin resistance and penicillinase production after 6 min of ultra-violet treatment of the phage was increased by a factor of 69 and 14, respectively, at a phage inactivation level greater than 90 per cent. However, under identical conditions, the frequency of tetracycline transductants showed no increase but fell with increasing doses of ultra-violet irradiation. These results add support to the chromosomal location of the genes for streptomycin resistance and penicillinase production as indicated by the phenotypic delay and segregation lag already described. The characteristics of tetracycline-resistant transductants, that is the absence of phenotypic or segregation lag and absence of increased transductional frequency using ultra-violet-irradiated phage, seem to point to a cytoplasmic location for this gene.

The results described here for phenotypic expression of the streptomycin marker agree with the findings of Morse[1] and those described for the effect of ultra-violet on transduction of streptomycin resistance with those of Korman and Berman[9]. On the other hand, the finding that the penicillinase gene seems to have a chromosomal location in this strain does not agree with Novick's results[3] which, using another strain, suggested a non-chromosomal (plasmid) location. This does not imply that either interpretation is wrong but suggests that the penicillinase gene can exist in either state depending on the strain. Many other genes have been shown to exhibit this behaviour.

I thank Dr. J. T. Smith for his help.

CHROMOSOMAL LOCATION OF THE GENETIC ELEMENTS CONTROLLING PENICILLINASE PRODUCTION IN A STRAIN OF *Staphylococcus aureus*

By ELIZABETH H. ASHESHOV
Cross-Infection Reference Laboratory, Colindale, London, N.W.9

EVIDENCE that the genetic elements controlling penicillinase production (and thus penicillin-resistance) in *Staphylococcus aureus* may be located on extra-chromosomal fragments or plasmids was presented by Novick and Richmond[1] and may summarized as follows. (1) The ability of a strain to produce penicillinase is lost spontaneously at a relatively high rate. This loss is apparently irreversible and may be accompanied by loss of other markers such as resistance to mercury salts[2] and in certain strains resistance to macrolide antibiotics[3]. (2) The ability to produce penicillinase can be transduced into suitable recipient strains but the rate of transduction is decreased if the transducing lysate is irradiated with ultra-violet light[4]. (3) Loss of the ability to produce penicillinase can be accelerated by agents not generally regarded as mutagenic—for example, elevated temperatures (43°–44° C)[5–7] or acridine dyes[3,8] and other substances (see ref. 1).

This article describes results obtained with three different strains of *S. aureus*. In one, the genes controlling penicillinase production would seem to be extra-chromosomal, in the second to be chromosomal, and in the third to have characteristics of both chromosomal and extra-chromosomal elements. These three strains and their derivatives are as follows.

(1) *PS* 80, the propagating strain for typing phage 80, is a naturally occurring penicillinase-producing strain, resistant to mercuric chloride. The ability to produce penicillinase is a stable character in this strain; it is not lost on storage or during growth at 43°–44° C (ref. 7). Resistance to mercury salts, however, is lost, both on storage on agar slopes at room temperature and as the result of growth at 43°–44° C. The difference in stability of these two markers suggested that they were not linked. Tetracycline-resistance was transduced into this strain from strain 2 (ref. 7) and this transductant (*PS* 80 P^rT^r) was used as donor of resistance to penicillin and to tetracycline in transduction experiments.

(2) Strain 2 P^rT^r (see ref. 7), a naturally occurring penicillinase-producing strain, resistant both to tetracycline and mercury salts. All three characters are unstable, in that they show a high spontaneous rate of loss which can be increased by growth at 43°–44° C. Resistance to penicillin and to mercury salts are nearly always lost together, indicating a close linkage between these two markers, while tetracycline resistance is lost independently. Strain 2 P^rT^r was used as donor of resistance to penicillin and to tetracycline in transduction experiments. A mutant of strain 2, sensitive to all three drugs, and designated strain 2/*S* was isolated after growth at 43°–44° C. It was used as recipient in transduction experiments where the donors were *PS* 80 P^rT^r and strain 2 P^rT^r.

(3) Strain 8325-18, described by Novick[4], produces penicillinase and is resistant to mercury salts. These two markers show a high spontaneous rate of loss which, however, is not increased by growth at 43°–44° C. They are linked in this strain in that they are lost together and are co-transduced. Strain 8325, the penicillin-sensitive, mercury-sensitive strain from which strain 8325-18 was

derived, was used in transduction experiments as recipient of these two markers from 8325-18.

Typing phage 80 was used as transducing phage in all experiments. It was propagated in lytic cycle on the three different donor strains, and preparations of phage are designated according to the strains on which they were propagated (phage 80/80 PrT^r, phage 80/2 PrT^r and phage 80/8325-18). Transducing lysates, diluted in nutrient broth, were irradiated for various lengths of time, using a 15-W germicidal lamp at a distance of 22 cm. After irradiation, samples were titrated for survivors and used in transduction experiments.

Transduction experiments were carried out as follows. A log-phase culture of the recipient strain containing 1–2 × 10^8 viable units/ml. was mixed with sufficient phage to give a multiplicity of infection of from 0·3 to 0·7. Sufficient calcium chloride was added to give a final concentration of 200 μg/ml. The mixtures were held at 37° C for 30 min to allow phage adsorption. They were then centrifuged, the supernatant fluid was discarded, and the bacteria were resuspended in broth containing 0·02 M sodium citrate to prevent further phage adsorption. Incubation was continued for a further 2 h. The cultures were then centrifuged, and the bacteria resuspended in a few ml. of broth. The whole of the suspension was examined for transductants by mixing 0·5 ml. volumes with 2·0 ml. of molten nutrient agar containing the appropriate antibiotic in the following concentration: penicillin—0·1 μg of benzyl penicillin/ml. : tetracycline—5·0 μg (= 5 u.) of tetracycline/ml. This was overlaid on agar plates containing the same concentration of antibiotic. Plates were incubated at 37° C, and transductants counted after 24 h and 48 h. Transduced clones were purified by streaking on antibiotic-containing medium. They were tested for resistance to mercury salts by a disk test[9]. The identity of a reasonable number was confirmed by phage-typing.

Figs. 1, 2 and 3 show the results of transduction experiments with three different phage lysates which had been exposed to various doses of ultra-violet irradiation. The frequency of transduction is plotted as a function of the dose of ultra-violet light given to the phage. Transduction frequencies were calculated as the ratio of the number of transductants to the number of plaque-forming particles in the unirradiated lysate.

In Fig. 1 the donor strain was 8325-18, the recipient strain was 8325 and the marker transduced was penicillin resistance. The rate of transduction decreased exponentially with the dose of ultra-violet light, confirming the

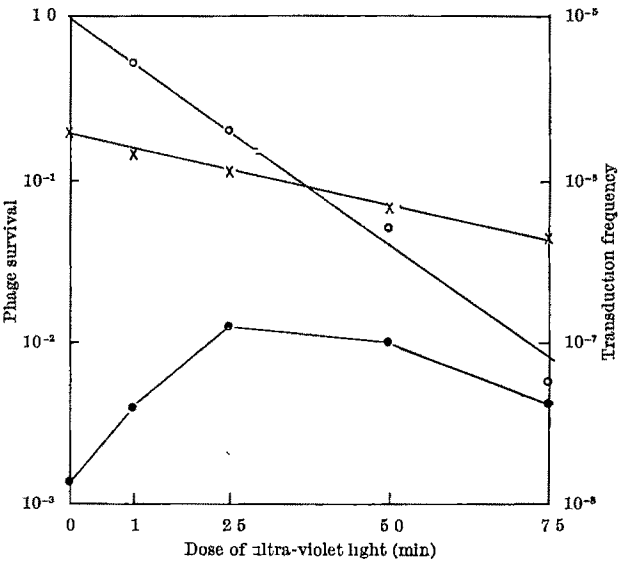

Fig. 2. Transduction frequency of resistance to penicillin and tetracycline as a function of ultra-violet irradiation of transducing phage. Donor = *PS* 80 PrT^r. Recipient = strain 2/*S*. ○, Phage survival curve; ×, tetracycline-resistant transduction curve, ●, penicillin-resistant transduction curve

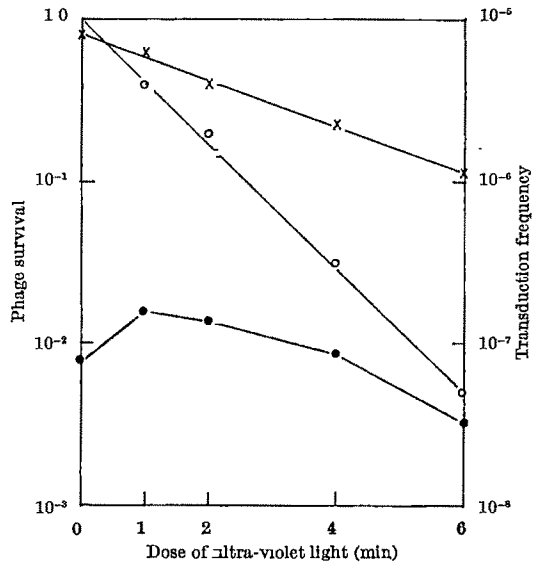

Fig. 3. Transduction frequency of resistance to penicillin and tetracycline as a function of ultra-violet irradiation of transducing phage. Donor = strain 2 PrT^r. Recipient = strain 2/*S*. ○, Phage survival curve; ×, tetracycline-resistant transduction curve; ●, penicillin-resistant transduction curve

results obtained by Novick[4]. Twenty of the transduced clones were tested for resistance to mercury salts, and all were found to have received this marker together with penicillin resistance.

Fig. 2 shows the results obtained when *PS* 80 PrT^r was the donor and strain 2/*S* the recipient. Transduction of resistance both to penicillin and to tetracycline was tested for in the same experiment by dividing the phage-treated bacterial suspension into two equal portions and screening each for one of the markers. The frequency of transduction of tetracycline resistance decreased exponentially with increasing doses of ultra-violet irradiation, but at a slower rate than that observed for penicillin resistance in Fig. 1, suggesting that the genes controlling tetracycline resistance are less sensitive to ultra-violet light than those controlling penicillin resistance. The curve for transduction of tetracycline resistance is consistent with the hypothesis that this marker is carried on a plasmid. The frequency of transduction of penicillin resistance, however, showed a ten-fold increase when the phage was given a dose of ultra-violet light sufficient to reduce the proportion

of survivors to 0·2. Penicillin-resistant transductants failed to show any co-transduction of mercury resistance, confirming that, in this strain, these two markers are not linked.

Fig. 3 shows the frequency of transduction of penicillin and tetracycline resistance when the donor was strain 2 P^rT^r and the recipient strain 2/*S*. The results obtained for the transduction of tetracycline resistance were similar to those in Fig. 2. The frequency of transduction of penicillin resistance showed a two-fold increase with a dose of ultra-violet which reduced the proportion of active phage to 0·4. This result was unexpected, since penicillin resistance in strain 2 P^rT^r is unstable and was, therefore, believed to be carried extra-chromosomally. The experiment was repeated a number of times, and this small increase in frequency occurred on each occasion.

Arber[10] investigated the effect of ultra-violet irradiation on transducing lysates of phage *P*1. He found that irradiation increased the frequency of transduction when the transduced marker was chromosomal, but decreased it when the marker was extra-chromosomal. The frequency of transduction of extra-chromosomal markers was approximately 100 times higher than for chromosomal markers. He attributed this difference to the fact that, when the transduced marker was chromosomal, transfer of the genetic determinants for the marker was not sufficient to produce a stable transductant. Recombination was necessary for the transduced marker to become stably integrated into the chromosome of the recipient. Ultra-violet irradiation of the transducing phage might increase the frequency of transduction of chromosomal markers by stimulating recombination.

The results obtained for transduction of penicillin resistance with phage 80/8325-18 are consistent with the hypothesis that, in this strain, the genetic elements controlling penicillinase production are carried on a plasmid which also carries those responsible for resistance to mercury salts. The frequency of transduction was high ($8·3 \times 10^{-6}$), but decreased when the transducing lysate was irradiated.

When the donor strain was *PS* 80 P^rT^r, however, the results were quite different. The frequency of transduction was low ($1·4 \times 10^{-8}$) but increased to $1·3 \times 10^{-7}$ when the transducing phage was irradiated. Both facts favour the hypothesis that the genes controlling this marker are on the chromosome in this strain. It might be argued that the phage preparation used was a poor transducing one, but the same preparation transduced tetracycline resistance with a high frequency ($2·1 \times 10^{-6}$). Consistent failure of attempts to isolate penicillin-sensitive mutants from this strain, both from old stored cultures and after growth at elevated temperatures, is further evidence in favour of a chromosomal location for the genes controlling penicillinase production.

It is more difficult to interpret the results obtained with strain 2 P^rT^r. It shows a fairly high rate of spontaneous loss of penicillin resistance, which can be increased by growth of the strain at 43°–44° C. This suggests an extra-chromosomal location for the genetic elements controlling penicillin resistance. When this marker was transduced to a sensitive recipient, however, the frequency of transduction was low ($8·3 \times 10^{-8}$) and showed a two-fold increase after a small dose of ultra-violet irradiation. These inconsistencies would be explained if it were assumed that the relevant genes are episomic, and have a chromosomal location in some cells and an extra-chromosomal location in others. If this were so it would follow, in view of the low frequency of transduction, that in the majority of cells the genes are located on the chromosome.

DELAYED UPTAKE BY TUMOURS OF TRITIUM FROM THYMIDINE

By DR. G. GORDON STEEL

Biophysics Department, Institute of Cancer Research (Surrey Branch), Belmont, Sutton, Surrey

IN most work on cell population kinetics in which tritium-labelled thymidine is used, the assumption is made that thymidine injected into an animal is rapidly metabolized and that after an 'availability time' of about half an hour no further uptake occurs[1,2]. The main reason for questioning this assumption is the possibility of the re-utilization of tritium-labelled DNA breakdown products from cells which were labelled during the initial availability time but which later die in the normal course of cellular renewal. There have been a number of claims[3,4] that this phenomenon has been observed autoradiographically. In general, the degree of re-utilization demonstrated has been slight except when tritium-labelled DNA has been transferred to non-radioactive animals[5], a situation which does not immediately indicate the extent to which re-utilization could arise as an artefact.

It was on the assumption that systemic re-utilization did not occur to a significant extent that an experiment was designed to detect cell loss from tumours. The rate of cell loss is an important parameter in any attempt to relate cell proliferation in tumours to their overall rates of growth, and no quantitative investigations have been made of it so far as I am aware. The experiment consisted in giving tritium-labelled thymidine to tumour-bearing animals and later following the total tritium content of the tumour. The initial experiment was made on a transplantable tumour carried subcutaneously in the August female rat; it arose as a mammary tumour in this strain in the laboratory of Dr. Goldfeder (United States), from whom it was obtained in 1952. It has now undergone many hundreds of transplants, is undifferentiated and has an initial volume doubling time of about 30 h. This is not, therefore, a tumour in which considerable cell loss would be expected, but it served to establish the method.

The total tritium uptake by the tumour was linearly related to tumour weight at injection, up to a size of 1 g, and therefore for this type of experiment the tumour size at injection must be accurately controlled. Each animal was selected on the morning of the day on which its tumour reached 7 mm. diameter (including skin thickness). It was injected intraperitoneally with 50 μc. of tritium-labelled thymidine (Radiochemical Centre, Amersham; 12·6 c./mmole) and then randomized into one of five groups, to be killed at intervals from 6 h to 7 days. The tumours were weighed fresh, then sliced and fixed in neutral

10 per cent formol saline. They were then desiccated, homogenized by grinding and assayed by liquid scintillation counter. It was anticipated that during the growth of a tumour the tritium content thus observed would stay constant or at least fall slightly with time. The results, shown in Fig. 1, show that there was, on the contrary, a four-fold increase of total tritium content during the week following injection; this has since been confirmed by a separate experiment. The growth-curve over the period of the experiment is also shown. Tumour weight increased by a factor of 25; most tumours at the 7-day interval showed fairly extensive necrosis and further protraction of the experiment was prevented by the larger tumours reaching a prohibitive size (the experiment cannot be started on smaller tumours on account of the difficulty of accurately establishing tumour size at injection).

There are two possible processes by which the acquisition of tritium by a tumour could occur: systemic re-utilization, and a net migration of labelled cells into the tumour. The second of these could scarcely explain an effect of the magnitude observed, for even if the migratory cells had a labelling index as high as the tumour itself (25 per cent), by 7 days more than 10 per cent of the cells present in the tumour mass would have to come by immigration. That this does not occur has been confirmed by autoradiography of tumours implanted into tritium-labelled animals.

The experiment as originally performed did not indicate whether it was the DNA of the tumour cells which incorporated the re-utilized activity. In a repeat of the original experiment, DNA extractions were therefore performed using a modified Schmidt–Tannhauser method and the total DNA tritium of the tumour was determined. These results, also shown in Fig. 1, confirm the acquisition of tritium by the DNA of the tumour. The rise in DNA tritium between 6 h and 1 day is difficult to understand. If it is a real effect it suggests that the metabolism of thymidine into the DNA of this tumour is not complete within 6 h.

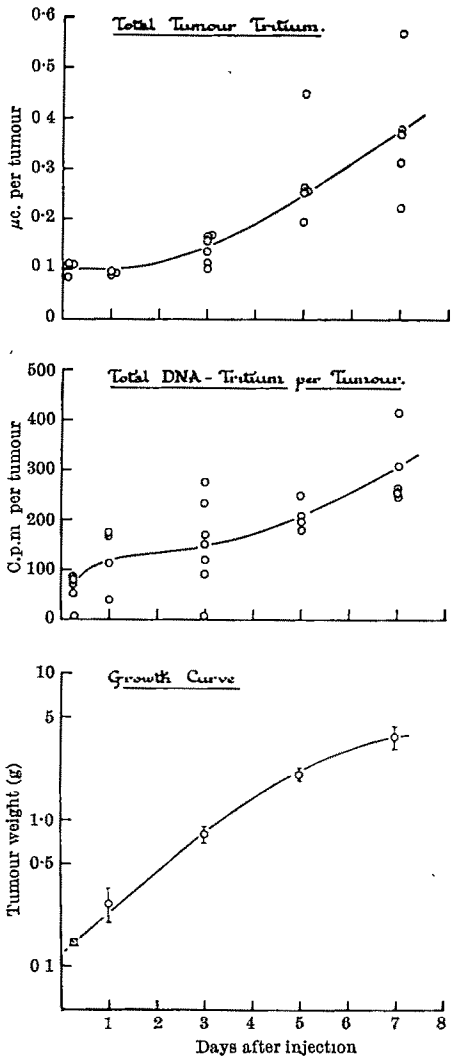

Fig. 1 Results on the August transplanted tumour

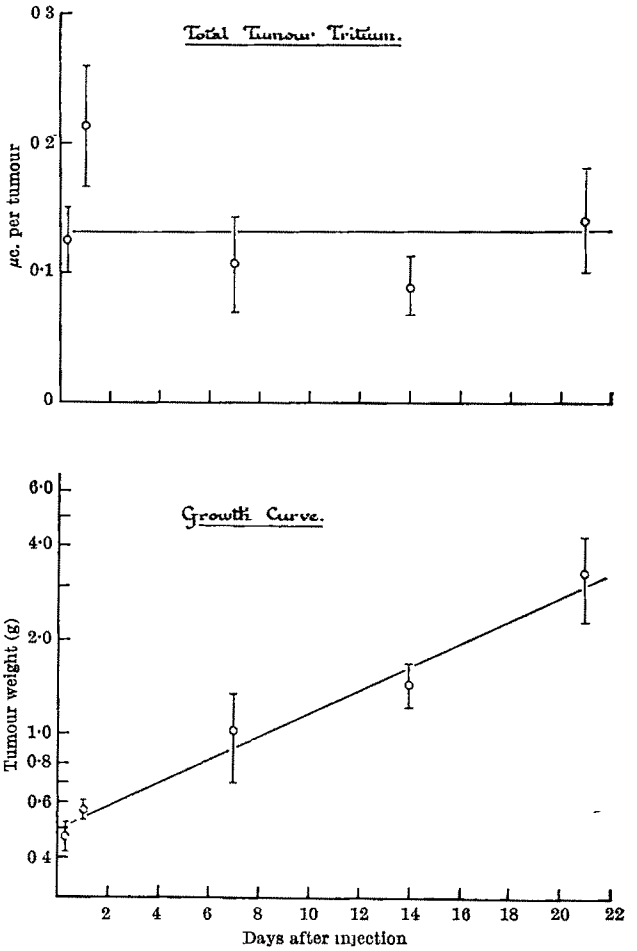

Fig. 2 Results on the spontaneous C^{+} mammary tumour

The immediate conclusion from these experiments is that cell loss from tumours cannot reliably be investigated by following total tumour tritium from thymidine. The underlying mechanism of the re-utilization process presents two main problems: first, the source of the re-utilized tritium; secondly, the molecular form in which it is re-utilized. The latter problem is now the subject of a considerable amount of investigation[6]. There is little doubt about the source of the re-utilized tritium. The work of Steel and Lamerton[7] on the retention of tritium from thymidine in eight renewal tissues of the rat showed that while there is little loss of incorporated tritium during the first 2 days following injection, considerable amounts of tritium leave the renewal tissues during the next 3 days. This is especially true of the small intestine which, within this 3-day period, discharges 5 per cent of the injected dose to the whole animal. The results shown in Fig. 1 fit into this picture remarkably well. There is no uptake by the tumour in at least the first day following injection, and the excess tritium acquired by 5 days amounts to 0·3 per cent of the injected dose. It is not possible to say how much of the activity which is made available following

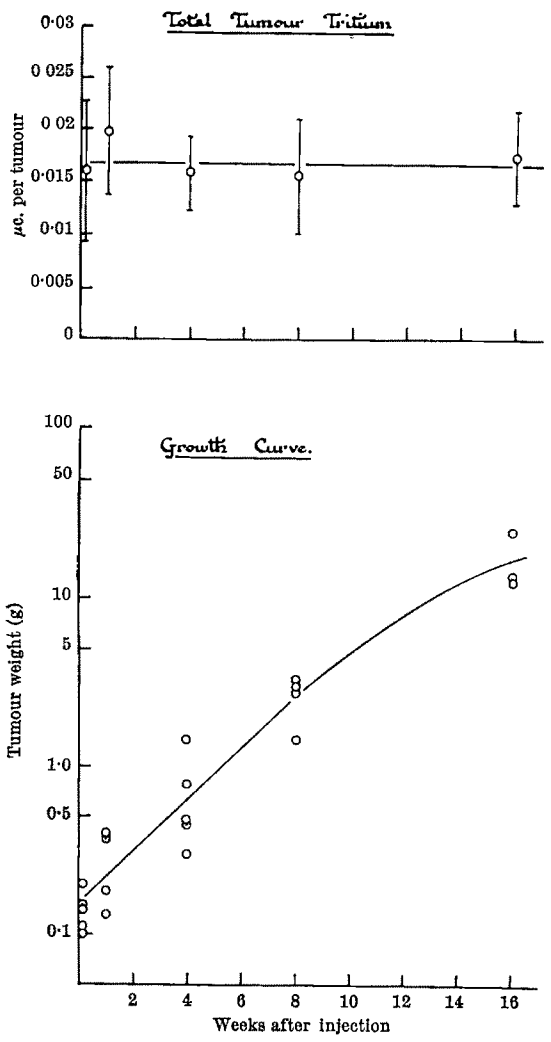

Fig. 3. Results on the transplanted Marshall fibrosarcoma

the death of a tritium-labelled cell is normally re-utilized within the animal as a whole, nor is it possible to say whether tumour tissue is more proficient than normal tissues in re-incorporating it. It is clear, however, that DNA tritium is released in amounts which are much greater than are found to be taken up by the tumour.

The question of whether tumour tissue preferentially utilizes the DNA breakdown products from dead cells is an interesting one, and it could have important implications. It is necessary first to establish whether re-utilization is demonstrable in a wide variety of tumours, and in particular whether the growth-rate of the tumour is a vital factor. Experiments were therefore carried out as before on two rather different tumours. The first was a spontaneous mammary tumour arising in the C^{+} mouse. In this case the tumours were selected for injection at a diameter of 10 mm, and because of the lower growth-rate the intervals were spread out to 21 days. The results are shown in Fig. 2. The second tumour was a fibrosarcoma which arose spontaneously in the Marshall rat and which has now been transplanted twenty-five times. This is a slow-growing tumour, and the intervals were therefore spread out to 4 months (Fig. 3). In each case there was no detectable re-utilization and, furthermore, no evidence of significant cell loss over the whole growth period. The most probable inference is that the change from a tumour doubling time of 30 h (August tumour) to 7·8 days for the spontaneous tumour and 14 days for the fibrosarcoma is sufficient to reduce the total gain of tritium by the tumour to an undetectable level. Presumably the tumour must have a reasonably high growth-rate during the period of high availability of tritium-labelled breakdown products, this period being 2–7 days following injection[7]. This requirement has received clear confirmation during the preparation of this report in the work of Bryant[8], who has grown ascites tumour cells in thymidine-labelled mice and shown that within this period the uptake of tritium by the tumour cells can be demonstrated autoradiographically. The present work supplements that of Bryant in showing that in tumours of high growth-rate it is a simple matter to demonstrate re-utilization of DNA tritium. It is clear that both in normal tissues[7] and in tumours the possibility of re-utilization artefacts in tritiated thymidine studies is of significant importance.

I thank Prof. L. F. Lamerton for his support and advice. I also thank Miss Kay Adams and Miss Sylvia Clack for their technical assistance and Dr. G. Threlfall for the DNA extractions.

SYNTHESIS OF ENZYMES AND DNA IN SYNCHRONOUS CULTURES OF *Schizosaccharomyces pombe*

By C. J. BOSTOCK, Dr W. D. DONACHIE*, Dr. MILLICENT MASTERS*† and Prof. J. M. MITCHISON
Department of Zoology, and Institute of Animal Genetics, University of Edinburgh

THERE has been considerable interest in recent years in the production of enzymes by synchronous cell cultures[1–13]. The long-term aim of this work is to understand the mechanisms which regulate the rate of synthesis of specific proteins during the cell cycle. We have assayed a number of enzymes in synchronous cultures of the fission yeast, *Schizosaccharomyces pombe*. We have also used these cultures to determine the pattern of DNA synthesis. This has previously been an intractable problem because of the difficulty of selectively labelling the DNA[14].

* Present address: Medical Research Council Unit for Microbial Genetics Research, Hammersmith Hospital, Ducane Road, London, W.12.
† Post-doctoral Fellow of the National Institute of Child Health and Human Development, U S. Public Health Service.

Synchronous cultures of 200–700 ml. of *S. pombe* (N.C.Y.C. 132) in Edinburgh minimal medium[15] ($1 - 4 \times 10^{6}$ cells/ml.) were prepared by the method of Mitchison and Vincent[16]. Glucose gradients were used instead of sucrose gradients in order to avoid perturbing the culture by changing the carbon source. In some cases, an asynchronous control culture was prepared from the remaining cells in the gradient after the top layer had been removed to make the synchronous culture. The cultures were grown at 32° C and samples removed at intervals for enzyme assay (washed and freeze-dried), DNA assay, scoring of cell plates and, sometimes, cell numbers. Aspartate transcarbamylase (ATCase) was assayed by

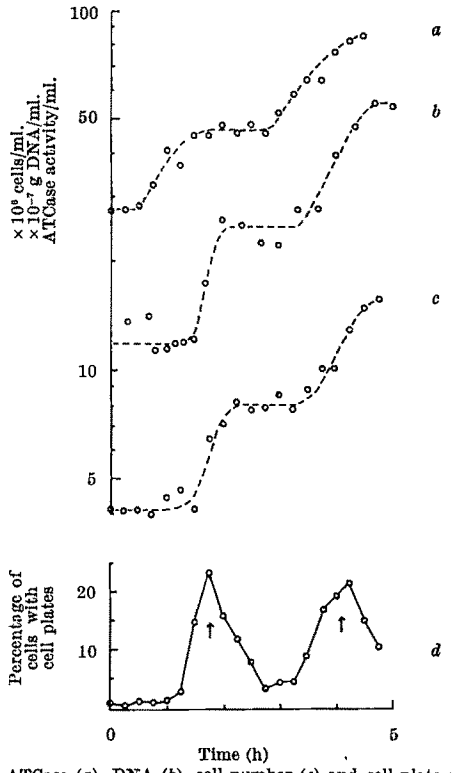

Fig. 1. ATCase (*a*), DNA (*b*), cell number (*c*) and cell plate index (*d*) in a synchronous culture

resuspending freeze-dried samples in 0·1 ml. 1 M glycine (*p*H 9·5) and 0·1 ml. 0·25 M L-aspartic acid (*p*H 9·5) in an ice bath and then adding 0·1 ml. carbamyl phosphate (4 mg/ml.) to complete the reaction mixture. The reaction was carried out at 28° C and the carbamyl aspartic acid formed estimated by the method of Gerhart and Pardee[17]. Ornithine transcarbamylase (OTCase) was assayed in exactly the same way, except that 0·03 M L-ornithine was substituted for the aspartic acid. The citrulline formed was estimated by the same method as was used for carbamyl aspartic acid. Alkaline phosphatase was assayed by the method of Torriani[18]. Sucrase (invertase) was assayed by the method of Masters *et al.*[2]. A similar method was used for maltase, with maltose as the substrate. DNA was measured by a modified version of the fluorometric technique of Kissane and Robins[19]. This is up to a hundred times more sensitive than the diphenylamine reaction[20]. Comparative tests with the two methods gave very similar DNA values with this material. The cell plate index (percentage of cells showing the transverse cell plate which precedes division) was measured on dried smears which were negatively stained with 10 per cent waterproof black drawing ink and then stained with 0·25 per cent crystal violet. This index is analogous to a mitotic index and is constant at about 10 per cent in a normal culture growing asynchronously. Cell numbers were determined by counting in a haemocytometer.

In the synchronous culture shown in Fig. 1, measurements were made of ATCase, DNA, cell numbers and cell plate index. There were two synchronous divisions and, slightly before them, two peaks in the cell plate index. DNA synthesis was sharply periodic with a doubling in total amount at about the time that the cell numbers doubled. In a series of similar experiments, the mean time of DNA doubling was a little earlier (about 15 min) than the doubling in cell numbers. This relation is shown in Fig. 3*c*. The single nucleus of *S. pombe* divides shortly before the appearance of the cell plate[21]. It seems, then, that DNA synthesis, at least in these synchronous cultures, has the following pattern. At the completion of nuclear division, the DNA synthetic period (*S*) commences almost immediately. There is therefore little or no presynthetic (*G*1) period between nuclear division and the *S* period. It is difficult to determine the exact length of the *S* period but in a number of experiments (including that in Fig. 1) the rate of increase of DNA during the *S* period was the same as that of the cell numbers. This would imply a very fast replication process. Finally, there is a long postsynthetic period (*G*2) before the next nuclear division. A restricted period of DNA synthesis during the cell cycle is the usual pattern of higher cells and it also occurs in budding yeast[22,23]. It is less common for *G*2 to occupy most of the cycle, though two other organisms in which this is known to happen are the slime mould *Physarum*[24] and sea-urchin eggs[25]. DNA synthesis in *S. pombe* is at present being explored by one of us (C. J. B.).

Fig. 1 also shows that ATCase activity rose in steps. Assuming that the enzyme is stable, it is synthesized only during a restricted period of the cell cycle. The length of this period would seem to be rather longer than that for DNA synthesis. The time of initiation of the burst of synthesis is the middle of the cycle in each of the two cycles. A similar result with another synchronous culture is shown in Fig. 2. In this experiment, a control asynchronous culture was set up from the same gradient and it showed an exponential increase in ATCase activity without any steps. The periodic nature of enzyme synthesis is therefore a property of the cell cycle and not simply the consequence of re-inoculating the cells from the gradient into fresh medium. The initiation times from five experiments are shown on a cell cycle map[2,4,8] in Fig. 3*a*.

OTCase activity followed a very similar pattern except that the steps were less well defined and somewhat more variable in their timing in the cycle (Figs. 2 and 3*b*). The average initiation times for the ATCase and OTCase steps are plotted on a cell cycle map in Fig. 3*c*, together with the mean cell plate peak and the mean mid-point of DNA synthesis. Although there is a difference between the ATCase and OTCase means, it is not statistically significant.

We have also measured the activity of three other enzymes—sucrase, maltase and alkaline phosphatase. The first two are at basal level in Edinburgh minimal medium (where the carbon source is glucose) but can be induced by the appropriate carbon source. Alkaline phosphatase appears to be constitutive since its activity per cell cannot be altered either by raising or by lowering the phosphate content of the medium. This enzyme has also

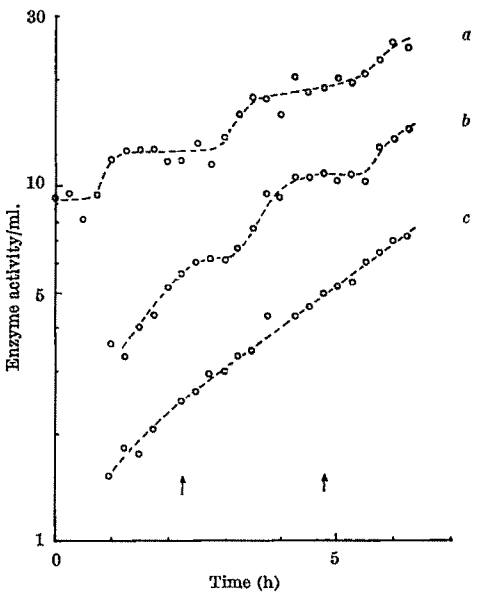

Fig. 2. OTCase (*a*) and ATCase (*b*) in a synchronous culture, and ATCase in a control (*c*) asynchronous culture from the same gradient. The arrows indicate the cell plate peaks in the synchronous culture, as in Fig. 1

been shown to be constitutive in another yeast[26]. With all three enzymes there was a continuous increase in activity through the cell cycle in synchronous cultures. Three experiments with synchronous and control cultures are shown in Fig. 4. There was an initial fluctuation in the maltase activity which occurred in both synchronous and control cultures and was probably a result of the synchronizing procedure. These enzymes, unlike ATCase and OTCase, appear to be synthesized continuously and smooth curves have been drawn provisionally through the points on the logarithmic plot in Fig. 4, but there may in fact be changes in the rate of synthesis similar to those found with repressed enzymes in synchronous bacterial cultures (alkaline phosphatase in *Bacillus subtilis*[5], alkaline phosphatase and β-galactosidase in *Escherichia coli*[3]). This point is being investigated by one of us (J. M. M.).

One purpose of this work was to discover whether all enzyme synthesis during the cell cycle was periodic, as reported for *Saccharomyces cerevisiae*[8,9], or whether it was periodic for some enzymes and continuous for others, as in bacteria[3,5,6]. The results reported here indicate that both periodic and continuous syntheses of enzymes occur. Furthermore, it was found that basal synthesis of the sucrase and maltase was continuous, while there was periodic synthesis of ATCase and OTCase which may be controlled autogenously[3]. In this respect, therefore, the results obtained with *S. pombe* are identical to those obtained with *B. subtilis* and *E. coli*[2-6]. The constitutive synthesis of alkaline phosphatase was also continuous. An opposite result to this has been found in budding yeast where there are two steps in this enzyme in each cycle[6]. This may be due to differences in the degree of repression in the two systems since alkaline phosphatase activity in synchronized *B. subtilis* is continuous when fully repressed[5] and stepwise when derepressed[6]. The continuous synthesis of this enzyme and of the sucrase and maltase is in accordance with the hypothesis that periodic enzyme synthesis results from the operation of a feed-back of end-product on enzyme synthesis[3,4,6,27,28]. It is also possible to explain continuous synthesis in terms of periodic transcription through the cycle of a number of genes in different positions on the genome[9]. Without very accurate assays, it is impossible to distinguish a curve showing continuous rise in enzyme activity from one with more than two or three steps. This explanation would not, however, account easily for the doublings in rate of synthesis at a particular point in each cycle in the bacterial systems[2,5].

Another object of this work was to determine whether the initiation of periods of enzyme synthesis was closely connected with periods of gene replication. The results show particularly clearly that initiation of enzyme steps can occur during periods when there is no net DNA synthesis. This confirms for *S. pombe* the conclusion reached for *B. subtilis*[6].

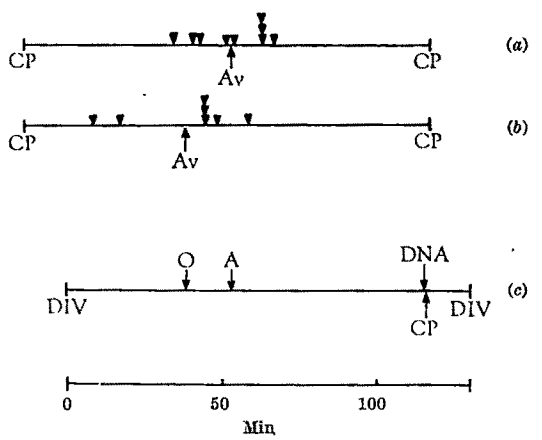

Fig. 3. Cell cycle maps of enzyme steps. (*a*) ATCase from five synchronous cultures. Each triangle is the initiation time. CP is the cell plate peak. (*b*) OTCase from four synchronous cultures. (*c*) Overall map for ATCase (A) and OTCase (O). DIV is cell division (mid-point of rise in cell numbers). DNA is the mid-point of rise in DNA

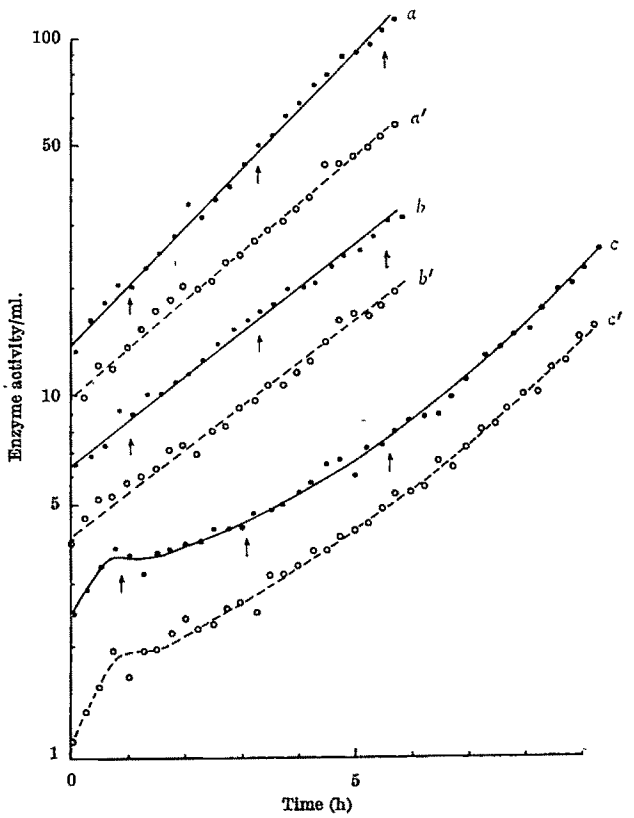

Fig. 4. Alkaline phosphatase (*a*), sucrase (*b*) and maltase (*c*) in synchronous cultures and in control (*a'*, *b'* and *c'* respectively) asynchronous cultures from the same gradients. The arrows indicate the cell plate peaks in the synchronous cultures, as in Fig. 1

These results therefore extend our knowledge of the cell cycle of fission yeast and indicate that similar modes of enzyme synthesis are found in both prokaryotic and eukaryotic cells.

We thank Mr. J. G. Creanor and Miss Helen Grozier for their technical assistance. This work was supported by a grant from the Science Research Council.

GENETICS OF STARCH-GEL ELECTROPHORETIC VARIANTS OF HUMAN 6-PHOSPHOGLUCONIC DEHYDROGENASE: POPULATION AND FAMILY STUDIES IN THE UNITED STATES AND IN MEXICO

By DR. JAMES E. BOWMAN, DR. PAUL E. CARSON and DR. HENRI FRISCHER
Genetics Clinic, Department of Medicine and Department of Pathology, University of Chicago

AND

PROF. ALFONSO L. de GARAY
Programa de Genética, Comisión Nacional de Energía Nuclear, México

FILDES and Parr[1] described a horizontal starch-gel electrophoretic technique to characterize human erythrocytic 6-phosphogluconic dehydrogenase (6-PGD). The enzyme migrated most commonly as a single fast (*A*) band or less frequently as two fast/slow (*A–B*) bands. In a population study in Great Britain, these investigators found the *A–B*, 6 PGD phenotype in the erythrocytes of ten out of 150 adults; the remainder had an *A* phenotype. Examination of the families of several *A–B*, 6-PGD subjects suggested that the *A–B* individuals were probably heterozygous for a gene pair with co-dominant autosomal transmission. Based on a prevalence of one *A–B* subject in fifteen, it was predicted that one person in 900 would be homozygous for the *B* variant of 6-PGD. A subsequent report by the same investigators introduced a modified genetic mechanism[2]. The more common form of 6-PGD still appeared as a single fast *A* band; the *A–B* variant, however, showed a band in the position of *A*, a slower band, *B*, and a third, very faint, *C*, the slowest of all. The *A* and *B* bands of this variant stained with equal intensity; both bands were less dense than the *A* pattern. These authors[2] then postulated a second genetic mechanism which produces sub-units of 6-PGD, two of which combine to form the whole enzyme. They further suggested that a pair of wild-type genes, $\alpha\alpha$, would synthesize the *A* enzyme, and that an individual heterozygous for the α and β alleles, producing equal amounts of α and β sub-units, would form 25 per cent *aa* (*A*), 50 per cent $\alpha\beta$ (*B*) and 25 per cent $\beta\beta$ (*C*); another variant was found[2] characterized by three evenly spaced bands; the intensity of the middle band was twice that of the faster and slower bands. A third allelic gene, γ, was postulated. The slowest band of the new variant was interpreted as $\alpha\alpha$, the middle band $\alpha\gamma$, and the fastest band $\gamma\gamma$.

In a population survey of variants of 6-PGD in Caucasians of European origin and of Negroes in the United States, a hitherto undescribed variant of 6-PGD, which will be described later, was first found in the erythrocytes of the mother of an *A–B*, 6-PGD subject of European origin. A similar variant was then found in a Turkish family; subsequently, several examples of the same variant were discovered in population and family studies of Lacandón Indians in Chiapas, México. Later, during the course of the United States survey, this new variant was also found in a Caucasian male of European origin. The 6-PGD electrophoretic variants and the results of population investigations in the United States and in Yucatán, México, will be presented first. Family studies in the United States and in the Lacandón Indians of Chiapas will then be summarized. These family studies give results compatible with the original hypothesis of Fildes and Parr[1]. Their explanation[2], however, of the minor bands of 6-PGD is either in need of modification, or the techniques of electrophoresis described in this report and that of Fildes and Parr are comparable only for the major 6-PGD electrophoretic bands.

The subjects in the United States consisted of blood donors of the University of Chicago Hospitals and Clinics, healthy employees of the University of Chicago and their unrelated spouses, as well as healthy volunteers at Stateville Prison, Joliet, Illinois. In this group, totalling 1,016, there were 600 Caucasians of European origin and 416 Negroes. Blood was drawn in ACD solution. Techniques for vertical starch-gel electrophoresis were modified from those previously reported for electrophoresis of haptoglobins, glucose-6-phosphate dehydrogenase and other proteins[3]. The starch-gel apparatus of Boyer and Hiner[4] was used, but 'Lucite' slot-formers (constructed by H. R. Smith) were substituted for the metal slot-formers. The stock buffer consisted of 0·9 M *tris*, 0·3 M boric acid and 2×10^{-2} M ethylene diamine tetraacetic acid (EDTA, free acid), *p*H 8·6. A 1/20 dilution of this buffer was prepared for the gel. Starch was obtained from Connaught Laboratories, Toronto, Canada. The amount of starch varied with the lot number. If, say, a starch concentration of 10·3 g/100 ml. was listed on the starch container as optimum for the boric acid–sodium hydroxide buffer of Smithies[3], the buffer already described required a starch concentration of 11·4 g/100 ml. The gel was prepared according to Smithies[3] and nicotinamide adenine dinucleotide phosphate (NADP) was added to a final concentration of $1{\cdot}6 \times 10^{-5}$ M in the hot gel just before degassing. The anodic compartment contained a 1/5 dilution of the stock buffer; the cathodic compartment contained a 1/7 dilution of the same buffer and a final concentration of NADP of $3{\cdot}2 \times 10^{-4}$ M.

Haemolysates for electrophoresis were prepared in the following manner: The erythrocytes were packed by centrifugation at 1,100 g at 4° C for 30 min; the plasma was removed and the red cells were washed three times by suspension in 0·154 M sodium chloride and centrifugation. After the last wash, the supernatant was removed, and the cells were lysed by rapid freezing and thawing three times. The haemolysate was then diluted 1 : 3 with *tris*-hydrochloric acid buffer (0·05 M, *p*H 8·6) and centrifuged at 4° C at 20,000*g* for 1 h in a Sorvall '*RC*-2' refrigerated centrifuge. The ghost-free haemolysate was then adjusted to a haemoglobin concentration of 3·5 g/100 ml. for electrophoresis. Electrophoresis was for 16 h, 6 V/cm at 4° C. The gels were stained for 3–4 h in the dark at 25° C in a solution of 150 ml. 0·5 M *tris*-hydrochloric acid, *p*H 8·6, to which was added 10 ml. 0·01 M magnesium chloride, 250 mg 6-phosphogluconate, hexylammonium salt, 10 mg nitro-blue-tetrazolium, 6 mg phenazine methosulphate, 40 mg NADP, and EDTA (disodium salt) to a concentration of 10^{-2} M.

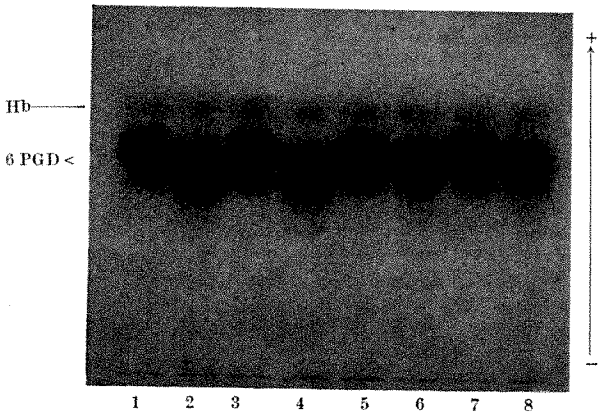

Fig. 1. Starch-gel electrophoresis of variants of 6-PGD. The blood samples were electrophoresed in an eight-slot gel and are from eight different subjects. In this figure, and subsequently in the text, 6-PGD phenotypes will be referred to as Pd *A*, Pd *A–B* and Pd *B*. Pd *B* is the new 6-PGD electrophoretic variant. The corresponding genotypes will be termed: Pd^A/Pd^A, Pd^A/Pd^B, and Pd^B/Pd^B. This terminology is analogous to the nomenclature of glucose-6-phosphate dehydrogenase variants recently introduced by Boyer and Graham (ref. 5). Slots 1, 3, 5 and 7 contain Pd *A*, slots 6 and 8, Pd *A-B*, and Pd *B* is in slots 2 and 4

In this buffer system, the 6-PGD bands migrated behind haemoglobin A (Fig. 1). Evidence for designating the new variant as representative of homozygous B 6-PGD will be presented later. A diagram of the 6-PGD patterns is shown in Fig. 2. Henceforth in this presentation the 6-PGD nomenclature outlined in Fig. 1 will be used. The erythrocytes of the first subject discovered to have the new 6-PGD variant were re-tested on nine occasions within a 10-month period without change in patterns. Samples of erythrocytes representing the three 6-PGD forms were stored at 4° C for at least 4 weeks and tested several times during this period; the 6-PGD patterns were not altered. Blood samples were also glycerolized and frozen at −20° C for 8 months without alteration of the 6-PGD bands. The buffer system of Boyer *et al.*[3] was initially used for electrophoresis; however, the Pd *A* band migrated in the position of haemoglobin A; consequently, haemoglobin A obscured the Pd *A* band, and the detection of fast minor bands was impossible. The three forms of 6-PGD were also distinguishable by electrophoresis with a different buffer system at a *p*H of 8·0. This analysis was performed by Dr. George J. Brewer, Department of Human Genetics, University of Michigan Medical School[6].

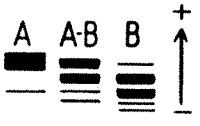

Fig. 2. Diagrammatic representation of 6-PGD phenotypes on starch-gel electrophoresis. The new variant is labelled *B*

Minor bands were also observed. A faint minor band (Figs. 1 and 2) was consistently noted behind the Pd *A* pattern. If results of the electrophoretic system used by Fildes and Parr[1] are comparable with those of this report, a comparison which may not be justified, the minor band in the Pd *A* phenotype is incompatible with their second hypothesis of the mechanism and formation of 6-PGD electrophoretic patterns. The intensity of staining of the two major bands of the Pd *A–B* phenotype was comparable to the description reported for this pattern[1]; additionally, however, at least two minor bands were observed behind the *B* band of Pd *A–B* (Figs. 1 and 2). One of these bands had the position and the intensity of the *B* band of the Pd *A–B* phenotype; the other band was comparable in position, but not in intensity, to the minor bands of the Pd *A* and Pd *A–B* phenotypes. Furthermore, at least three other minor bands were found in the new variants: two of these migrated behind the slower of the major bands; the other minor band was in the position of the major band of the Pd *A* phenotype. Gels were incubated without substrate; no staining in the position of the major or minor 6-PGD bands was observed. When gels were prepared without NADP or with nicotinamide adenine dinucleotide phosphate (NAD) alone, the 6-PGD patterns were diffuse.

During the course of these investigations, several hypotheses to account for the electrophoretic patterns of 6-PGD variant were considered. The first two families in which the new 6-PGD variant was found, however, provided the major clue to the working hypothesis of this study. Late in the United States survey, another very important family was discovered through a PD-*B* propositus. The pedigrees of these three families are illustrated in Fig. 3.

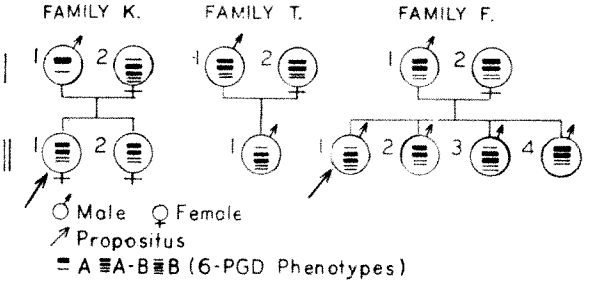

Fig. 3. Pedigrees of three key families showing that the new variant is the homozygous form of B 6-PGD. In Family *K.*, the mating Pd *A* × Pd *B* = Pd *A–B*, only; in Family *T.*, the mating Pd *A–B* × Pd *A–B* = Pd *B*. The mating of Family *F.* is similar to Family *T.*; however, Family *F.* is more informative: Pd *A–B* × Pd *A–B* = Pd *A–B*, Pd *B*, Pd *A* would also be predicted from this mating. Blood from Family *T.* was referred for electrophoresis of glucose-6-phosphate dehydrogenase by Dr. Izzet Berkel, Ankara University Hacettepe Medical Center, Hacettepe Faculty of Medicine, Ankara, Turkey

The nature of the minor or multiple bands of 6-PGD will rest on further studies. This report is concerned only with the genetics of these 6-PGD variants. The slower major band of the new 6-PGD variant might be thought to represent the gene product of a third allele at the 6-PGD locus. However, Family *T.* and Family *F.*, Fig. 3, disprove this hypothesis. Population and additional family studies of 6-PGD electrophoretic phenotypes indicated that the new variant represents the homozygous *B* phenotype and not the product of a third allele at the 6-PGD locus.

The results of population studies in the United States are recorded in Table 1. A pattern comparable to the γ allele[2] was not found. In the Caucasian population of European origin (Table 1), the observed and expected numbers of Pd *A*, Pd *A–B* and Pd *B* were such that chi-square calculations were unnecessary. It was also

Table 1. POPULATION STUDIES OF STARCH-GEL ELECTROPHORETIC PATTERNS OF 6-PHOSPHOGLUCONIC DEHYDROGENASE IN THE UNITED STATES

6-PGD phenotypes	Caucasians of European origin			Negroes		
	Males	Females	Total	Males	Females	Total
Pd *A*	514	40	554	379	6	385
Pd *A–B*	40	5	45	31	0	31
Pd *B*	1	0	1	0	0	0
Total	555	45	600	410	6	416

Estimated gene frequencies*

	Caucasians of European origin				Negroes		
	Pd *A*	Pd *A–B*	Pd *B*	Total	Pd *A*	Pd *A–B*	Total
Observed:	554	45	1	600	385	31	416
Expected:	553·9	45·2	0·9		$2\,p\text{–}2p^2 = 0{\cdot}0745$		
	$Pd^A = 0{\cdot}9608$				$Pd^A = 0{\cdot}9613$		
	$Pd^B = 0{\cdot}0392$				$Pd^B = 0{\cdot}0387$		
	1·0000				1·0000		

(Expected frequency of Pd^B/Pd^B in each population = 0·0015.)

* Pd^A and Pd^B gene frequencies in Caucasians of European origin were estimated by the gene counting method; in Negroes, these gene frequencies were estimated from the prevalence of heterozygotes, Pd A-B.

apparent that there were no significant differences among the frequencies of the 6-PGD phenotypes in Caucasians of European origin and Negroes of the United States and the British population. The frequency of the *A–B* phenotype in the British study of 150 study subjects[1] was 0·0714; in the present United States survey, the frequency of this phenotype in Caucasians of European origin was 0·0750, and in Negroes, 0·0745.

A survey of 85 unrelated males and females in Yucatán, México (Mestizos), revealed that all had the Pd *A* phenotype. The Pd *A–B* phenotype was not found. Although the sample was small, this suggests that the frequency of the Pd^B allele in this population is lower than in the Negro and the Caucasian population of European origin studied in the United States and than in the population reported from Great Britain.

Additional family studies in the United States and in the Lacandón Indians of Chiapas, México, supported the concept that the first mechanism of inheritance of 6-PGD electrophoretic variants proposed by Fildes and Parr[1] is valid, and that the new variant described in this report is the homozygous *B* pattern. The results of family studies in the United States and in México are listed in Table 2 and are classified according to a two-allele system. This scheme, of course, does not exclude additional alleles at the 6-PGD locus. The variant[2] described by Fildes and Parr may be an example of a heterozygous form of a third allele, as these authors suggest.

Table 2. FAMILY STUDIES OF STARCH-GEL ELECTROPHORETIC VARIANTS OF 6-PHOSPHOGLUCONIC DEHYDROGENASE

Matings*	No. of families	No. of children	Phenotypes Pd *A*	Pd *A–B*	Pd *B*
(1) $Pd^A/Pd^A \times Pd^A/Pd^A$	21	54	54	0	0
(2) $Pd^A/Pd^A \times Pd^A/Pd^B$	6	18	10	8	0
(3) $Pd^A/Pd^A \times Pd^B/Pd^B$	2	3	0	3	0
(4)† $Pd^A/Pd^B \times Pd^A/Pd^B$	2	5	0	2	3

* Matings: $Pd^A/Pd^B \times Pd^B/Pd^B$ and $Pd^B/Pd^B \times Pd^B/Pd^B$ were not observed in this survey.

† In a Lacandón family, the mother was Pd *A–B*; one child was Pd *A*, one child was Pd *A–B* and two children were Pd *B*. Blood from the father was not available; however, according to this hypothesis, he could only be Pd *A–B*.

The survey of the Lacandones, a markedly inbred Mayan Indian population, provided direct as well as indirect support for the view that the new variant of this report is homozygous 6-PGD *B*. These Indians number approximately 200 and live in scattered small family and clan groups in the jungles of Chiapas; 150 members were available for study. The Lacandón Indians now form two separate breeding groups: (1) the populations of Lacanjá and San Quintín, and (2) the groups of Najá, Metzabok, Monte Líbano, Arroyo Mendez and Santo Domingo. These two populations are separated by distance and dense jungle and have had no contact for many years. The Lacandones in Santo Domingo were not examined. Pd *A*, only, was found in 62 family members from Lacanjá and San Quintín. In the Najá, Metzabok, Monte Libano and Arroyo Mendez groups, Pd *A–B* was found. The probability of finding subjects who are homozygous for the 6-PGD *B* variant would be higher in this inbred population than in the random mating populations investigated in the United States; conversely the probability of finding a rarer third allele in these Indians would be small. Thus, in the Lacandón Indians a variant other than Pd *A* or Pd *A–B* would in all likelihood be Pd *B*. In the samples of subjects of Najá, Metzabok, Monte Libano and Arroyo Mendez, four had the new variant, PD *B*. From estimates of the frequency of the Pd^B/Pd^B homozygote in Caucasians of European origin and in Negroes in the United States (Table 1), a sample size of slightly in excess of 2,600 Caucasians of European origin or Negroes would be necessary to obtain the number of Pd *B* subjects found in these 88 Lacandones.

We thank Lic. José M. Ortiz Tirado and Sr. Don José Gorostiza, the former and the present president of the Comisión Nacional de Energía Nuclear de México, and Dr. Alfonso Caso, director, Instituto Indigenista de México, for their facilitation and encouragement of the studies in México. Dr. Benjamin F. Elson, director in México of the Instituto Liguista de Verano, and Sr. Elias Hatcher, director general, Alas del Socorro, graciously provided air transportation to the Lacandones, and Sra. Gertrude Duby gave valuable historical and family advice on these Indians. Prof. Armando Aguirre and Drs. Joaquin Zapiáin and Juan Gomés provided professional assistance, and Ubaldo Rodarte, Tayde García, Beatriz Vélez, María L. Díaz, Claudina Berlanga and Teresa Zenzes rendered technical assistance in the field in México. The technical assistance in the United States of Miriam Gower, Judy Krol, Irene Yachnin, Evelyn Westerman, and Tamara Thabes is gratefully acknowledged. Dr. Robert Kellermeyer, Department of Medicine, Western Reserve University School of Medicine, Cleveland, Ohio, kindly sent blood samples from the relatives of the propositus of Family *F*., Fig. 3.

These investigations were supported by grants from the U.S. Public Health Service, and from the Comisión Nacional Energía Nuclear de México.

ELECTROPHORETIC DEMONSTRATION OF STROMAL EFFECTS ON HAEMOLYSATE GLUCOSE-6-PHOSPHATE DEHYDROGENASE AND 6-PHOSPHOGLUCONIC DEHYDROGENASE

By DR. PAUL E. CARSON, DR. FRANCO AJMAR, FRED HASHIMOTO and DR. JAMES E. BOWMAN

Genetics Clinic, Department of Medicine and Department of Pathology, University of Chicago

THE present electrophoretic demonstration of stromal effects on haemolysate enzymes stems from two sources: (1) previously reported changes[1–6] in enzymatic activities of haemolysates of normal human erythrocytes induced during incubation of the haemolysates with their stromata, and (2) the genetics of human 6-phosphogluconic dehydrogenase (6-P-GD) as revealed by the starch-gel electrophoresis of haemolysates described by

Bowman *et al.*[7]. The induced changes are (1) inactivation of glucose-6-phosphate dehydrogenase (G-6-PD), (2) apparent activation of glutathione reductase (GSSR-R), and (3) partial inactivation of 6-P-GD.

The inactivation of G-6-PD is caused by stromal NADP-ase which removes bound NADP necessary for stability of the enzyme[2,8,9]. The mechanism for the apparent activation of GSSG-R is unknown; however, the activation does not occur during incubation of haemolysates of G-6-PD deficient erythrocytes which have intrinsically elevated GSSG-R activity[6,10,11]. The inactivation of G-6-PD during these incubations can be prevented by addition of protective NADP and it was in this situation that the third change, partial inactivation of 6-P-GD, was found[6].

The data for these changes were obtained only in terms of determinable activity by enzymatic assay of haemolysates. The observations presented by Bowman *et al.*[7] stimulated our interest in the electrophoretic patterns with respect to these changes. Unlike the X-linked G-6-PD which migrates as a single band in haemolysates of blood from hemizygous males and homozygous females, 6-P-GD migrates in multiple bands in three genetically determined forms, Pd *A*, Pd *A–B* and Pd *B* (ref. 7). The question, therefore, with respect to 6-P-GD, was whether or not the partial inactivation of 6-P-GD would be distinguishable electrophoretically as well as by decreased activity. If so, would the effect also be distinguishable among the three forms, hopefully, by specific removal of one or another of the major or minor bands.

Packed erythrocytes prepared by repeated centrifugation and washing (three times) with 0·162 M sodium chloride from fresh heparinized blood (drawn from healthy individuals) were haemolysed by rapid freezing and thawing. After dilution with 0·162 M sodium chloride to a final haemoglobin concentration of 5–7 g/100 ml., aliquots were prepared for incubation as follows: (I) stroma-free haemolysate. Stromata were removed by centrifuging at 30,000*g* (in a 'Lourdes' refrigerated centrifuge), (II) whole haemolysate (stromata not removed), (III) whole haemolysate as in (II) but NADP (P-L Biochemicals, Inc.) to a final concentration of 10^{-4} M was added at the beginning of incubation, (IV) stroma-free haemolysate as in (I), but also with NADP (10^{-4} M) added at the beginning of the incubation.

Incubation was performed at 45° C so that the effects could be demonstrated in 1 or 2 h; lower temperatures require longer incubation. Immediately after incubation stromata were removed from haemolysates II and III by centrifuging at 30,000*g*. Aliquots of the incubated haemolysates and of the control non-incubated stroma-free haemolysate were taken for starch-gel electrophoresis using conditions identical to those described by Bowman *et al.*[7]. The gels were then sliced horizontally and one half stained for G-6-PD, the other half for 6-P-GD. The remainder of the haemolysates were diluted for assay of G-6-PD and 6-P-GD by the method of Glock and McLean[12] using the conditions reported in ref. 6. GSSG-R was assayed by the method of Long and Carson[13] (except that the final *p*H was 6·7–6·9 instead of 7·6). For the assays a 'Beckman *DU*' spectrophotometer fitted with a 'Gilford' multiple sample absorbance recording system was used.

1-h incubations performed during this series gave activity changes entirely similar to those previously reported[6]. Therefore, for this report we show in Table 1 the results of the 2-h incubations which were used to enhance the 6-P-GD effect found with haemolysate III. The results are tabulated according to the electrophoretic type of 6-P-GD for enzyme activities, 6-P-GD, G-6-PD and GSSG-R. The chief difference from the results for 1-h incubations is the increased loss of G-6-PD activity by heat denaturation especially in haemolysate I. The increased activity of GSSG-R in haemolysates II and III, compared with haemolysates I and IV, is similar to the results for 1 h.

Table 1. RESULTS OF ENZYME ASSAYS OF HAEMOLYSATES I, II, III, IV PREPARED AS DESCRIBED IN THE TEXT, AFTER 2-H, INCUBATION AT 45° C

Values are percentage of the initial values of the stroma-free, non-incubated haemolysate. All individuals gave normal initial values

Enzyme	6-P-GD Type	Haemolysate I	II	III	IV
6-P-GD	Pd *A**	97	82	55	96
	Pd *A–B*†	77	63	37	57
	Pd *B*‡	65	56	30	51
G-6-PD	Pd *A**	21	5	72	86
	Pd *A–B*†	18	5	83	94

GSSG-R	Pd *A**	107	136	136	111
	Pd *A–B*†	107	138	137	112
	Pd B§	118	138	148	118

* Average of two experiments with blood from two individuals.

† Average of two experiments with blood drawn at two different times from the same individual.

‡ Average of three experiments with blood drawn at three different times from the same individual.

§ One experiment.

The data for 6-P-GD activities reveal the principal loss of activity to be in the incubated haemolysate III, that is, both stromata and NADP were required for this loss of activity. The results for the Pd *A* type both at 1 and 2 h are entirely consistent with the previous series; there is negligible loss of activity in haemolysates I and IV and less than 20 per cent loss in haemolysate II. However, all the haemolysates, I, II, III and IV, for the Pd *A–B* and Pd *B* types showed greater loss of activity than the Pd *A* type not only after 2 h incubation but also after 1 h. This suggests that the 6-P-GD of the Pd *A–B* and Pd *B* types may be more labile than the 6-P-GD of the Pd *A* type and is consistent with the recent communication of Parr and Parr[14].

The electrophoretic patterns for G-6-PD after 1 h incubation of haemolysates prepared from a single blood

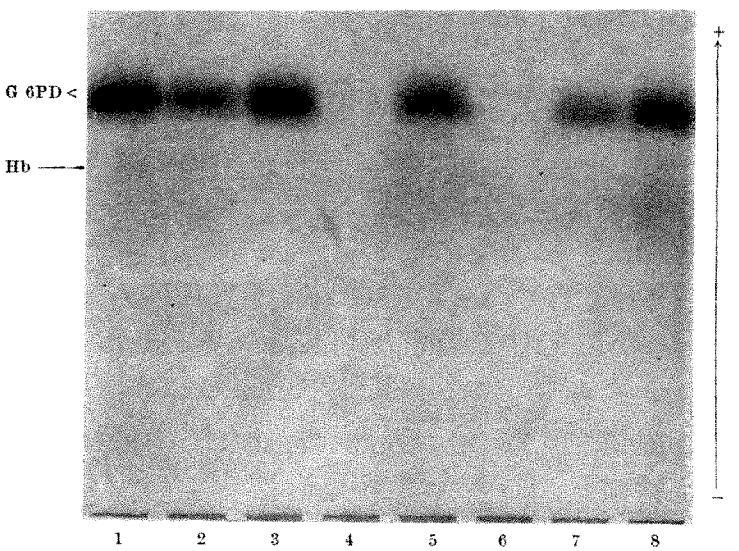

Fig. 1. Starch-gel electrophoresis of haemolysate G-6-PD, 1 h incubation of haemolysates prepared as described and numbered in the text. Aliquots were placed in the slots as follows: (1) control, no incubation, (2) haemolysate I, (3) haemolysate IV, (4) haemolysate II, (5) haemolysate III, (6) haemolysate I treated with 'Norit' prior to incubation, (7) same as (6) with NADP added after removal of 'Norit', (8) duplicate of (5)

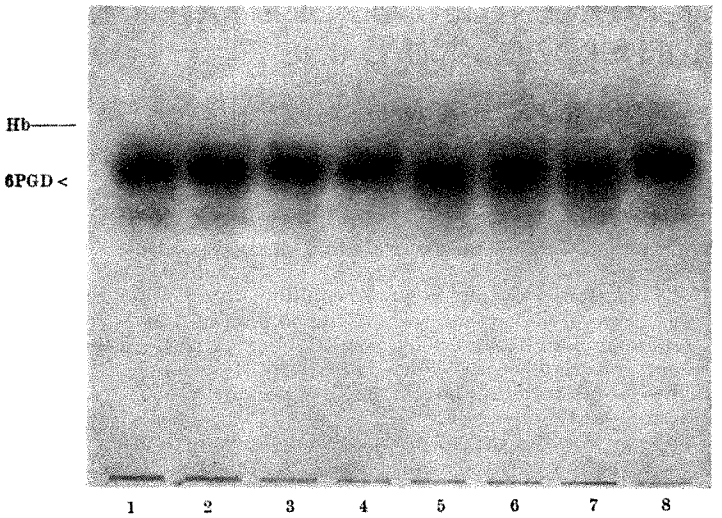

Fig. 2. Starch-gel electrophoresis of haemolysate 6-P-GD, Pd *A* types, 2 h incubation (except for slot 6) of haemolysates prepared as described and numbered in the text. Aliquots were placed in the slots as follows: (1) Control, no incubation, (2) haemolysate I, (3) haemolysate IV, (4) haemolysate II, (5) haemolysate III, (6) haemolysate III after 1 h instead of 2 h incubation, (7) haemolysate III treated with 'Norit' after incubation, (8) duplicate of (4)

sample are shown in Fig. 1. Slot 1 is the non-incubated control. Slot 2 shows the partial loss of activity by heat denaturation of the stroma-free haemolysate and slot 3 the protection by added NADP. Slot 4 demonstrates the loss of G-6-PD when incubated with stromata and slot 5 the protection by NADP. (Slot 8 is a duplicate of slot 5.)

In Fig. 2 are shown the results for 6-P-GD of the Pd *A* type. All haemolysates except haemolysate III retained their configuration; haemolysate III is distinguishable as a diffuse spot without clear bands occupying a larger area both after 1 and 2 h of incubation (slots 6, 5). Entirely similar results have been obtained in the bloods from the Pd *A–B* and the Pd *B* types. That is, the usually distinguishable bands have merged, there is no specific removal of any band, and the effect is essentially that of smearing. Although the Pd *A–B* and Pd *B* types of 6-P-GD were more labile than the Pd *A* type in this study, the electrophoretic smearing occurred only in haemolysate III.

Elucidation of this effect will require extensive investigation, especially after purification of both the enzyme and of the membranes. However, the following additional experiments have been performed.

(1) Dialysis of the haemolysates by gel filtration (through 'Sephadex *G*-25') after incubation removes free coenzymes, reduced and oxidized glutathione (GSH and GSSG), but not bound coenzymes. This procedure did not restore the 6-P-GD pattern or activity in haemolysate III, nor alter the patterns of the control haemolysate or of haemolysates I, II or IV.

(2) Acid-washed 'Norit' (45 mg/ml.) added to stroma-free haemolysate, prior to incubation, shaken and then removed by filtration, removes GSH, GSSG, free and bound coenzymes. Removal of the bound NADP results in a very labile G-6-PD and this activity, as with the stromal effects, is lost on incubation unless prevented by addition of NADP[2]. Pontremoli and co-workers made use of this effect of 'Norit' to remove G-6-PD in their procedure for crystallization of 6-P-GD from *Candida utilis*[15]. In Fig. 1 the loss of G-6-PD after treatment with 'Norit' is shown in slot 6 and the protection by added NADP in slot 7. However, no loss of 6-P-GD activity or smearing of the electrophoretic pattern is observed after treatment of stroma-free haemolysates with acid-washed 'Norit' prior to incubation with added NADP. Neither does the treatment with 'Norit' cause increased activity of GSSG-R. For both of these changes stromata are required. In addition, treatment of haemolysate III with 'Norit' after incubation does not restore either 6-P-GD activity or the electrophoretic pattern (slot 7, Fig. 2). (Experiment performed with the Pd *A* and Pd *A–B* type but not with the Pd *B* type.)

(3) Substitution of NAD for NADP in haemolysates III and IV fails to protect G-6-PD and also fails to induce the 6-P-GD effect in haemolysate III, that is, activity is not decreased and the electrophoretic pattern does not change or smear.

(4) However, alteration in the electrophoretic pattern of 6-P-GD has been obtained by modifying the preparation of the starch-gel. If NADP is not added to the gel, or if NAD instead of NADP is added to the gel, the 6-P-GD bands in all the haemolysates no longer appear separately, the spots are diffuse, and haemolysate III can no longer be distinguished from the others (either before or after incubation). Similarly, the Pd *A*, Pd *A–B* and Pd *B* types also cannot be distinguished unless NADP is added to the gel.

The decrease in 6-P-GD activity of haemolysates induced by incubation with stromata and NADP may be associated with an actual alteration of enzyme protein. Unlike the inactivation of G-6-PD and apparent activation of GSSG-R by stromata, NADP is also necessary to effect this change. The effect is not reversed by dialysis or treatment with 'Norit', nor can NAD be substituted for NADP to induce the effect. On the other hand, similar electrophoretic effects are observed by failing to add NADP to the starch gel; again, NAD cannot substitute for NADP. Thus, although NADP does not seem to be directly necessary for protection of the catalytic activity of 6-P-GD as it is for G-6-PD, this compound may affect the structural state of 6-P-GD, a fact not apparent in our previous investigations.

Whether these stromal effects in haemolysates are of physiological or pathophysiological significance is not known. The erythrocyte membrane does appear to have the capability of altering the metabolism of the erythrocyte by effecting changes in the cytoplasmic enzymes.

DETERMINATION OF TRACES OF ETHYLENEGLYCOL DINITRATE (AND NITROGLYCERINE) IN BLOOD AND URINE

By A. F. WILLIAMS and W. J. MURRAY

Research Department, Imperial Chemical Industries Limited, Nobel Division, Stevenston, Ayrshire

AND

B. H. GIBB

Cardiac Department and University Department of Medicine, Gardiner Institute, Western Infirmary, Glasgow

THE physiological action of ethyleneglycol dinitrate (EGDN) and nitroglycerine (NG) is of considerable interest to medical personnel associated with the manufacture of explosives[1-3]. Up to the present time, workers in this field have determined EGDN and NG in body fluids by using colorimetric methods to estimate nitrate or nitrite ions[1]. We have found that such methods are not only insufficiently sensitive but they suffer from the serious disadvantage that they do not readily distinguish between organic and inorganic nitrates. It seemed to us that the electron capture detector used in conjunction with gas chromatography might form the basis for a reliable method for the quantitative determination of EGDN and NG because it was already known that the electron capture detector was extremely sensitive towards certain organic chlorinated and nitrocompounds[4]. We have devised a method which can readily determine less than 0·04 ng (= 0·04 × 10^{-9} g) of EGDN, and preliminary experiments have shown that a lower limit of detection of less than 1 ng could be reached for NG.

EGDN is considerably more volatile than NG and readily penetrates a wide range of materials[5]. It is therefore likely to be found in the blood and urine of explosives workers. By the application of this method we have confirmed the presence of EGDN in such samples.

The determination of EGDN in a sample of heparinized blood or in urine was made in the following way. A measured volume (usually 0·5 ml.) of the sample was transferred to a stoppered glass tube (10 ml.) followed by the addition of 1 ml. of water and 0·3 g of sodium chloride, which was dissolved by shaking the tube. The solution so obtained was thoroughly shaken with 2 ml. *n*-hexane and the organic extract was then used directly for chromatography after centrifuging. The gas chromatographic separation was carried out using 10 per cent '*E*301' silicone elastomer (Imperial Chemical Industries, Ltd.) as stationary phase on 'Embacel' (May and Baker, Ltd.) utilizing a metal column 2 ft. long and of 0·25 in. diameter. The column was heated in an oven at 140° C with a sample preheater and vaporizer[6] at 160° C, the electron capture detector being connected to the outlet of the column at the top of the oven. Nitrogen (oxygen free), previously dried with molecular sieves, was used as carrier gas at a flow-rate of 150 ml. per minute. It was necessary to pay careful attention to the design and geometry and conditioning of the electron capture detector for it was found that even two apparently identical detectors could behave markedly differently. The detector finally chosen for this work was made in the laboratory workshops; the body, consisting of a 'Teflon' cylinder (4 cm long, 2·5 cm external diameter and 1 cm internal diameter), was closed with brass end pieces which served as the electrodes and enclosed a gas volume of about 1·5 c.c. The cathode was hollowed out to accommodate a standard tritium source consisting of a strip of titanium-plated copper foil (supplied by the Radiochemical Centre, Amersham), 3 cm × 1 cm, activity 300 mc. The greatest sensitivity was obtained when the foil was positioned so that it protruded a distance of about 1 mm beyond the end of the cathode. Under the conditions used, a potential of about 30 V applied to the detector gave the most satisfactory background current (1–2 × 10^{-9} amp using a Perkin–Elmer amplifier). Before a definite response could be obtained for EGDN, it was necessary to preheat the column at 180° C for about an hour followed by conditioning of the column at its working temperature with 1-μl. amounts of hexane solution containing 1 μg NG per μl., injected at about hourly intervals.

For the actual analysis of a hexane solution derived from a blood or urine sample, a volume of 10–40 μl. was transferred to the column and the peak due to EGDN was compared with standards. The standards were prepared under the same conditions as the test by extracting dilute aqueous solutions containing known amounts of EGDN with hexane. Fig. 1 shows a series of chromatograms derived from 10-μl. amounts of hexane obtained in the manner described earlier from samples of blood containing amounts of EGDN equal to zero, 0·02, 0·04, 0·08, 0·12 p.p.m. (that is, zero, 0·05, 0·10, 0·20, 0·30 ng).

As the rate of disappearance of EGDN in human blood *in vitro* is not known, this was determined by adding small amounts of EGDN to a series of blood samples and following the rate of fall in EGDN concentration over a period of time. Fig. 2 shows the results obtained from studying blood samples which originally contained between 0·03–0·18 p.p.m. of EGDN. It is quite clear that the rate of fall of EGDN is sufficiently slow to allow for a delay between the taking of a blood sample and its subsequent analysis. However, as the fall is appreciably more rapid at the lower concentrations of EGDN, estimation is ideally performed as soon as possible.

Because of the great sensitivity of the analytical method and the likelihood of contamination during the collection of blood and urine samples, the degree of persistence of EGDN on the skin was studied. About 5 mg of EGDN was spread over part of the palm of the hand with the aid of a glass rod, so that it covered an area of 4 sq. cm. After an interval of 3 min the hand was washed with hot soapy water, rinsed and dried. Using a scalpel, about 5 mg of skin was removed from the area to which the EGDN had been applied and extracted with a suitable volume of hexane and EGDN determined by the method

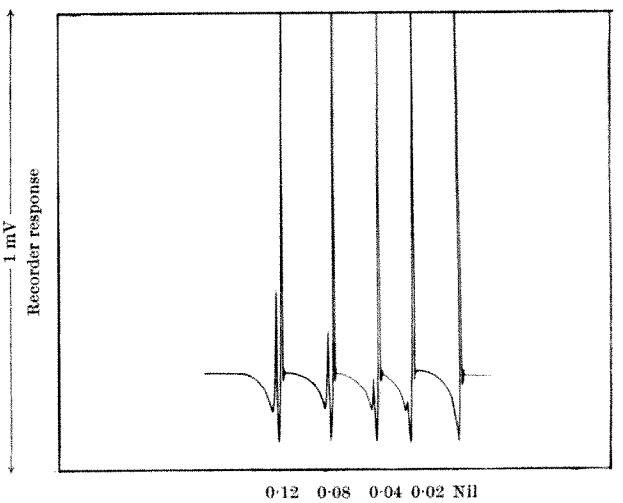

Fig. 1. Chromatograms for EGDN (p.p.m.)

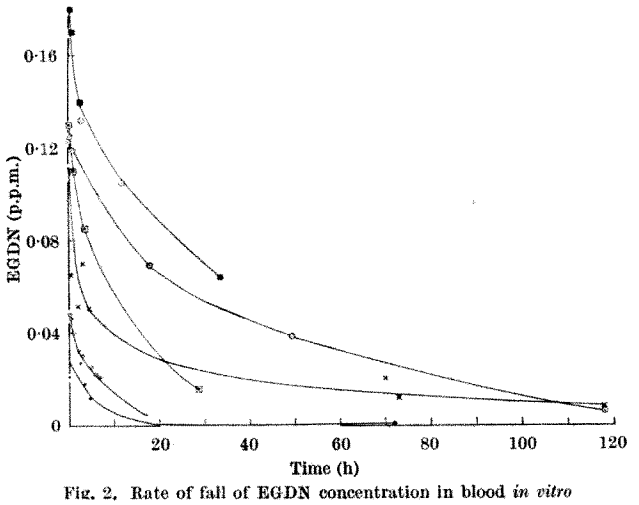

Fig. 2. Rate of fall of EGDN concentration in blood *in vitro*

described. An amount equivalent to 30 ng/mg skin was found. After a further period of 1 h (without further washing of the hand) this fell to 3·5 ng/mg skin; 30 min later the hand was washed again in hot soapy water and a final sample of skin yielded 2 ng EGDN/mg skin. These results showed that EGDN, when applied to human skin, may persist after ordinary methods of cleansing. The method subsequently used for cleansing, before taking a blood sample, was to wash the skin with 'Saroul' followed by absolute alcohol.

The blood and urine of a number of plant operatives were examined for EGDN. The analyses were made on blood samples taken from five different operatives working on a section of an explosives plant where EGDN contamination was likely to be greater than at other parts of the plant. The samples of blood were obtained from a peripheral vein within a few minutes of the operator leaving his work, and all the samples were examined within a period of 30 min of being taken. The blood samples for the five operatives contained 0·04, 0·01, 0·07, 0·06 and 0·05 p.p.m. EGDN respectively. The corresponding urine samples contained 0·02, 0·03, 0·02, 0·04 and 0·08 p.p.m. EGDN. The blood and urine of two control personnel gave negative tests. When the same operatives were re-examined after a period of 16 h away from explosives manufacture, EGDN was no longer detectable in either their blood or their urine.

Work on the fate of EGDN in the human circulation is in progress and is being extended to the study of the pharmacological action of NG.

We thank Dr. J. D. Paterson and Dr. A. J. V. Cameron for their interest and encouragement in this work which for one of us (B. H. G.) is supported by a research fellowship financed by Nobel Division, Imperial Chemical Industries, Ltd.

ROLE OF LONG EXTRACELLULAR CHANNELS IN FLUID TRANSPORT ACROSS EPITHELIA

By DR. JARED M. DIAMOND
Biophysical Laboratory, Harvard Medical School, Boston, Massachusetts
AND
DR. JOHN McD. TORMEY
The Wilmer Institute, The Johns Hopkins University School of Medicine, Baltimore, Maryland

THIS article presents the results of correlated physiological and anatomical experiments to identify the route by which water is transported across epithelial cells such as those of the intestine, gall-bladder, and kidney. Such epithelia produce specific secretions or absorbates by active transport of some solute, with water movement probably a secondary result of local osmotic gradients set up within the tissue by active solute transport[1]. The main problem is to explain how local osmotic equilibration can be so complete that water follows solute in virtually isotonic proportions. Calculation shows that the measured passive permeability of many epithelia to water would be much too low to account for the observed isotonicity of transported fluid without some special geometrical arrangement. A hypothesis for the route of water transport must therefore answer this question—What structural device prevents actively transported solute from diffusing away before sufficient water has followed to achieve osmotic equilibrium?

The epithelium selected for these experiments was the gall-bladder of the rabbit. This tissue offers the advantage of a relatively simple anatomy and physiology, and is able to maintain a high rate of water transport *in vitro*[2]. To concentrate bile, the gall-bladder reabsorbs sodium and chloride actively, with water following the salt in isotonic proportions[3–7].

Water transport in isolated, cannulated rabbit gall-bladders was measured under various physiological conditions by means of a gravimetric method already described[2,3]. At the end of each experiment the gall-bladders were fixed by buffered osmium tetroxide and embedded in 'Epon 812'. Sections 2μ thick were examined in a phase contrast microscope, employing Zeiss 'Neofluar' optics. In some cases thin sections from the same specimens were also examined in an electron microscope. The electron microscope findings in general confirmed those obtained with the light microscope, and will be presented in detail elsewhere.

The organ consists of a sac, with a single layer of epithelial cells supported by an outer layer of connective tissue. As shown in diagrammatic form in Fig. 1, the epithelium possesses several salient features found under all the experimental conditions to be reported: (1) The cells are tall and slender. (2) The apical surface of the cell (that is, the surface facing the lumen of the gall-bladder) contains an array of microvilli, similar in structure to those found, for example, in the brush border of intestinal and kidney epithelia. (3) The cells are joined together at their luminal borders by a continuous system of terminal bars (tight junctions)[8]; by this structural device, the luminal contents of the gall-bladder are sealed off from direct access to the lateral intercellular spaces. (4) The area of the lateral cell surface is greatly increased by numerous cytoplasmic projections into the lateral intercellular space. These projections bear a superficial resemblance in size and shape to microvilli, but otherwise

lack certain distinctive morphological features of the latter. The width of the intercellular space separating the lateral borders of adjacent cells is quite variable, depending on the experimental conditions. Under conditions where this width is minimal, the cytoplasmic projections from each cell form complex mutual interdigitations with those of neighbouring cells. (5) The basal cell surface is without membrane infoldings and rests on a typical basement membrane. (6) The only prominent cytoplasmic organelles are the abundant mitochondria, which are absent only in the terminal web immediately beneath the apical microvilli. Elsewhere they are distributed fairly uniformly throughout the cell, although at a somewhat higher concentration towards the apical pole. (7) Vesicles occur but are quite few in number. The other usual cytoplasmic systems and organelles (such as endoplasmic reticulum, Golgi apparatus) are unimpressively represented.

In preliminary experiments, gall-bladders were placed in fixative within 50–100 sec after interruption of the blood supply. The epithelial cells were found to be separated from one another by lateral spaces whose width was variable but averaged approximately 0·4μ. The extent to which these freshly excised gall-bladders had completed concentrating bile and hence to which they were still absorbing water is unknown and was probably variable.

In order to obtain preparations known to be transporting water at maximal rates, gall-bladders were cannulated and incubated at 37° C in a Ringer's solution containing 110 mM sodium chloride and 25 mM sodium bicarbonate. After transport rates of 228–592 μl./h had been measured for 1 h, the gall-bladders were fixed and examined as described above. These organs differed from freshly excised preparations in that the lateral intercellular spaces were quite dilated (see Fig. 2*A*). The measured width of these spaces in five gall-bladders was found to average 0·9μ (standard error = 0·1μ, $n = 58$). (These and all subsequent measurements of the lateral spaces were made half-way between the basal and apical surfaces of the cells, using a ×100 Zeiss 'Neofluar' oil immersion lens, $N.A. = 1{\cdot}3$. The smallest separation measurable in this manner was approximately 0·2–0·3μ,

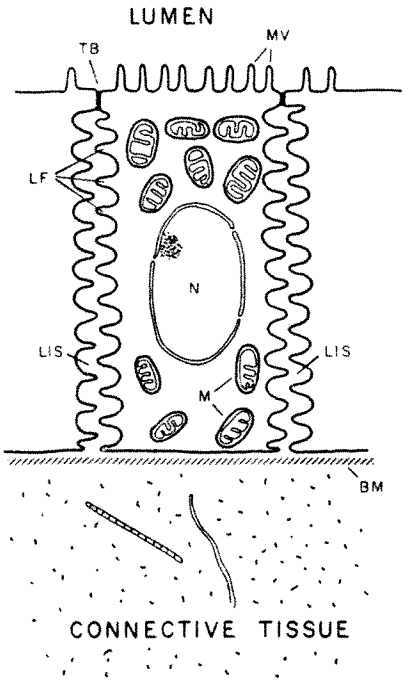

Fig. 1. Schematic representation of the structure of an epithelial cell from rabbit gall-bladder (not to scale). The height of the cells relative to their width is actually more than twice that depicted here. An unbroken sheet of such cells faces the lumen of the gall-bladder. *TB*, terminal bar; *MV*, microvilli; *LF*, lateral folds; *LIS*, lateral intercellular spaces; *M*, mitochondria; *N*, nucleus; *BM*, basement membrane

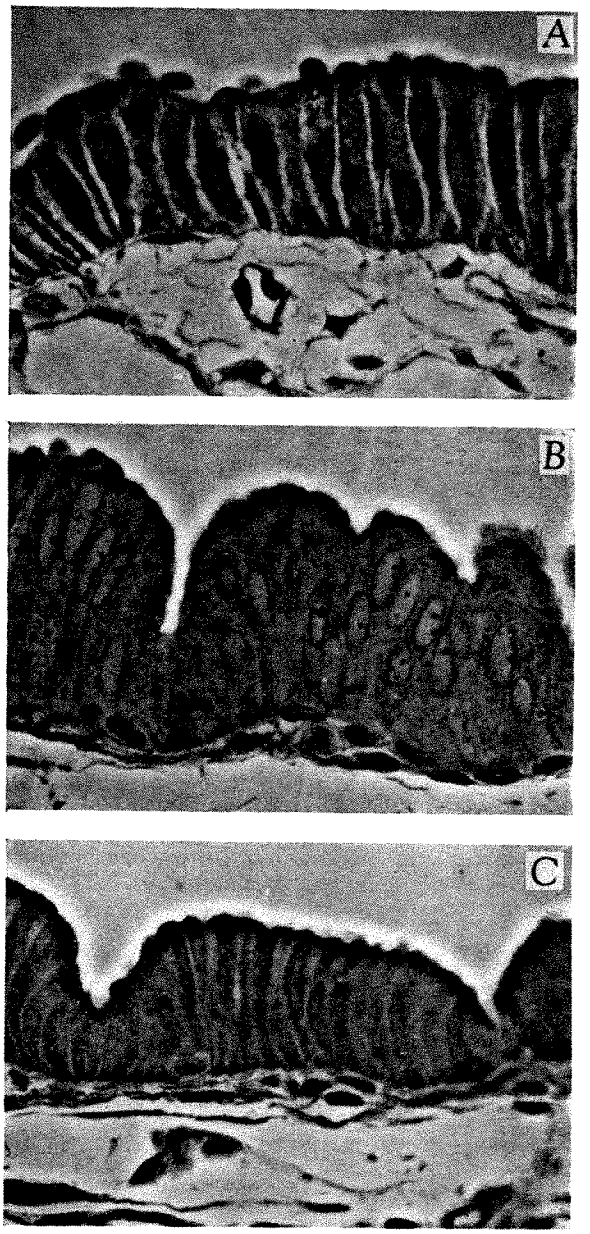

Fig. 2. Phase contrast micrographs of rabbit gall-bladder epithelium *in vitro* under three different experimental conditions. All three photographs are at identical magnifications of ×800. (*A*) Actively transporting preparation in sodium chloride Ringer's solution at 37° C. Note the clear spaces, approximately 1μ wide, between adjacent cells. (*B*) Transport stopped by 10^{-3} M ouabain. There are no intercellular spaces visible so that it is difficult to see precisely where one cell steps and the next begins. The cells are also substantially taller than in the actively transporting preparation. (*C*) Transport stopped by substitution of sucrose for sodium chloride in the luminal bathing solution. As in 2*B*, there are no spaces evident between the cells. The cells are also substantially smaller than in the actively transporting preparation

that is, at the limit of resolution of the light microscope.) While the spaces were generally dilated for most of their length, adjacent cells always remained tightly attached to one another at the terminal bar. Similar observations have recently been reported[9].

To determine whether this dilation of the spaces was correlated with fluid transport, we next examined gall-bladders in which water transport had been stopped by four different sets of conditions. In each experiment the rate of water movement was followed gravimetrically for 30–60 min before fixation to make sure that water transport had ceased. The four conditions used to stop transport, and their effects, were as follows:

(1) *Low temperature.* Gall-bladders were maintained in Ringer's solutions containing 110 mM sodium chloride

and 25 mM sodium bicarbonate, but at 4° C. The rate of water transport dropped to between 4 and 10 μl./h. The principal difference in the appearance of these cells from those of transporting preparations was that the lateral spaces were nearly closed. No space was visible between 75 per cent of adjacent cell pairs with the × 100 objective, and spaces between the remaining cells were no more than 0·4μ wide.

(2) *Ouabain.* This cardiac glycoside inhibits active transport in the gall-bladder[3,7] as well as in many other tissues. In the present experiments 10^{-3} M ouabain reduced fluid absorption at 37° C to an average level of 20 μl./h. The morphological findings (Fig. 2*B*) were that almost all the lateral spaces were completely closed, so that the borders between adjacent cells became difficult to recognize. In addition, the cells appeared substantially taller than transporting cells.

(3) *Isotonic luminal sucrose.* When the solution in the lumen of the gall-bladder is replaced by an isotonic sucrose Ringer's solution, there is no longer any luminal salt that can be actively transported, and two phases of salt and water movement across the gall-bladder wall follow. First, there is a brief transient during which fluid continues to pass outwards (that is, into the serosal bathing solution). This movement has been shown to be the result of the epithelial cells pumping some of their own salt and water content out across their serosal surfaces, with consequent cell shrinkage[3]. It is noteworthy that this salt does not leave the cells by diffusing down the sodium chloride concentration gradient from the cells to the salt-free solution in the lumen, but rather is pumped in the opposite direction against the concentration gradient. This has been interpreted as evidence for the location of a salt pump at the lateral and/or basal cell surface. Secondly, at the end of the initial transient a steady state is reached in which fluid slowly moves from the serosal solution into the lumen of the gall-bladder. This is due to water accompanying the slow passive diffusion of salt back down its concentration gradient into the lumen[2,3,7].

In the present experiments a small reversed movement of fluid into the lumen at 12–20 μl./h was observed in the steady state. As expected, the cells appeared considerably shrunken in comparison with transporting cells. Despite this shrinkage, about 50 per cent of the cells showed no separation at all in the phase-contrast microscope (Fig. 2*C*) and the remainder were separated by an average of 0·4μ.

(4) *Hypertonic luminal solutions.* The gall-bladder can transport water against osmotic gradients between the luminal and serosal bathing solutions[2,5–7], until these external gradients exert a force exceeding that of the local osmotic gradients developed within the tissue by active solute transport. Hence gall-bladders were investigated in Ringer's solutions at 37° C containing 110 mM sodium chloride and 25 mM sodium bicarbonate, but with the luminal solution made hypertonic by addition of 120–200 mM sucrose. The rate of fluid transport dropped below 28 μl./h, and either no net flow or small reversed flows were observed in most cases. The principal morphological change, as compared with normally transporting preparations, was that the lateral spaces decreased in width to an average of 0·4μ.

It therefore appears that the lateral spaces are dilated when fluid transport is occurring, and closed or nearly closed under four different sets of conditions which prevent fluid transport. The simplest explanation for the dilation of the lateral spaces during water flow would be that the route of transport proceeds from the cells by means of the lateral spaces out through the basement membrane. However, two other possible explanations must be considered:

(1) If water transport caused consistent changes in cell size, the changes in the lateral spaces could be secondary to changes in cell geometry, for example, because of cells shrinking and pulling apart. To check this possibility, cell dimensions were measured in transporting gall-bladders and under the four sets of conditions used to stop transport. For each type of experiment a total of 20–50 cells from two or more gall-bladders was measured. The average height and width of cells from transporting gall-bladders were 33μ and 5μ, respectively. Cells from gall-bladders maintained at 4° C were appreciably larger (41μ × 4·5μ), and cells from gall-bladders poisoned with ouabain were larger still (44μ × 5μ). Hypertonic luminal solutions caused little if any, cell shrinkage (30μ × 5μ) compared to conditions of maximal transport. Isotonic luminal sucrose caused considerable shrinkage (26μ × 4μ). Since non-transporting cells may thus be either swollen or shrunken with respect to transporting cells, transport does not produce consistent changes in cell geometry that might expand lateral spaces secondarily.

(2) When blood circulation is intact, absorbed fluid is removed by way of capillaries present near the basement membrane. However, *in vitro*, absorbed fluid must traverse the connective tissue layer beyond the basement membrane. If sufficient pressure were built up within the connective tissue, this back pressure might force the cells apart without providing any clue to the route of water transport through the cells. To determine whether physiologically reasonable back pressures are sufficient to dilate the lateral spaces to the degree observed during transport, we everted gall-bladders so that the epithelial cell layer faced outwards. The cannula was then connected to the inside fluid compartment (facing the connective-tissue layer). At 4° C, back pressures from the connective tissue towards the cells were maintained by filling the cannula to various heights for 10 min, after which time the gall-bladder was fixed. When back pressures of 2·0, 2·1, 4·3, or 4·9 cm of water were applied, the lateral spaces were not found to be significantly wider than those in non-transporting gall bladders. A pressure of 9·7 cm of water damaged the preparation irreversibly, as judged by the sudden onset of leakiness, and morphologically there was not only dilation of some lateral spaces but also rupture of the cell layer at several points. It is also noteworthy that Diezschy found that back pressures as small as 1–5 cm of water already suffice to impair the transport function irreversibly. The pressures of 2·0–4·9 cm of water employed in our experiments must therefore be greater than those present in a transporting gall-bladder, but they nevertheless fail to cause a significant increase in width of the lateral spaces. Hence back pressures generated by water flow through connective tissue during transport are unlikely to be the explanation for the observed dilation of the lateral spaces.

Because changes in cell geometry and back pressures do not account for the dilation of lateral spaces associated with transport, the correct explanation is probably the simplest—that water flow goes through these spaces. Fig. 3 shows the route of water transport deduced from these experiments. Presumably, sodium chloride is being actively transported out of the cells into the spaces, and this is where the local osmotic gradient responsible for water transport is built up. (*A priori*, salt could also have been transported into these spaces across the terminal bar without entering the cells. However, this is rendered unlikely by the previously cited observation that after removal of luminal salt, the cells can pump out more salt and water and thus shrink themselves.) The solution near the luminal end of the spaces would be hypertonic, and the resultant water flow into the spaces would carry out the salt towards the basement membrane. With the entire length of the space available for osmotic equilibration, salt could gradually become diluted to an isotonic concentration by the time it is swept out of the basal end of the space.

In most other epithelia carrying out isotonic transport, one also observes long extracellular channels which could serve the same purpose as the lateral spaces of rabbit gall-bladder—to permit complete osmotic equilibration

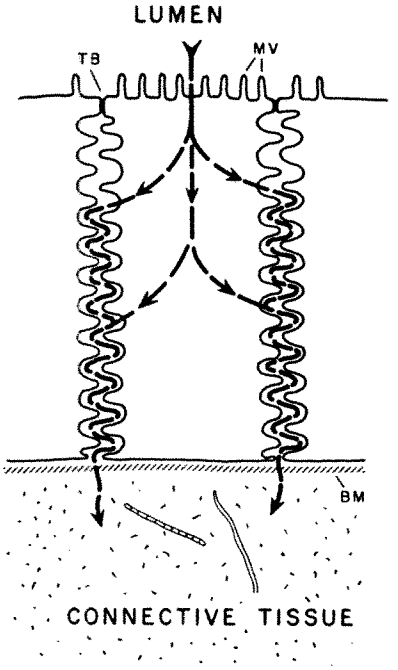

Fig. 3. Route of water transport across the epithelial cells of rabbit gall-bladder deduced from the present experiments. Water enters the cells at the surface facing the lumen, then goes out across the lateral cell membrane into the lateral intercellular spaces. These spaces are presumably hypertonic because of active transport of sodium chloride. The fluid passes down these long spaces and has equilibrated to isotonicity by the time it reaches the basal end. Finally, fluid crosses the underlying basement membrane and leaves the epithelium

of actively transported solute. Familiar examples are the basal membrane infoldings of kidney proximal tubule cells, lateral spaces of intestinal absorptive cells, and secretory canaliculi of parietal cells. The significance that has generally been attached to these membrane elaborations is that of providing greater membrane area and more transport sites. The present work, however, suggests that such structures may also possess a geometrical significance. If solute is actively transported into the closed end of a long channel bounded by cell membrane, osmotic equilibration can go on continuously as the solute moves down the channel. In a long, narrow channel, high linear velocities of water flow would be generated, and the sweeping effect of the osmotic water flow caused by solute transport would probably be more important than diffusion in carrying solute out of the channel. One would therefore have a self-regulating arrangement to ensure equilibration of actively transported solute to isotonicity, regardless of the transport rate. This geometrical arrangement might also explain why values reported for the passive osmotic permeability of epithelia appear to be too low to account for the water flow during solute transport[1,10]. Osmotically active solutes added to the external bathing solution might not measure the water permeability of the long spaces, since water flow out of the dilated spaces might bar them to external solutes during transport and since the spaces collapse in the absence of water flow.

In summary, we have observed that the lateral spaces between epithelial cells of the gall-bladder are dilated during solute-linked water transport and are closed when water transport is stopped by any one of four sets of conditions. The probable explanation for these changes is that water transport goes by way of the lateral spaces, as pictured in Fig. 3. Structures with similar geometry in other epithelia (for example, basal infoldings and secretory canaliculi) may also serve the function of preventing actively transported solute from diffusing away until water can follow in isotonic proportions.

This project was supported in part by a U.S. Public Health Service Research grant of the National Institute of Neurological Diseases and Blindness and by the U.S. Atomic Energy Commission. The work was carried out during tenures of a junior fellowship in the Society of Fellows, Harvard University (Jared M. Diamond), and a Special Fellowship of the National Institute of Neurological Diseases and Blindness (John McD. Tormey). We are indebted to Prof. K. R. Porter and Dr. A. K. Solomon for advice and encouragement, and to Mrs. Lee Carter for patient technical assistance.

SIGNIFICANCE OF THE HISTOCHEMICAL DEMONSTRATION OF ATPASE IN EPITHELIA NOTED FOR ACTIVE TRANSPORT

By DR. JOHN McD. TORMEY
The Johns Hopkins University School of Medicine, Baltimore, Maryland

THE histochemical localization of ATPase has been described in a variety of epithelia noted for active transport of electrolytes. The enzyme has been demonstrated by both light and electron microscopy in such systems as kidney tubules[1,2], frog skin[3], toad bladder[4,5], gall-bladder[6], and ciliary epithelium[7–9]. Activity is often found associated with those very subcellular structures which are believed on other grounds to play a major part in transcellular transport. The question is: What physiological conclusions, if any, can be derived from such histochemical results?

The principal justification for relating ATPase activity to ion pumps, and hence to transcellular active transport, comes from a growing body of biochemical investigations which point to the conclusion that Na^+ is transported by a mechanism very intimately associated with a specific ATPase[10–12]. This specific enzyme is biochemically distinguished from other forms of ATPase by the following criteria: (1) Sodium and magnesium ions are absolutely necessary for its activation. (2) In many cases, potassium ions are also necessary for its activation. In no case, however, is the enzyme activated by potassium in the absence of sodium. (3) It is inhibited by calcium and low concentrations of cardiac glycosides, such as ouabain. Hence, before a role in ion pumping can be assigned with some confidence to a histochemically demonstrated ATPase, it must be shown to be activated and inhibited in accordance with these criteria.

Unfortunately, most histochemical investigations have not included rigorous attempts to establish the nature of the ATPase described. A notable exception is an investigation by Novikoff *et al.*[13], who used the conventional Wachstein–Meisel ATPase medium and were unable to find any evidence of sodium-pump ATPase.

Bonting *et al.*[14] have stated that the Wachstein–Meisel medium and similar histochemical procedures based on

the Gomori technique cannot be used to demonstrate sodium-pump ATPase. This conclusion is based on unpublished experiments in which they found that the addition of 0·01 M Pb^{++} to mixtures used for the biochemical assay of sodium-pump ATPase caused almost 100 per cent inhibition of this enzyme. Nevertheless, Berg[15] has recently shown that the chemical mechanisms involved in histochemical stains for triphosphatases are more complicated than those proposed by Gomori. Most of the lead in ATPase media seems to be present not as the free plumbous ion but in the form of chelation complexes with other components of these mixtures. In the present state of incomplete knowledge about the chemistry of ATPase staining procedures, it remains conceivable that media might be developed which contain lead in chemical states such that sodium-pump ATPase would not be completely inhibited.

It is of great interest, therefore, that both Cole[7] and McClurkin[16] have recently published reports of successful attempts at histochemically localizing sodium-pump ATPase by using substantial modifications of the Wachstein–Meisel medium.

Recognizing the importance of demonstrating specific sodium-pump ATPase, this laboratory has undertaken a careful histochemical study of the ciliary epithelium of the rabbit eye. These cells secrete the aqueous humour, apparently by means of a sodium pump. Biochemical investigations have shown that about 40 per cent of the total ATPase present in the ciliary epithelium is typical sodium-pump ATPase[12,17].

Ciliary bodies from the eyes of adult albino rabbits were frozen in isopentane at −70° C. Frozen sections about 6μ thick were cut in a cryostat. The sections were either used unfixed or first fixed in ice-cold solutions of either 6 per cent calcium–formol, 2·5–10 per cent α-hydroxyadipaldehyde, or 3 per cent glutaraldehyde. The last two fixatives were buffered at *p*H 7·3 by 0·1 M sodium cacodylate. Fixation times varied from 5 to 60 min. Sections were washed in *tris*-maleate or *tris* buffer for 5–30 min before being incubated at 37° C in the media of either Wachstein and Meisel[18], Cole[7], or McGlurkin[16], as described later.

Using any of the above fixatives for times longer than 10 min, and using the conventional Wachstein–Meisel medium, ATPase activity was found to be localized principally in the 'non-pigmented' epithelial layer of the ciliary epithelium. Most of the ATPase activity was found in large patches adjoining the peripheries of the individual cells (cf. Fig. 1*A*). This corresponds to the location of the elaborate membranous interdigitations that are the most striking feature of these cells as seen in the electron microscope[19]. Similar localization has been reported by others[9], and the reaction product has been shown by electron microscopy to lie within the interdigitations[8]. Such localization is most intriguing, since there is reason to believe that these interdigitations play a major part in electrolyte secretion. The enzyme is also found to a lesser extent in the neighbourhood of the basal infoldings of the 'pigmented' cell layer and at the junction between the 'non-pigmented' and 'pigmented' epithelial layers.

(1) *Effect of ouabain.* This cardiac glycoside inhibits the sodium-pump ATPase of the ciliary epithelium, as determined *in vitro* by both physiological[20] and biochemical[12,17] methods. When ouabain concentrations of the order of 5×10^{-5} M are employed, inhibition is virtually complete within a few minutes. In our experiments, 10^{-4} M ouabain was added to either the Wachstein–Meisel medium or the Cole medium. Several lots of the drug, from various sources, were tried. In some instances the sections were soaked in cold buffer containing the drug for up to four hours before incubation. The incubation time was varied over a range from 5 min to 3 h. Serial sections were incubated alternately in media with and without ouabain. Later, individual ciliary processes were followed from section to section and the reaction was compared in the same cells. In some cases the ouabain-treated processes were less intensely stained than the controls, but the reverse was found with equal frequency. Thus we were unable to find any evidence that ATPase activity was inhibited by ouabain during total periods of exposure to the drug of up to seven hours.

(2) *Effects of sodium and potassium ions.* Using the media recently described by McClurkin, an attempt was made to demonstrate sensitivity of the histochemical reaction to sodium and potassium. Unfixed serial sections were incubated alternately in three different media. The 'control' medium contained buffer, magnesium, and sodium-free ATP (prepared by treatment of the barium salt of ATP with 'Dowex 50*W*' ion exchange resin). The 'Na-K' medium was identical to the control but contained in addition 100 mM sodium and 30 mM potassium, which is close to the optimal concentration of these two ions for activating sodium-pump ATPase. The 'K' medium was similar but contained 130 mM potassium only.

Sections incubated in the 'Na-K' medium exhibited much greater activity than sections incubated in the 'control' medium. However, the 'K' medium consistently yielded staining effects indistinguishable from those obtained with the 'Na-K' medium. Theoretically, if the difference in results between McClurkin's 'control' and 'Na-K' media was due to sodium-pump ATPase, the 'K' medium should have produced results identical to those obtained with 'control'. That this was not the case

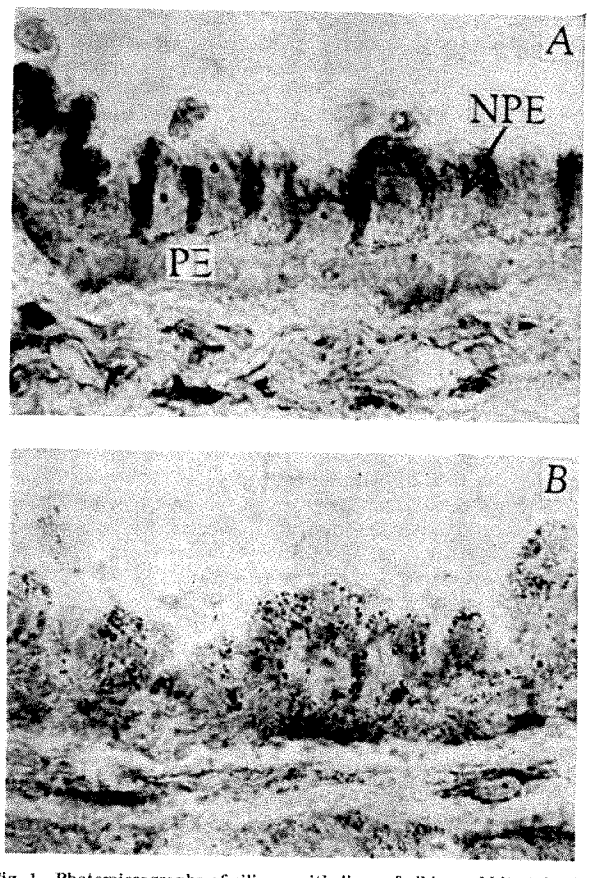

Fig. 1. Photomicrographs of ciliary epithelium of albino rabbit stained with Wachstein–Meisel ATPase medium (× 1,100). *A*, fixed 15 min with 3 per cent glutaraldehyde, shows membrane-associated ATPase activity. Most of the reaction product is found in the 'non-pigmented' epithelial layer (*NPE*), where it is localized adjacent to lateral cell borders and, to a lesser extent, near the free cell surfaces. This distribution corresponds to the distribution of plasma membrane interdigitations (infoldings), as seen by electron microscopy. Very small amounts of reaction product are also found in the basal portion of the 'pigmented' epithelium (*PE*) and between the two epithelial layers. *B*, Fixed 5 min with 2·5 per cent hydroxyadipaldehyde, shows punctate reaction product corresponding to distribution of mitochondria through the cytoplasm of both cell layers. A considerably weaker, diffuse staining is associated with the interdigitations

indicates that the different results with 'Na-K' and 'control' media were due not to specific enzyme activation but to a non-specific effect of the total ionic strength of the medium. Other experiments were carried out in which sodium and potassium ions were added to the conventional Wachstein–Meisel medium, and no differences were observed.

(3) *Effects of magnesium and calcium ions.* Both mitochondrial ATPase and sodium-pump ATPase are specifically activated by magnesium and inhibited by calcium. It was therefore of interest to compare the effects of these two cations on the ATPase activity associated with mitochondria and that associated with interdigitations. When the sections were fixed for 5 min in 2·5 per cent α-hydroxyadipaldehyde, both forms of activity were well preserved and localized, with mitochondrial activity evident as discrete, short rods distributed throughout the cytoplasm of both cell layers of the epithelium (Fig. 1*B*). Serial sections fixed in this way were incubated alternately in three media. The 'Mg' medium was identical to the one originally described by Wachstein–Meisel, containing 0·01 M magnesium ions. The 'Ca' medium was the same, except for the replacement of magnesium with an equimolar concentration of calcium. The 'control' medium contained neither cation.

In the 'Mg' medium the mitochondrial reaction was quite pronounced, whereas the interdigitations showed relatively moderate activity. In the 'Ca' medium the mitochondrial activity was extremely weak, but the reaction of the interdigitations gained considerably in strength. Virtually no activity was present after incubation in the 'control' medium. This result argues directly against the view that the activity associated with interdigitations is related to the sodium pump. Not only is it not inhibited by calcium, but it seems to be more strongly activated by it than by an equal concentration of magnesium. Mitochondrial ATPase, on the other hand, demonstrates the same specificity to divalent cations as predicted from biochemical experiments. The results with mitochondria help to confirm the reliability of the histochemical methods employed here; if the sensitivity of mitochondrial ATPase to various cations can be clearly demonstrated in tissue sections by standard histochemical techniques, there seems to be little room for believing that the specificities of other types of ATPase should not be equally well demonstrated by the same techniques.

The only reasonable conclusion from the foregoing experiments is that sodium-pump ATPase is not demonstrated by either the Wachstein–Meisel medium or the variant methods proposed by Cole and by McClurkin. Since about 40 per cent of the biochemically demonstrated ATPase activity of the ciliary epithelium is sodium-pump ATPase, and since a wide variety of conditions of fixation were employed, it seems unlikely that failure to demonstrate the enzyme can be attributed to a low concentration or to sensitivity to fixation. The *p*H of the incubating media employed here was 7·2–7·3, which is close to the optimum for sodium-pump ATPase. The most likely explanation, in keeping with the observations of Bonting[14], is that the lead which is a necessary component of these media has inhibited the enzyme to the point that it is virtually undetectable.

In spite of the present lack of methods for demonstrating clearly sodium-pump ATPase, it is still a remarkable coincidence that widely differing transporting tissues reveal striking localization of ATPase at those very membranes across which active transport is thought to occur. An absence of membrane-associated ATPase activity, furthermore, has been reported in the case of human epidermis, where no active transport is believed to occur[22]. On the basis of comparative observation of a variety of epithelia, both transporting and non-transporting, might one be justified in concluding that histochemical ATPase activity is related to active transport, although

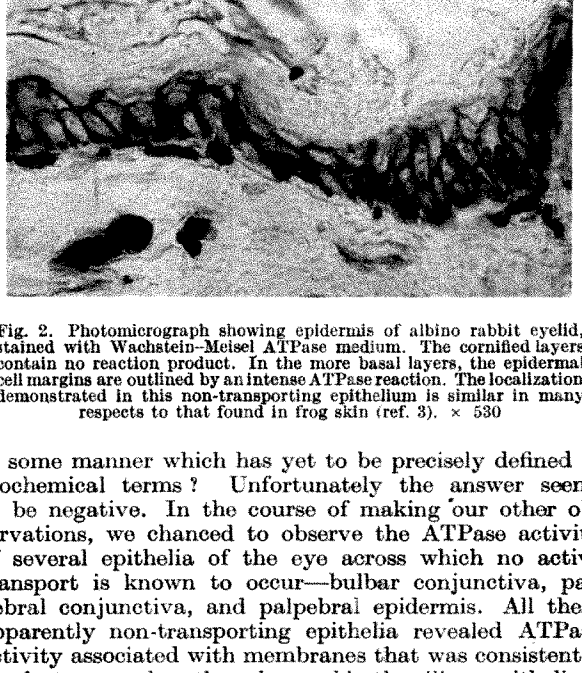

Fig. 2. Photomicrograph showing epidermis of albino rabbit eyelid, stained with Wachstein–Meisel ATPase medium. The cornified layers contain no reaction product. In the more basal layers, the epidermal cell margins are outlined by an intense ATPase reaction. The localization demonstrated in this non-transporting epithelium is similar in many respects to that found in frog skin (ref. 3). × 530

in some manner which has yet to be precisely defined in biochemical terms? Unfortunately the answer seems to be negative. In the course of making our other observations, we chanced to observe the ATPase activity of several epithelia of the eye across which no active transport is known to occur—bulbar conjunctiva, palpebral conjunctiva, and palpebral epidermis. All these apparently non-transporting epithelia revealed ATPase activity associated with membranes that was consistently much stronger than that observed in the ciliary epithelium (Fig. 2). Moreover, an absence of histochemically demonstrable ATPase activity has been reported in the case of the secretory epithelium of the avian salt gland[23] in spite of the fact that such glands are notably engaged in electrolyte transport and contain high concentrations of sodium-pump ATPase[24]. Clearly, then, there is no necessary relationship between histochemically demonstrated ATPase and transcellular transport.

The answer to the question posed at the beginning seems clear. There is at the present time no warrant for drawing physiological conclusions from the histochemical localization of ATPase in active transport systems.

This project was supported in part by a grant from the National Institute of Neurological Diseases and Blindness, U.S. Public Health Service. The work was carried out during the tenure of a special fellowship of the National Institute of Neurological Diseases and Blindness. I thank Mrs. Lee Carter for technical assistance.

RESTORATION OF THE RESPONSE OF THE ISOLATED ATRIA OF GUINEA-PIGS TO TYRAMINE AND POSSIBLE SIGNIFICANCE OF β-HYDROXYLATION

By DR. B. BHAGAT, LYNNE GRAY and N. S. DHALLA
Department of Pharmacology, College of Medicine, Howard University, Washington, D.C.

AFTER pretreatment with reserpine, an organ usually loses its responsiveness to tyramine or other substances which act through the release of catecholamine from the postganglionic sympathetic nerve endings[1]. However, when such an organ is exposed to, or perfused with, norepinephrine, its responsiveness to tyramine is restored. This is usually interpreted as a 'refilling' by exogenous norepinephrine of the previously depleted stores and subsequent release by tyramine of the stored norepinephrine. However, this phenomenon is not restricted to norepinephrine; several of its precursors, such as dopamine, have been found quite effective in this regard[2,3]. However, the significance of β-hydroxylation, which is a final step in the synthesis of norepinephrine, in the restoration by these precursors of the response to tyramine has yet to be determined. The experiments described in this article were undertaken to obtain information on this point. Disulfiram, which is a potent inhibitor of dopamine β-oxidase[4], was used as a means of inhibiting β-oxidase in this investigation. The effect of inhibition of dopamine β-oxidase by disulfiram on the restoration by α-methyl dopa and α-methyl dopamine of the response to tyramine was also investigated.

Isolated atrial preparation from guinea-pigs. Guinea-pigs of 400–500 g weight were killed by a blow at the base of the neck, decapitated and the heart rapidly removed. The atria were freed of ventricular muscle, connective tissue, fat and blood vessels, then placed in a modified Tyrode solution maintained at 33° ± 1° C and containing $2{\cdot}9 \times 10^{-6}$ M atropine sulphate. A mixture of 95 per cent oxygen and 5 per cent carbon dioxide was bubbled through the bathing fluid through a sintered glass plate at the bottom of the bath.

The spontaneous beat of the preparation was recorded by connecting the atria to a strain gauge transducer and recording the beat on the 'Sanborn' model 321 by direct writing lever. A counter-weight of 0·5 g was used. The atria were allowed to equilibrate until their spontaneous resting rate did not change by more than 5 beats/min during a 10-min period of observation. This took about 1–1·5 h. During this time, the bathing solution was repeatedly changed.

The procedure of the experiment was the same as described by Trendelenburg and Crout[5]. After a steady rate of spontaneous beat was attained, 10 μg/ml. of tyramine hydrochloride was introduced into the bath and left for 5–6 min. Later, the atria were repeatedly washed and then incubated with other drugs for 15–20 min. Whenever disulfiram was present during the period of exposure to amines it was added 30 min before the addition of amine and removed together with it. After thorough washing for 30 min the atria were again tested with tyramine. The restoration of the response to tyramine was calculated as the difference between the initial and final response to tyramine.

In experiments with male Sprague–Dawley rats, weighing 180–220 g, disulfiram was administered 1 h before intravenous administration of 20 μc. of norepinephrine-7-^{3}H (13 mc./mg, New England Nuclear Corp., Boston). Tyramine (20 mg/kg) was administered intramuscularly at 15 min after the labelled catecholamine. 1 h later, the animals were killed by a blow at the base of the neck and the heart removed, dissected free of atrial tissue and homogenized quickly in 10 ml. of ice-cold 0·4 N perchloric acid. After centrifugation the catecholamines in the clear supernatant were absorbed on alumina, eluted with 0·04 N perchloric acid, and assayed for tritiated norepinephrine[6].

The following substances were used: levarterenol (*l*-norepinephrine) bitartrate, *l*-dopa, dopamine hydrochloride, *l*-alpha methyl dopa hydrochloride, alpha methyl dopamine, *l*-alpha methyl norepinephrine hydrochloride, reserpine ('Serpasil', Ciba Chemicals, Ltd.), tyramine hydrochloride, tetraethylthiuram disulphide (antebuse, disulfiram) and atropine sulphate. The doses of norepinephrine, dopa and reserpine are given in terms of free base. Unless otherwise indicated, doses of other substances are expressed in terms of the salt used. Details of doses are given in a later part of this article. Student's *t*-test[7] was used for all statistical evaluations.

Effect of disulfiram on the depletion of ^{3}H-norepinephrine by tyramine. Since disulfiram was to be used as a pharmacological tool to inhibit the β-oxidase, it was considered necessary to determine its effect on uptake of norepinephrine or the release of norepinephrine by tyramine. Results presented in Table 1 show that disulfiram did not influence significantly the uptake of norepinephrine-^{3}H by the rat heart. About 40 per cent of the myocardial norepinephrine-^{3}H taken up by the rat heart was released by tyramine, whether or not the animals had been pretreated with disulfiram.

Table 1. EFFECT OF DISULFIRAM ON RELEASE OF NOREPINEPHRINE

Drug	None	Disulfiram
None	265 ± 15	268 ± 13
Tyramine	147 ± 9	151 ± 11

Rats were given disulfiram (400 mg/kg, intraperitoneally) 1 h before intravenous administration of 20 μc. *d,l*-norepinephrine-^{3}H. These and other animals which received only the labelled norepinephrine were given tyramine (20 mg/kg) intramuscularly 15 min after the norepinephrine. 1 h later, hearts were removed and assayed for norepinephrine-^{3}H. Results are expressed as mμc. norepinephrine-^{3}H per g tissue ± *S.E.M.* for groups of six animals.

Response of the isolated atria from reserpinized guinea-pig to tyramine before and after 'repletion'. Atria from the guinea-pigs pretreated with reserpine (1 mg/kg, 24 h before the experiment) failed to respond to 10 μg/ml. of tyramine. However, when these atria were exposed to 5 μg/ml. of *l*-norepinephrine for 15–20 min, response to tyramine (determined 20 min after exposure) was partly restored. Likewise, other sympathomimetic amines were effective in restoring the response to tyramine. The results are summarized in Table 2.

Effect of disulfiram on restoration of the response to tyramine. In this series of experiments disulfiram was introduced in the bath 30 min before the atria were exposed to various sympathomimetic amines. The response to 10 μg/ml. of tyramine hydrochloride was determined 20 min before the addition of disulfiram and 30 min after the exposure of the atria to various amines. The results are summarized in Table 2. Disulfiram did not affect the normal response of the atrial pacemaker to tyramine. Restoration of the response of the atrial pacemaker to tyramine by norepinephrine and α-methyl norepinephrine was unaltered by disulfiram, but disulfiram did antagonize the restoration by the precursors of these amines.

Table 2. EFFECT OF INHIBITION OF β-HYDROXYLATION BY DISULFIRAM ON RESTORATION BY VARIOUS SYMPATHOMIMETIC AMINES OF THE RESPONSE OF THE ATRIAL PACEMAKER TO 10 μg/ml. OF TYRAMINE

Treatment	Concentration (μg/ml.)	Mean increase (beat/min) ± S.E.		P
			Disulfiram pretreatment	
Atria from normal guinea-pigs				
None	—	62 ± 3·6 (16)	63 ± 3·2 (6)	*N.S.*
Atria from reserpinized guinea-pigs				
None	—	1·4 ± 0·8 (40)	—	
Dopa	50	21 ± 2·7 (5)	3·7 ± 2·7 (6)	< 0·001
Dopamine	50	30 ± 3·1 (16)	5·1 ± 2·1 (5)	< 0·001
Norepinephrine	5	45 ± 3·8 (16)	42 ± 4·6 (6)	*N.S.*
α-Methyl dopa	50	39 ± 3·0 (12)	5·6 ± 3·2 (6)	< 0·001
α-Methyl dopamine	20	32 ± 4·3 (6)	7·4 ± 3·7 (6)	< 0·001
α-Methyl norepinephrine	10	48 ± 4·2 (12)	46 ± 4·5 (6)	*N.S.*

Isolated atria were obtained from guinea-pigs pretreated with 1 mg/kg of reserpine 24 h before the experiment. They were first tested with tyramine, then exposed to the amine, washed repeatedly for 30 min and tested again with tyramine. The values are the mean difference between the first and second response of the pacemaker to tyramine. Disulfiram (20 μg/ml.) was added in bath 30 min before atria were exposed to various amines. *P*, value for difference between the means. *N.S.*, no significant difference.

Tyramine owes its sympathomimetic effect, at least in part, to a release of catecholamine from its storage site(s) in postganglionic sympathetic nerve endings. Depletion of the norepinephrine stores by pretreatment with reserpine greatly reduces the response to tyramine. However, the response to tyramine is partly restored after treatment with norepinephrine. Muscholl[8] presented evidence that reserpine pretreatment almost abolishes the uptake of norepinephrine by various tissues. However, the recent study by Trendelenburg and Crout[3] has shown that isolated atria of reserpine-pretreated guinea-pigs take up from the bath small but measurable amounts of norepinephrine. These findings suggest that there are some stores of norepinephrine which are still functional in the reserpinized animals.

In the present investigation, dopamine, like norepinephrine, was able to restore the response of the atrial pacemaker to tyramine. The restored response after dopamine could be due either to a release of retained dopamine itself or of norepinephrine synthesized by β-hydroxylation of this substance in the atrium. In reserpinized animals the heart was able to synthesize norepinephrine from its precursor dopamine[9]. The restored response after *l*-dopa is in all likelihood due to a release of either dopamine or norepinephrine or both, synthesized by this substance in the atrium and then retained, since *l*-dopa itself has no sympathomimetic activity.

The importance of β-hydroxylation in the restoration by dopamine of the response to tyramine is demonstrated by its inhibition. Following pretreatment with disulfiram, a potent inhibitor of dopamine β-oxidase[4,10], incubation with dopamine or dopa failed to restore the response of the atrial pacemaker to tyramine (Table 2). Disulfiram did not interfere with response of the atrial pacemaker to tyramine (Table 2) or with restoration by norepinephrine (Table 2) or with release of norepinephrine from the heart by tyramine (Table 1). It could be concluded, therefore, that precursors of norepinephrine themselves cannot restore the response of the reserpinized preparation to tyramine but must be β-hydroxylated to form norepinephrine in order to restore the response to tyramine.

The effect of α-methyl dopa in restoring response of the atrial pacemaker to tyramine closely resembles the effect of dopa in restoring the response to tyramine. α-Methyl dopa, like dopa, is a substrate for dopa decarboxylase, thus being converted to α-methyl dopamine and dopamine respectively. α-Methyl dopamine can be further β-hydroxylated to form α-methyl norepinephrine[11,12]. It is difficult to explain the restoration of the responses of the atrial pacemaker by α-methyl dopa, α-methyl dopamine or α-methyl norepinephrine by assuming that norepinephrine is formed; there are no published results indicating that α-methyl groups can be removed. While, in the presence of disulfiram, α-methyl norepinephrine restored the response of the atrial pacemaker to tyramine, α-methyl dopa and α-methyl dopamine must be β-hydroxylated to form α-methyl norepinephrine, and α-methyl norepinephrine can serve in place of norepinephrine to mediate response to tyramine.

To sum up, isolated atria obtained from guinea-pigs pretreated with reserpine (1 mg/kg given 24 h before the experiment) were exposed to norepinephrine and its precursors dopa and dopamine. 30 min after the removal of these amines from the bath the response of the atrial pacemaker to tyramine was partly restored. α-Methyl dopa, α-methyl dopamine and α-methyl norepinephrine were also able to restore the response to tyramine.

Disulfiram antagonized the restoration of the response to tyramine when it was present during the period of exposure to dopa, dopamine, α-methyl dopa or α-methyl dopamine. Since disulfiram did not influence the restoration of response by norepinephrine and α-methyl norepinephrine or the release of catecholamine by tyramine, these results suggest that β-hydroxylation of amines is important to restoration of the response to tyramine.

It is concluded that precursors cannot restore the action of tyramine themselves—they must first be β-hydroxylated in order to be effective.

We thank Dr. Karl Pfister of Merck, Sharp and Dohme for the α-methyl dopa and α-methyl dopamine; and Drs. R. O. Clinton and L. S. Harris of the Sterling Winthrop Research Institute for the dopamine, norepinephrine and α-methyl norepinephrine used in these experiments.

This investigation was supported, in part, by a grant from the Washington Heart Association.

EFFECTS OF LIGHT ON 3,4-BENZPYRENE CARCINOGENESIS

By PROF. L. SANTAMARIA, G. G. GIORDANO, M. ALFISI and F. CASCIONE
Department of General Pathology, Faculty of Sciences, University of Sassari, Italy, and Institute of Cancer Research, Naples, Italy

THE problem of the conflicting data from *in vivo* experiments on the influence of light on the carcinogenic processes evoked by tars or polycyclic hydrocarbons has been approached by our group. We have assumed that the accelerations of cancer induction by light so far reported[1–4] are dependent on a definite optimum concentration of photodynamic substance and intensity of radiation[5,6]. The inhibition of cancer induction by light[7–9] may be due to a higher than optimum level of these factors. At this level, these factors destroy susceptible cellular components and thereby reduce the total number of potential malignant cells. The lack of action by ultraviolet and visible light on tar and polycyclic hydrocarbon carcinogenesis[10–12] would then be a result of a level of

experimental conditions filling in between those already mentioned.

We report here the preliminary data of three experiments carried out on 955 mice given 3,4-benzpyrene (3,4-BP) and irradiated with Wood light or kept in normal daylight. The purpose of the research was to test the aforementioned theoretical assumptions.

Swiss albino mice raised in the laboratories of the Institute of General Pathology, University of Milan, and of the Institute of Cancer Research, Naples, were used. The mice were painted (one drop) twice weekly with 3,4-benzpyrene (0·5 or 0·25 per cent in acetone or in benzene) in the interscapular region. All animals were kept in dark rooms. The irradiation was carried out using a high-pressure Wood 125-W Philips bulb '57236 *E*/70' at 30 cm. This source has its maximum output at 365 mμ in the long ultra-violet, and is capable of exciting 3,4-BP. The energy delivered by one bulb was about $1·5 \times 10^5$ ergs/cm²/sec at 30 cm according to measurements by an 'Eppley' calibrated thermopile.

The general procedure consisted in keeping control groups in dark rooms under thick black curtains, and in exposing the experimental groups twice weekly soon after painting in the same room to irradiation for different periods of time ranging from 30 min to 3 h.

Three experiments are reported here, two of which were carried out in the Institute of General Pathology of the University of Milan and one in the Institute of Cancer Research in Naples. In the latter experiment, a group of mice given 3,4-benzpyrene was kept in a room illuminated by daylight through conventional windows.

Experiment 1. An experiment was set up using 300 male mice, 8–12 weeks old. The mice were divided into six groups, treated respectively only with Wood light twice weekly, only with 3,4-BP (one drop of acetone solution = 100 μg) twice weekly, and with 3,4-BP plus Wood light twice weekly for 0·5, 1, 2 and 3 h. The irradiation was carried out for 28 weeks. The experiment lasted 32 weeks. The total light dosages were 12×10^{10}, 8×10^{10}, 4×10^{10} and 2×10^{10} ergs/cm². The irradiation was carried out on groups of twenty mice in plastic cages 35 × 48 cm with high walls and a metallic net at the bottom. A fan set underneath the cages regulated air circulation and temperature. The 3,4-BP was given by dropping at random within a clipped area of about 1·5 cm² interscapularly. In this experiment attention was paid only to the onset of malignant growths. The principal results of this experiment were as follows: (*a*) very low tumour incidence (4 per cent) in the group of mice treated with 3,4-BP and kept in the dark; (*b*) highest tumour incidence (58 per cent) in the group treated with 3,4-BP plus Wood light at a dosage of 8×10^{10} ergs/cm². This was not the highest dose used.

Experiment 2. It was decided to repeat the foregoing experiments in the Institute for Cancer Research at Naples. 480 Swiss mice of both sexes 7–8 weeks old were used. The animals were divided into five groups treated, respectively, only with Wood light, only with 3,4-BP (one drop of a benzene solution = 100 μg) twice weekly, with 3,4-BP plus Wood light twice weekly for 2 and 3 h and with 3,4-BP plus normal daylight. The latter experimental condition was achieved by keeping the animals in metallic cages covered by a net in a room illuminated by conventional windows. The 3,4-BP was given by dropping in a clipped interscapular area of about 1 cm², when skin was in resting phase. The total Wood light dosages were about $10 \times$ and 6×10^{10} ergs/cm². The duration of the experiment was 24 weeks. Wood light irradiation was carried out keeping each mouse in sections of special containers 3 cm high covered by a loose net. A fan system directed at the light beam regulated temperature at about 24° C at the level of the mice. In this experiment attention was also paid only to the onset of a carcinoma. The results showed that 3,4-BP, in the presence of Wood light, produces carcinomata earlier (at the eleventh week) than in the dark (at the seventeenth week). However, on continued irradiation the effect of light on BP-induced carcinoma formation is inhibitory (at twenty-fourth week: 8 per cent in Wood light, 27 per cent in the dark). The daylight, within the seasonal (autumn, winter and spring) and environmental variations, also induces an acceleration of carcinoma onset, which, however, leads later to an increase of carcinoma with respect to the dark (at the twenty-first and twenty-fourth weeks, respectively: 35 per cent and 47 per cent in daylight, 5 per cent and 27 per cent in dark).

Experiment 3. Another experiment was set up in the laboratory at Milan using 175 mice, 8–12 weeks old, of both sexes. The animals were divided into four groups treated, respectively, only with Wood light twice weekly, only with 3,4-BP (one drop of an acetone solution = 50 μg) twice weekly, and with 3,4-BP plus Wood light twice weekly for 1 and 2 h. The total light dosages were $8·6 \times 10^{10}$ and $4·3 \times 10^{10}$ ergs/cm². The irradiation was carried out on groups of twelve mice kept in 'Plexiglass' containers, 4 cm high, divided into four sections, and covered by a loose set. A fan system regulated air circulation and temperature at about 24° C during irradiation. The 3,4-BP was given by dropping in a 1 cm² clipped area in the interscapular region. In this experiment attention was paid to the onset of both papilloma and carcinoma. The results showed that Wood light brings about a definite increase of the neoplastic processes as follows: papilloma formation was up to 60 per cent at the twenty-second week in the irradiated group, and up to 60 per cent at the twenty-eighth week in the control group (dark); the carcinoma incidence was up to 100 per cent at the thirtieth week in the irradiated group, and only 3 per cent at the same week in the control group. Detailed results of histological observations will be reported in a subsequent publication.

On the whole, the results demonstrate that (*a*) 3,4-BP is carcinogenic independently of light, and (*b*) the 3,4-BP carcinogenicity can be influenced by Wood light as well as by daylight with phenomena either of acceleration or of inhibition. The acceleration by light is interpreted as a process due to an excitation of 3,4-BP which is still compatible with cellular life. The inhibition by light is interpreted as the consequence of a photodynamic process leading to a severe damage of cellular components rather than to the alteration of the carcinogen due to a photosensitized oxidation, thus decreasing its effective dose[13,14]. This is supported by histofluorescence and histological observations, still in progress. The results are consistent with the theoretical approach.

We thank Prof. E. Ciaranfi, director of the Institute of General Pathology, University of Milan, for suggestions and generous consultations, and Prof. P. Verga, director of the Institute for Cancer Research in Naples, for interest and encouragement.

GEOPHYSICS

Backscattering from the Upper Atmosphere (75–160 km) detected by Optical Radar

A COMMUNICATION with the above title was recently published by McCormick *et al.*[1]. This work gave, for October 29, 1965, a light return of about 10 counts per pulse at heights from 75 km to 125 km and, for October 31, about 1·5 counts per pulse at heights from 75 km to 100 km. If one takes the system parameters given and assumes 3 per cent photomultiplier quantum efficiency, 30 per cent receiving system transmission and 80 per cent atmospheric transmission, then the 10 counts per pulse corresponds to a return 150 times greater than that which would be given by Rayleigh scattering from molecules at 75 km, and 10^5 greater at 125 km.

We carried out observations with an optical radar of similar performance during ten nights between October 10 and November 14, 1965; this work is being fully reported elsewhere[2]. We calibrated the sensitivity of our equipment on the Rayleigh scattering from molecules observed below 60 km and found it to be about half that calculated above for McCormick's equipment. However, our estimates of transmission through their receiving system and atmosphere may be much too high, in view of measurements on our own system. Although our background count is much lower, we have never detected any light from above 80 km, and in the region 70–80 km our return was not more than a factor of three greater than Rayleigh scattering from molecules. To achieve these results, a rotating shutter had to be fitted to prevent the escape of fluorescent light after the transmission of the main *Q*-switched pulse; previously a large apparent return from high levels had been obtained.

These results indicate a very large difference in the constitution of the upper atmosphere above Maryland and South-east England at this time; data from their observations on other nights, which were not reported, would show if this was exceptional. Alternatively, McCormick *et al.* may not have succeeded in removing the effects of fluorescent light from their results, despite their measurement of the background count.

The Satellite Geoid may have a Westward Drift

SOME time ago in a communication, I presented a model which speculated on the origin of the D″ layer between the mantle and the core of the Earth[1]. This layer is believed to be predominantly a molten sludge of mantle material but is richer in silica and lighter in density than the mantle because some iron has been lost to the core. At the core–mantle boundary, the electric currents generate Peltier heating; mantle material will be melted, gradually become a molten sludge and produce undulations at the boundary.

If the process of Peltier melting is slightly dominant over the process of Peltier freezing, the molten sludge will gradually accumulate. By integrating the equation of state at the core–mantle boundary, we note that Peltier heating is aided by ohmic heating while, of course, Peltier cooling is suppressed; since the electrical resistivity of mantle is much larger than the resistivity of the core, the ohmic heating is quite significant within the mantle. Thus we speculate that the electric current loops which give rise to non-dipole magnetic secular variations give rise also to a molten sludge and some undulations at the core–mantle boundary.

The molten sludge with lower density than mantle gives rise to a negative gravity anomaly, while the molten iron of the core with respect to the sludge yields a positive anomaly.

If the gravity anomalies are due to the sludge and the molten iron, then a westward drift of the gravity anomaly is also expected. Vogel[2] and Egyed[3] have also speculated on the possible relationship between magnetic secular variations and the gravity anomalies. The model which I introduced[1] attempted to describe the relationship between the magnetic and the gravity anomaly and predicted a similar westward drift for the gravity anomalies.

The total gravity anomalies on the equatorial belt have a maximum amplitude of ±20 mgals over some 10,000 km distance. If the westward drift is uniform and about 0·5 degree per year, this leads to a 0·2 mgal change per year which cannot be easily distinguished with the present gravity meters. The mean free air anomalies calculated by Jeffreys[4] for gravity data recorded before 1950, when compared with the satellite geoids calculated by Izsak[5] and Kaula[6] for 1960, show a distinct westward drift of 12–15 degrees (Fig. 1). Kaula's data are based on observations made during 1960, while those of Jeffreys probably extend over a much longer period. The westward drift on the non-dipole magnetic anomalies according to Runcorn[7] is 0·2–0·8 degrees per year. If the longitudinal location of the anomalies calculated by Jeffreys, Izsak and Kaula are reliable, then the estimated westward drift of gravity anomalies is of the same order of magnitude as the westerly drift of the non-dipole magnetic anomalies.

Some of my colleagues believe that if the satellite geoid had a westerly drift, such a phenomenon would

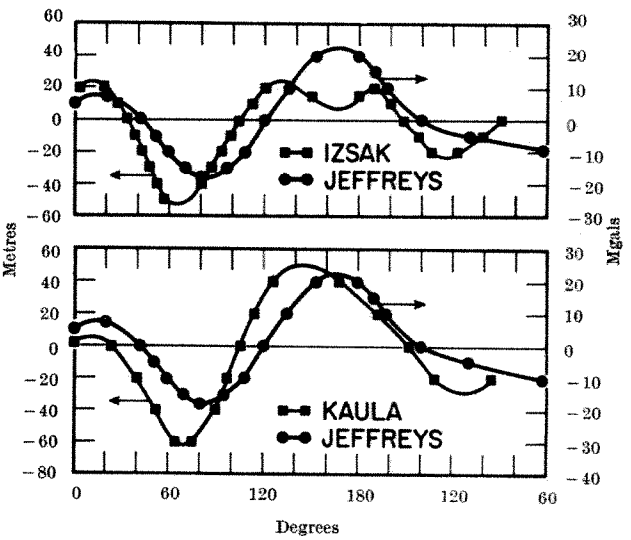

Fig. 1

have been reflected on tidal measurements at various stations; on the other hand, others indicate that the density of data available for Jeffreys was not adequate to form a reliable comparison. In spite of all these arguments, it seems to me a remarkable coincidence that: (1) the drift is in a westward direction; (2) the drift is not of a local nature, but covers half-way across the globe; (3) the magnitude of the drift is of the same order of magnitude as that of non-dipole magnetic field.

Woolard *et al.*[8] have observed some systematic increase of 0·4–1·5 mgals over a period of a few years for the gravity measurements in India. Although Woolard assigns this systematic change to the eccentricity of the screw of the gravity meter, it can also be interpreted as a westward drift of the gravity anomaly. In the same communication Woolard indicates that the value of the gravity at Dehra Dun increased about 0·8 mgals at a rate of 0·1 mgal per year. If the westerly drift of the free air gravity anomalies exist, for the next few decades one would expect a gradual drop in gravity field in the Middle East, Sudan and Egypt, and conversely a gradual increase in South-east Asia.

For an unequivocal answer regarding the westward drift of gravity field, either we have to design and construct gravity meters with extremely small drift or wait another 10 years and compare the present satellite geoids with those of the 1970's.

I am at present investigating the possibility of designing and building such a sensitive gravity meter, which will make use of super-conductivity and modern cryogenic techniques.

Non-Eckersley-law Whistlers observed at Equatorial Latitudes with Satellite *Injun* 3

THIS communication reports two new whistlers discovered in the very-low-frequency radio noise data from *Injun* 3 satellite. This satellite carried a very-low-frequency receiver with a magnetic loop antenna oriented so as to detect the component of the wave magnetic field which is propagating perpendicular to the geomagnetic field. The pass band of the very-low-frequency receiver was about 0·5–7 kc/s. Altitudes ranging from 237 km to 2,785 km are covered by the *Injun* 3 very-low-frequency data.

Frequency-time spectrograms of the two new whistlers are shown in Figs. 1 and 2. A unique feature of these whistlers is that over the observed portion of the frequency spectrum the delay time increases with increasing frequency, thus deviating markedly from the Eckersley law for whistlers (time delay inversely proportional to the square root of frequency). Because of their appearance on a frequency-time spectrogram, we call the whistlers in Figs. 1 and 2 the 'riser' and the 'check whistler', respectively.

Both the riser and the check whistler have been received simultaneously from two different satellite tracking stations; therefore we are certain that these signals are not caused by interference in the data transmission. We also note that the whistler signals show strong attenuation above 7 kc/s, corresponding to the upper cut-off frequency of the *Injun* 3 very-low-frequency receiver[1]. Thus we feel certain that these signals were detected by the loop antenna.

We present the following evidence to substantiate our claim that these events are whistlers. As will be shown, all these events occurred in the vicinity of the magnetic equator at altitudes above 900 km. In the *Injun* 3 data, Eckersley-law whistlers are quite regularly observed in this region whereas commonly known types of very-low-frequency emissions are virtually never observed here. Also, a common feature of very-low-frequency emissions is repetition at short intervals[2]. No such repetition is found with the events on which we report. In fact, often only one or two events are found in a 20-min satellite pass.

From the analysis of 20 h of very-low-frequency data a total of seventy risers has been found. All risers observed thus far were received within 23 degrees (magnetic latitude) of the magnetic equator and above 900 km altitude. The majority (80 per cent) of these whistlers

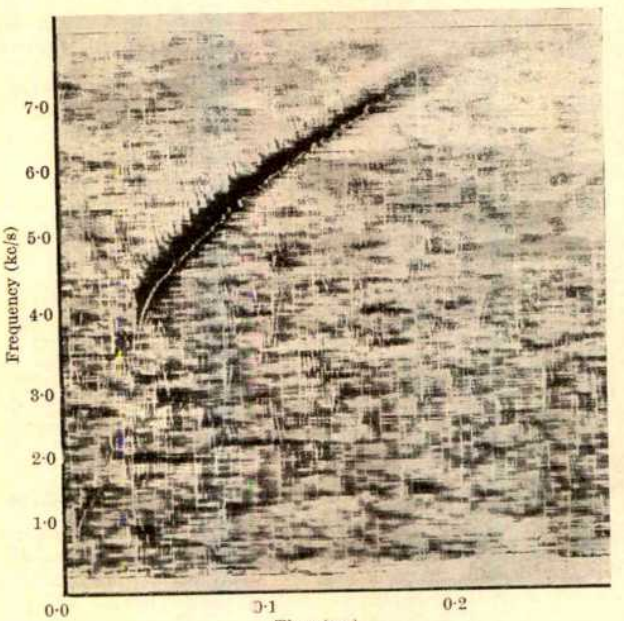

Fig. 1

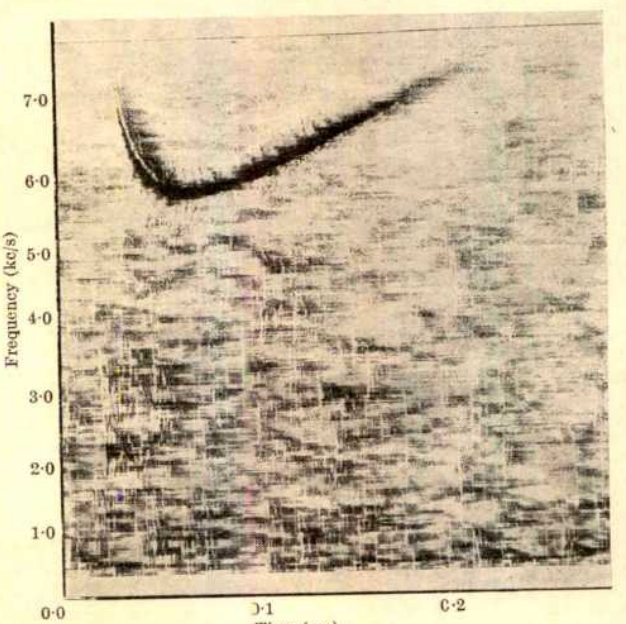

Fig. 2

are found within 15 degrees of the magnetic equator and above 2,000 km altitude.

The equatorial very-low-frequency data used for the riser study has yielded six occurrences of the check whistler. All six were received within 23 degrees of the magnetic equator and above 2,000 km altitude.

In considering possible explanations for the riser and check whistler we have eliminated the possibility that these whistlers are nose whistlers[3] because the nose frequencies at these invariant latitudes are at least ten times the frequencies at which we observe these new whistlers. Because waves from equatorial lightning sources received in the ionosphere near the equator are likely to be propagating nearly perpendicular to the geomagnetic field, we believe that the unusual dispersion of the riser and check whistler arises because of the lower hybrid resonance[4]. The lower hybrid resonance frequency can range between 3 and 8 kc/s in the region of the ionosphere at which we observe these whistlers.

GEOCHEMISTRY

Major Element Composition of Georgia Tektites

Clarke and Carron[1] reported the first major element analysis of a Georgia tektite (*USNM* 1396) and discussed its composition in relation to analyses of moldavites and the tektite from Martha's Vineyard, Massachusetts. King[2] published an analysis of a second Georgia tektite (*DGA*-1), and compared it with the previous analysis of *USNM* 1396. Clarke and Henderson[3] and King[4,5] have discussed the chemistry of Georgia tektites in relation to tektites from other occurrences and possible parent materials. Zähringer[6] has established identical potassium–argon ages of 34 ± 1 million years for all the North American tektites.

A new analysis of a Georgia tektite (*DGA*-2) is presented in Table 1 together with the previously available major element data. *DGA*-2 has been described and illustrated by King[4].

Table 1. CHEMICAL ANALYSES OF GEORGIA TEKTITES (PERCENTAGE)

Oxide or element	*USNM* 1396 (*a*)	*DGA*-1 (*b*)	*DGA*-2 (*c*)	Range

(*a*) From Clarke and Carron (ref. 1); analysts, M. K. Carron and W. W. Brannock.
(*b*) From King (ref. 2); analyst, Jun Ito; weight of analysed fragment—4·442 g.
(*c*) Analyst, Jun Ito; weight of analysed fragment—2·152 g. Analysis reported June 1, 1964.

The Georgia tektites are characterized by high silica, high alumina, very low ferric to ferrous iron ratio, and an excess of potash over soda—as are almost all tektite analyses. The silica values are among the highest reported for any tektites, and are exceeded or equalled only by a few of the moldavites and bediasites, and the single specimen reported from Martha's Vineyard, Massachusetts, by Kaye *et al.*[7]. The inverse variations of alumina (Fig. 1) and ferrous iron (Fig. 2) with the silica content are apparent even though the three analyses have a small range of silica values. The analyses also suggest an inverse variation of titania with silica as observed in the bediasites by Chao[8]. The major element composition of the Georgia tektites is almost identical to the silica-rich bediasites. Clarke and Carron[1] and Chao[8] noted the compositional similarity of the Martha's Vineyard tektite, silica-rich bediasites and *USNM* 1396, the only Georgia specimen then analysed. The very low lime and magnesia contents observed in the Georgia specimens are typical of North American tektites (Chao[8], King[9]). The total iron values of Georgia tektites are in the extreme low portion of the range reported in bediasites (Barnes[10,11]; Chao[8]). The $(FeO + MgO + CaO)/(K_2O + Na_2O)$ values of the Georgia tektites range from 1·06 to 1·14, within the range reported

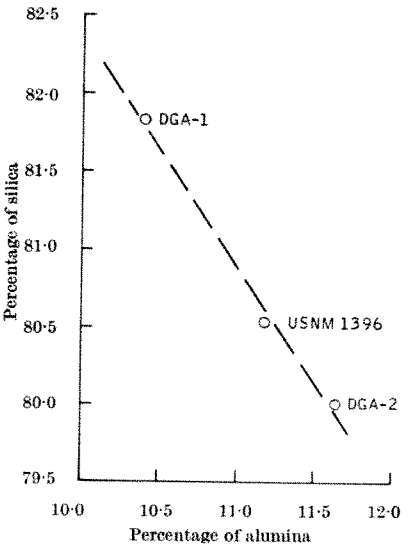

Fig. 1. Variation of alumina with silica in three Georgia tektites

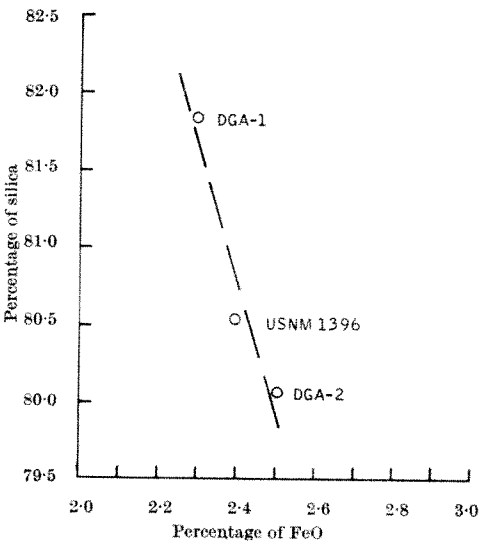

Fig. 2. Variation of FeO with silica in three Georgia tektites

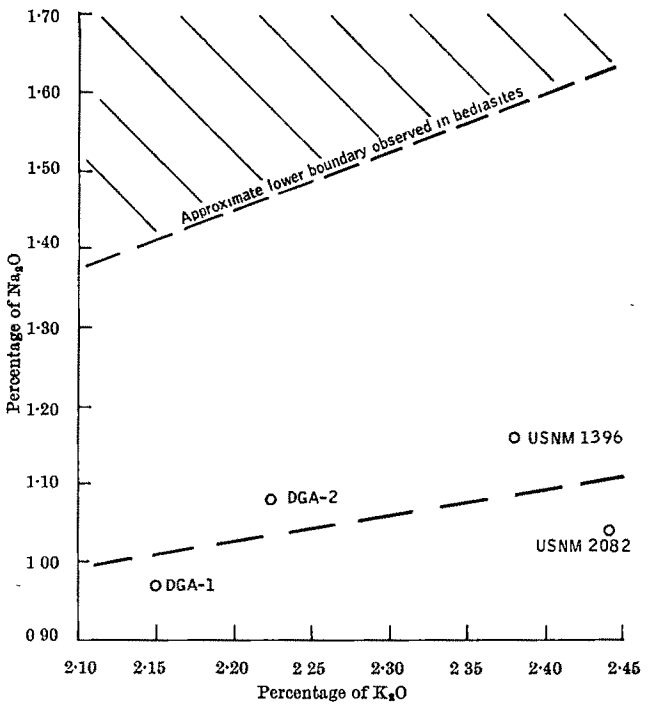

Fig. 3 Variations of K_2O with Na_2O in the Martha's Vineyard and Georgia tektites as compared with the range of values reported in bediasites

for silica-rich bediasites (Chao[8]). The 'essential' water values reported for *DGA*-1 and *DGA*-2 are higher than the water contents reported in tektites by Friedman[12,13] and may be in error. Potash plus soda in the Georgia tektites is well within the range observed in bediasites, but the Georgia specimens are significantly lower in their soda to potash ratio than the bediasites (Table 2). The Martha's Vineyard tektite shows the same low soda to potash value. A plot of K_2O with Na_2O (Fig. 3) shows a trend that is roughly parallel to but lower in soda than that given by Chao[8] for the bediasites. The difference in the soda to potash ratios between the bediasites and other Northern American tektites probably resulted from a difference of the ratios in the parent materials.

Table 2. SODA TO POTASH RATIOS IN NORTH AMERICAN TEKTITES*

Specimen	Locality	Na_2O/K_2O
DGA-1	Dodge Co., Georgia	0·45
DGA-2	Dodge Co., Georgia	0·48
USNM 1396	Dodge Co., Georgia	0 49
USNM 2082	Martha's Vineyard, Mass.	0·43
BM-1	Fayette Co., Texas	0·65
BM	Fayette Co , Texas	0·69
BM-14	Fayette Co., Texas	0 69
30775-77	Grimes Co. (?), Texas	0 68
Average Bediasite Texas		0·74 ±

* Values for bediasites calculated from analyses reported by Chao (ref. 8); *USNM* 1396 from Clarke and Carron (ref. 1); *USNM* 2082 from Kaye *et al.* (ref. 7), *DGA*-1 from King (ref. 2).

The systematic relation of physical properties and composition in tektites has been demonstrated by Barnes[10], Chao[8] and others. Relatively few precise determinations of Georgia tektite specific gravities are now available, but it would seem that the range is only about 0·06. This is about half the range of specific gravities observed in bediasites. Although the few Georgia tektites now known may not be entirely representative of the total group, the variations in physical properties are less than would be obtained in an equal number of randomly selected bediasites. It is probable that the Georgia tektites have an even more restricted range of composition than the bediasites. Analyses of Georgia tektites covering a wider range of physical properties and precise measurements of physical properties on additional specimens will be necessary to establish the exact range of composition.

On the basis of the Georgia tektite analyses now available, the Georgia tektites are very similar in their major element composition to silica-rich bediasites. The Georgia tektites show decreasing contents of alumina, ferrous iron, and possibly titania with increasing silica. The variation of soda with potash defines a trend that does not overlap values observed in any bediasite yet analysed. In view of the identical potassium–argon ages, close chemical similarity, and general geographic association, the North American tektites are probably the product of a single event. However, the Georgia tektites and the specimen from Martha's Vineyard can be classed as a distinct sub-group characterized by low soda : potash ratios.

Possible Rubidium–Iron Covariance in Potassium Feldspars

THE existence of Fe^{3+} in potassium feldspars is well known and it has been assumed that the iron is substituting for aluminium[1]. We have been investigating the geochemical characteristics of the Enchanted Rock batholith, Llano Uplift, Texas[2,3], and have noted the rubidium–iron covariance reported here (see Fig. 1).

The batholith is a Precambrian granitic intrusion which exhibits a gradual trend from a more mafic interior to more felsic outer zones[4,5]. The samples were taken along

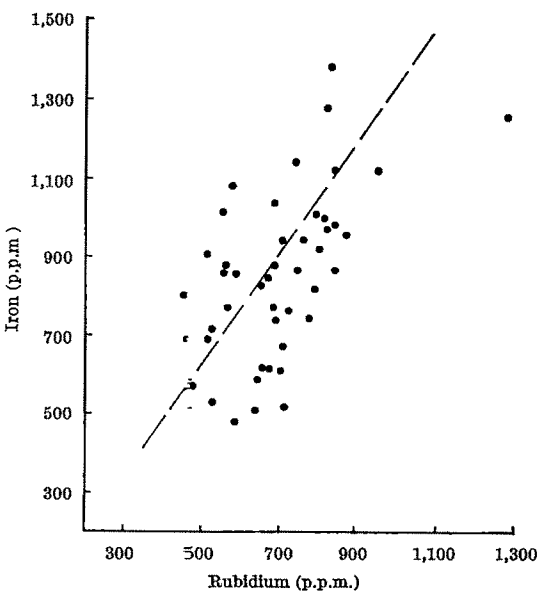

Fig. 1. Rubidium–iron covariance

four profiles radiating from the centre of the batholith to the outer margin. The potassium feldspars were separated by standard heavy liquid methods and checked for purity both petrographically and by X-ray diffraction. Rubidium and iron were determined by atomic absorption. The analytical techniques and precision tests (Rb = ± 1·5 per cent; Fe = ± 2·5 per cent) have been reported elsewhere[6].

The data presented in Fig. 1 suggest a covariance between rubidium and iron in the potassium feldspars. The correlation coefficient is +0·561 which is significant at the 0·9995 level. Since the analytical method reports total iron, Fe^{2+} is included. If the following hypothesis is correct, a correlation of rubidium and only Fe^{3+} would be even more significant.

We would like to submit a possible explanation of the rubidium–iron correlation. The Rb^{1+} ion is larger than the K^{1+} ion and may expand the feldspar lattice sufficiently to allow (require?) replacement of an Al^{3+} ion ($r = 0{\cdot}57$ Å) by Fe^{3+} ($r = 0{\cdot}67$ Å). This is indirectly supported by the fact that the mean concentration of rubidium (675 p.p.m.) is similar to that of iron (807 p.p.m.). In addition, Rb^{1+} has a slightly lower ionization potential than K^{1+} which results in a more easily polarized oxygen ion, which, in turn, benefits Fe^{3+} substitution since it is a more polarizing ion than Al^{3+} ($Fe^{3+}_I = 30{\cdot}6$; $Al^{3+}_I = 28{\cdot}44$).

Rosenquist[7] and Divljan[8] have proposed that the large ionic radius of K^{1+} relative to Na^{1+} or Ca^{2+} allows substitution of Fe^{3+} for Al^{3+}. If this simple relationship is true, rubidium-iron covariance might be expected because of the increase in lattice size resulting from substitution of rubidium for potassium.

A possible test of the hypothesis proposed here would be to examine the spatial relationship of rubidium and iron in potassium feldspars by electron probe microanalysis. Assuming that rubidium is not uniformly distributed throughout the feldspar crystal, indirect support of the hypothesis would be given if rubidium and iron covaried spatially.

GEOLOGY

Olivine–Liquid Reaction and the Depth of Crystallization of the East Aberdeenshire Gabbros

RECENTLY, Weedon[1] has argued that the presence of corona structures surrounding olivines in the Aberdeenshire gabbros implies a low pressure of crystallization, equivalent to a depth of burial of less than 9 km, and comments that this is inconsistent with published views on the time of emplacement and depth of burial of the gabbro masses. Weedon's argument rests on two assumptions: that the suppression of an olivine–liquid reaction relationship in the system $MgO–SiO_2$ by increasing pressure is an accurate indicator of the behaviour of the olivine–liquid relationship in basic magma, and that the corona structures described from the gabbros indicate crystal–liquid reaction, not solid–solid reaction after consolidation.

Boyd *et al.*[2] have shown that the olivine–liquid reaction relationship in the system $MgO–SiO_2$ is suppressed by a pressure not greater than 5·4 kbars (~20 km depth of burial) and suggest that it might be suppressed by pressures as low as 2·3 kbars (~9 km). Increasing pressure may consequently be expected to suppress the related reaction relationships between olivine and liquid to form pyroxenes observed in the systems $MgO–FeO–SiO_2$ (ref. 3), $CaO–MgO–FeO–SiO_2$ (ref. 4), $CaO–MgO–SiO_2$ (ref. 5) and $CaO–MgO–Al_2O_3–SiO_2$ (refs. 6 and 7). Pressures of 20 kbars[8] and 10 kbars[9], respectively, are known to be adequate for the suppression of the reaction relationships in the two last-mentioned systems. The experimental evidence does not at present support any stronger statement than that increasing pressure is likely to suppress the olivine–liquid reaction relationship in dry tholeiitic silica-saturated magmas at some pressure less than 10 kbars (~35 km).

However, these are not the only olivine–liquid reaction relationships known. Reaction between olivine and liquids initially undersaturated in silica to yield diopsidic pyroxene is reported at atmospheric pressure from the systems nepheline–diopside plus forsterite, silica, wollastonite or akermanite[10,11], while reaction between olivine and silica saturated and undersaturated liquids to yield pyroxene plus magnesio-ferrite is reported during crystallization at constant $pp O_2$ at atmospheric pressure in the system $MgO–FeO–Fe_2O_3–SiO_2$ (ref. 12).

There is no evidence to suggest that the latter relationship at least is suppressed by increase of pressure. The suppression of the reaction relationship in nepheline-diopside bearing systems may occur with increasing pressure but is clearly independent of relationships in the $MgO–SiO_2$ system.

In water-bearing systems, moreover, there is abundant evidence of reaction relationships between olivine and a variety of liquids to yield, among other products, amphiboles and pyroxenes. In the system $CaO–MgO–Al_2O_3–SiO_2–H_2O$ this relationship persists to above 10 kbars[13] and similarly in the systems olivine tholeiite–water, high alumina basalt–water and alkali olivine basalt–water[14], reaction relationships between olivine and liquid are observed at pressures up to and presumably beyond 10 kbars.

It appears, therefore, that olivine–liquid reaction relationships of four characters exist, and that two at least of these (those due to changes in oxygen content or the presence of water in the magma) are likely to persist to pressures at least as great as those resulting from a postulated depth of burial of about 30 km[15]. The presence of olivine–liquid reaction relationships in the Aberdeenshire gabbros cannot, therefore, be taken as evidence of high-level emplacement until the character of the reaction relationship has been established, and even in the interpretation most favourable to Weedon[1] they would at present only indicate pressures less than 10 kbars (~35 km).

The interpretation of textures is notoriously difficult, and the described reaction textures quoted by Weedon from the literature might alternatively be post-consolidation features produced by reaction in the presence of volatiles derived either from the magma itself, or from the later granites, or may be an incipient metamorphic event consequent on a change of mineral facies as the gabbro cooled at relatively great depth. Such alternative origins were clearly envisaged by Stewart[16] and Sadashivaiah[17], and a subsolidus origin appears likely for those described by Read[18] being developed between olivine and plagioclase. Those described by Read[19] and Read *et al.*[20] are clearly of the oxidation type (magnetite–hypersthene rims about olivine) or involve phases (amphibole, biotite) implying the presence of water in the system. In these circumstances, the suppression of the reaction relationship in $MgO–SiO_2$ is irrelevant to the problem under discussion,

and the depth of emplacement of the Aberdeenshire gabbros is in no way restricted by available evidence on olivine–liquid reaction relationships.

We have suggested that the experimental work cannot be used to indicate a high-level intrusion of these bodies. Other factors suggest a relatively deep level of intrusion. The Huntly complex, for example, lies close to the boundary of the kyanite and andalusite zones of metamorphism of the Dalradian rocks. It is probable that the main metamorphism and the intrusion of the gabbros both occurred between the F_2 and F_3 fold movements. Although these events may not have been synchronous, the temperatures of this part of the region probably remained high until and during the F_3 movements as there is no evidence of widespread retrograde metamorphism attributable to these[21]. Other features which may relate to deep-seated consolidation are the relatively highly aluminous character of some of the orthopyroxenes[22,23], and the unusually widespread effects of contamination and remelting near the margins of some of the Aberdeenshire intrusions (see, for example, refs. 19 and 24).

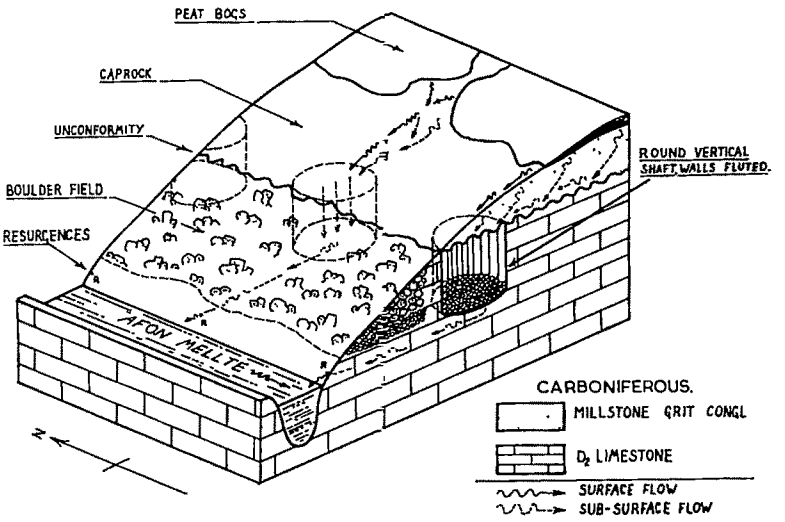

Fig 1. Block diagram of the E bank of the Afon (River) Mellte showing relationships between vertical shafts and geological structure. The shaft illustrated in section lies midway in the mature stage of development, and hydrological connexions from peat bogs via shafts to the river are shown

A New Mechanism for the Formation of Vertical Shafts in Carboniferous Limestone

In the course of study of a newly discovered series of caverns in Carboniferous Limestone at Ystradfellte, Breconshire (National Grid Refs. *SN* 91 : 926·115 to 929·112), we have observed a process of spelaeogenesis apparently unrecorded hitherto.

In this area the limestone series is about 1,000 ft. thick and is covered unconformably (the post-Avonian Unconformity) by a comparatively thin layer of the Basal Quartz Conglomerate of the Millstone Grit, both rocks dipping 10° south in the vicinity of the caverns.

The outstanding feature of these caverns is the presence of incised vertical grooving, that is, fluting, which is due to the process of formation by drip. Water leaving a series of peat-bogs at the top of the hillside (see Fig. 1) runs both over and within the grit, eventually reaching the limestone. The *p*H is on the acid side, gradually becoming neutral as it traverses the limestone. Figures recorded are: (i) before reaching the limestone, 3·8–4·2; (ii) within the caverns, 5·2–5·6; (iii) water of the presumed resurgence, 5·6–7·4. Subsequent to the formation of a small initial solution cavity on the plane of unconformity, water drips on the limestone from the overlying Grit caprock, dissolving a series of drip-pockets. These are vertically orientated cavities of circular cross-section and with a concave base. Examples were found from 2·5 to 10 cm diameter and from 2·5 to 17 cm depth respectively. Penetration by dripping water beyond the base of a drip-pocket extends it mainly vertically rather than laterally. Recent work by one of us (A. R. B.) indicates that vertical growth proceeds four times as fast as lateral growth during juvenile stages. Lateral growth is responsible for the eventual coalescence of neighbouring juvenile tubes. As a result of this coalescence, slender columns of limestone remain. These eventually collapse, forming debris at the base of the shaft.

The mature shaft of greater diameter thus formed eventually causes collapse of the roof due to lack of support. At this stage, the shaft can be termed senile. When the ratio of shaft-diameter to caprock thickness is adequate, collapse extends to the surface and a doline of collapse results. This can be shallow- or steep-sided, or vertical, depending on the angle of grading of the limestone walls by collision or frost-action. Collapse of the roof causes a simultaneous advance of the surface-junction between limestone and grit and hence also of the area of maximum drip. The process of formation then continues to enlarge headward, and less mature, cavities further up the valley side, leaving lower abandoned caverns to grading, forming an inclined boulder-field.

Fig. 2 shows diagrammatically the stages assumed by any one cavern over time, superimposed on calculated curves of vertical and lateral growth over time.

We have concluded that:

(1) In the aforementioned caverns, the roofs are flat because they coincide with the plane of unconformity. Somewhat similar shafts have been studied in the United States[1], but they have dome-shaped roofs and they originate in the limestone at a lower level, developing upwards till caprock is reached, at which stage the roofs become flat.

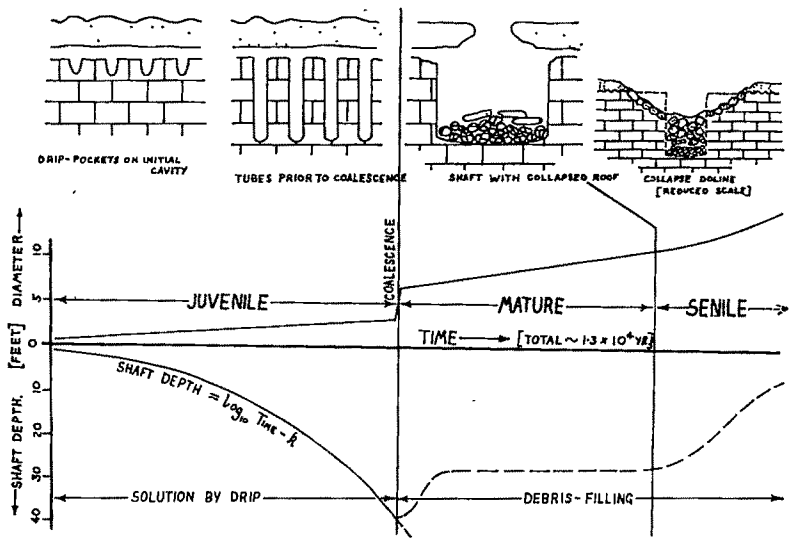

Fig. 2. Showing the relationships between shafts in various stages of development, superimposed on calculated depth and diameter versus time curves

(2) The United States workers propose abrasion by dripping and the effects of trickling water as being responsible for shaft formation. They make no mention of solutional effects. In contrast to this, the caverns described here are considered to be formed mainly by the solutional effect of water of an acid *p*H. It has been found that carbonic and organic acids are present in the incoming water. Titrations using EDTA reveal an increasing amount of calcium carbonate in solution, with a range of 0–105 p.p.m. (Corresponding *p*H readings have been given previously: (i). (iii).) No abrasive materials from either the grit or the limestone have been found in the pocket bases, but the abrasion due to friction of dripping water on limestone is yet to be estimated. It is considered that solutional effects, rather than physical ones, predominate.

(3) The transition from the juvenile to the mature stage has been observed to be due to lateral coalescence. This does not appear to have been mentioned in the American literature.

(4) Similar features have been located in other caverns of the same nature within the area (for example, Coeden Prop and Pulpit Hole).

(5) The formation of collapse dolines at senility illuminates the views of Thomas[2] and is correlated to the distributions which he illustrates, that is, that they are concentrated on the Millstone Grit.

Full results will be published elsewhere.

Salt Weathering and Inselbergs

RECENTLY, Wellman and Wilson[1] have directed attention to 'salt weathering', that is, 'the fragmentation of rocks by the crystallization of salts', as a geomorphic process of appreciable efficiency, especially in arid regions and along the sea coasts, but also at other places. They have shown that the formation of 'rock meal' and the development of pitted and cavernous rock surfaces are the most obvious symptoms of this type of rock decay.

During my field work, particularly in the Alps of Central Switzerland, I have here and there come across rock meal linings as described by these authors, for example, under overhanging rock ledges and at cave entrances, and in some cases the presence of 'salts' was obvious, either visible in form of efflorescences or verifiable by the taste of the rock meal. Once, I could even watch a mouse licking eagerly the salty rock meal. Such observations certainly lend support to the authors' findings.

Wellman and Wilson, however, also suggest that salt weathering has been, and is, operative in the formation of "some kinds of tors, and at least some hills that have been described as inselbergs". While I do not intend to question their observations of salt weathering and its influence on such land forms, I feel it should be emphasized in this context that salt weathering cannot—in the overall picture—be considered the principal, or even a major, process leading to the development of inselbergs and related forms. During geomorphic studies made over several years in West Africa[2], I have become convinced that these land forms are essentially developing under semi-arid climatic conditions as a late stage in the sequence (or cycle) of pediplanation (scarp retreat and pedimentation)[3]. An assessment of the late Quaternary progress of pediplanation in Ghana has revealed that the scarp retreat associated with pedimentation is an astonishingly fast process and must—apart from erosive removal of debris—be due principally to vigorous physical breakdown ('exfoliation' in the widest sense, that is to say, the result of release of internal stress in the bedrock at or near its surface, ascribed either solely to removal of load by erosion, or to temperature variations, or differential hydration, or a combination of these and other causes[4]). While rounded exfoliation forms are preponderant on inselbergs consisting of granite or similar massive bedrock, sharply sculptured surfaces usually occur on the inselbergs of less massive bedrock. I do not remember having seen the symptoms of salt weathering on West African inselbergs and am inclined, therefore, to assume that this agent can only have very minor, if any, significance in that region.

It is now well established that the Quaternary climatic changes have left their traces not only in the higher but also in the lower latitudes of the Earth, and that, in the latter regions, they consisted essentially in variations of rainfall, or humidity. Thus it is understandable that inselberg landscapes, although developing typically in areas of moderate rainfall, are frequently found outside the present-day semi-arid zones in both humid and arid climatic regions. While with increased humidity they undergo modifications chiefly by chemical weathering under soil and vegetation cover (see, for example, the special cases described by Twidale[5]), an arid environment would obviously favour modifications by salt weathering as described by Wellman and Wilson.

PHYSICS

Electrical Simulation of Optics of Moving Media

THE early experiments of Fresnel-Fizeau on the velocity of light in a moving medium can be described in modern terminology as the development of an optical delay line with controlled dwell time. Similar changes in a light beam can be generated by present-day versions of an optical delay line (of which there are a number), where controlled dwell time is achieved by the use of an electro-optic medium[1,2].

It should be mentioned that the explanation of the Fresnel-Fizeau experiment is in terms of the Doppler effect of the virtual Huygens sources. The description of Fizeau's experiment rests on the following fact[3]: If a refracting medium of index n is moving away from a stationary observer with a velocity v and if ν is the frequency of the light relative to an observer moving with the medium, then the Lorentz transformation requires the frequency to assume the value

$$\nu' = \nu\beta\,[1 + n(v/c)] \qquad (1)$$

relative to a stationary observer. Thus, to a first approximation, the velocity of propagation of light in the moving medium relative to the stationary observer is

$$u' = \lambda'\nu'/n = (c/n)\,[1 + n(v/c)\,(1 - 1/n^2)] \qquad (2)$$

(the primes being used to denote quantities relative to the stationary observer). To the stationary observer, the velocity of light in the moving medium may be increased or decreased as compared to the value c/n determined by an observer moving with the refracting medium.

As would be expected, the value for ν' is that measured by an observer for a source moving relative to the observer with a velocity v, that is, the virtual Huygens sources act as sources moving with a velocity v.

In Fresnel's terminology, the effect considered so far may be called the convection Doppler effect. This is not directly observable. What is observable is only the overall result, the controlled dwell time of an optical delay line. More direct is the possibility of simulating the Doppler effect resulting from reflection at a moving mirror. This is based on the characteristics of a symmetrical side band generator. It is well known and can be shown from the representation of the electromagnetic field in terms of Hertz vectors that side bands occur when the electric susceptibility of the medium varies harmonically with time[4].

The equations defining these vectors are[5]:

$$\nabla^2\Pi_e - \ddot{\Pi}_e/c^2 = -4\pi P$$

$$\nabla^2\Pi_m - \ddot{\Pi}_m/c^2 = 0 \qquad (3)$$

if $M = 0$.

In terms of these vectors,

$$B = H = \mathrm{curl}\,(\dot{\Pi}_e/c + \mathrm{curl}\,\Pi_m)$$

$$D = E + 4\pi P = \mathrm{curl}\,(-\dot{\Pi}_m/c + \mathrm{curl}\,\Pi_e) \qquad (4)$$

In a refracting medium, the polarization P varies directly as the electric field E, that is,

$$P = \eta E, \text{ where } \eta \text{ is the electric susceptibility} \qquad (5)$$

The case of interest for the operation of the simulator has the following characteristics: The medium through which the light beam is propagated is isotropic and the susceptibility η is specified by

$$\eta = f(\nu)e^{2\pi i\nu_P t} + \ldots + \text{constant term} \qquad (6)$$

where $\nu_P \neq \nu$ is a frequency which determines the harmonic variation of ν with time, the constant term is proportional to $n^2 - 1$, and $f(\nu)$ is independent of the spatial co-ordinates. It follows from equations (5) and (6) that the strength of the polarization generated by the light beam depends on its frequency.

In the case $f(\nu) \equiv 0$, the Hertz equations lead to the familiar result $\lambda\nu = c/n$. Independently of the form of $f(\nu)$, both side bands, $\nu \pm \nu_P$, are present. Depending on the dimensions of the medium, its optical characteristics, and the Poynting flux of the incident radiation, the energy in the incident light beam will eventually be concentrated in the side bands. In general these side bands will consist not only of the two bands $\nu \pm \nu_P$ adjacent to the frequency of the incident light but also of the extended spectrum of side bands $\nu \pm m\nu_P$ where $m > 1$ is an integer. When the radiation is coherent, it would simplify simulation if conditions could be formulated under which only one side band is generated. In a highly dispersive medium, the side bands may be markedly deflected from the direction of the light beam of frequency ν, depending on the uniformity of the susceptibility of the medium.

Consider the special case where in certain definite regions the function $f(\nu)$ decreases steeply with ν, such regions of abrupt descent being separated by less sharply reached maxima or, possibly, by plateaux. The light in the side bands is channelled into these frequency ranges of steep descent. Let ν_M be the frequency at the edge of a region in which $f(\nu)$ tends rapidly towards zero; the radiation in the side bands will tend to concentrate near $\nu = \nu_M$, and on the side of the maximum where the susceptibility decreases sharply with ν. Such an asymmetrical distribution of radiant energy with frequency relative to that of the incident light beam would correspond roughly to the pattern expected for a Doppler shift.

The structure required for achieving a time-dependent polarization with a dependence on ν consisting of steep descent and shallow rises would occur in a medium with a sharp absorption (resonance) line in the neighbourhood of ν, the frequency of the incident radiation, provided the strength of the absorption line could be made to vary harmonically with time. This condition could be achieved if the concentration in the lower level of the radiative (absorption) transfer were made to vary harmonically with time, for example by optical pumping with high intensity coherent radiation varying harmonically with time.

Fresh Fall-out in Israel from the Second Chinese Nuclear Detonation

A NUCLEAR detonation was reported to have occurred on the Chinese mainland on May 14, 1965. The test was apparently conducted in the atmosphere and involved a uranium-235 fission device[1]. Fall-out attributable to this detonation was first detected in Israel on air filters on May 28, 1965. About 3 weeks later, iodine-131 was detected in milk samples and in animal thyroids. Monitoring of iodine-131 in these samples was continued for several months.

Surface air activity. About 200 m³ of air were sampled daily, using a 'Victoreen' positive displacement pump. The activity collected on the filter paper was determined using a well-type sodium iodide (thallium-activated) scintillation crystal coupled to a multi-channel gamma-spectrometer.

Iodine-131 was first detected in air on May 28, 1965, and zirconium-95–niobium-95 appeared 3 days later. Barium-140–lanthanum-140 were detected on June 1, 1965. The fact that radio-iodine was detected in surface air

prior to barium-140–lanthanum-140 may be due to the difference in transport mechanisms of gaseous fission products as compared with particulate debris. Many countries use barium-140 rather than iodine-131 as the first indicator of new fission products[2], since traces of radio-iodine may be present in the environment as a result of normal operation of nuclear installations. Table 1 shows the radio-iodine activity concentrations detected in the air.

Table 1. IODINE-131 ACTIVITY IN SURFACE AIR

Collection date	^{131}I Activity (pc./m^3)	Activity corrected to date of detonation (pc /m^3)
May 28, 1965	0 015	0·05
May 30, 1965	0·02	0·08
June 1, 1965	0·04	0·18
June 2, 1965	0 02	0·10
June 3, 1965	0·03	0·16

After June 3, the presence of barium-140–lanthanum-140 in the gamma spectrum made iodine-131 determinations difficult without resorting to chemical separations, and iodine measurements in the air samples were therefore discontinued. Following the detection in air of the short-lived isotopes, tests were started on samples of milk, as well as animal thyroids.

Milk samples. Samples of cows' milk were collected regularly from more than ten different locations scattered throughout the country and they were routinely analysed for strontium-90 and caesium-137 (ref. 3). These samples were also tested for iodine-131. Sodium hydroxide and sodium iodide were added, after which the milk was ashed at about 400° C. The elementary iodine was separated and extracted with carbon tetrachloride[4]. Table 2 shows the results of our milk tests for 3 months following the detonation.

Table 2. ^{131}I ACTIVITY IN MILK

Date of milking	No. of samples	^{131}I on date of milking (pc./l. per sample)
June 1–10	1	0
June 11–20	2	0, 0
June 21–30	4	0, 8, 10, 32

August 11–20	1	4
August 21–31	—	—

* Sheep's milk.

Thyroid glands. Thyroid glands of sheep and goats slaughtered in two municipal abattoirs were tested for the presence of iodine-131. Composite samples were prepared from the thyroids of ten to twenty animals. The sample was ashed at about 400° C after the addition of sodium hydroxide and sodium iodide in order to ensure trapping of the free or organic iodine. Iodine-131 was identified by its peak at 0·36 MeV and 0·64 MeV using a multichannel gamma spectrometer. Because of the relatively high activity in the samples it was possible to check the half-life of the activities at both peaks, which proved conclusively that the activity at 0·64 MeV was due to iodine-131 and not to 0·66 MeV peak of caesium-137. Results of iodine-131 activity tests in sheep and goat thyroids are summarized in Table 3.

In the case of the first Chinese nuclear detonation (October 1964) no fresh fall-out was detected in Israel. A rise in gross beta activity in air was detected during the month of October 1964, but this was attributed to a seasonal increase in activity after the first winter rains, as encountered during past seasons. Short-lived nuclides associated with fresh fall-out were not detected[5]. These findings were consistent with the data presented by Krey and Rosa that the southernmost edge of the debris passed over northern Europe and did not enter the Mediterranean area[6]. A map of the path of the debris from the second Chinese test, which appeared in the same report, though not complete, indicates a more southerly route.

CHEMISTRY

Calculations of the Racah Parameter B for Nickel (II) and Cobalt (II) Compounds

RECENTLY, numerous papers have been published on the spectra of nickel (II)[1–3] and cobalt (II)[4,5] complexes in which the Racah parameter B has been deduced. For those octahedral nickel (II) complexes where only the $\nu_2(^3A_{2g} \rightarrow {}^3T_{1g}(F))$ and the $\nu_3(^3A_{2g} \rightarrow {}^3T_{1g}(P))$ bands were observed, Dq and B were found by solving the secular equation[6] by trial and error[2]. We have found that in these circumstances it is possible to simplify the problem to that of solving a quadratic equation in Dq, ν_2 and ν_3 only. The equations for finding Dq and B from ν_2 and ν_3 for octahedral nickel (II) complexes (d^8) are:

$$340Dq^2 - 18(\nu_2 + \nu_3)Dq + \nu_2\nu_3 = 0 \qquad (1)$$

$$B = \frac{\nu_3 + \nu_2 - 30Dq}{15} \qquad (2)$$

The solution of equation (1) gives two values for Dq and thus two values of B are obtained. It is always obvious which values of Dq and B are the required solutions. The same equations will, of course, apply to ions with a d^3 configuration in an octahedral field and to ions with d^2 and d^7 configurations in tetrahedral fields.

Table 1. CALCULATED VALUES OF Dq AND B (cm^{-1})

Compound	Ref.	Observed bands ν_2	Observed bands ν_3	Calculated from equations (1)–(4) Dq	Calculated from equations (1)–(4) B	Reported values Dq	Reported values B
Ni(3Etpy)$_4$Br$_2$ (d^8, octa.)	1	12,970	23,000	781 1,123	835 152	789	830
NiMpCl$_2$ (d^8, octa.)	2	13,150	23,000	795 1,118	819 173	794	825
NiMp$_2$Cl$_2$ (d^8, tetra.)	2	9,200	15,620	497 −350	808 −884	500	810
CoO (d^7, octa.)	7	16,680	18,450	887 −98	780 −1,190	888*	780†
Cs$_3$[CoCl$_4$]Cl (d^7, tetra.)	5	5,580	14,800	320 759	719 −159	320	719

3Etpy is 3-ethyl pyridine, Mp is methylpyrazine.
* Calculated from ν_2 band.
† Calculated from diagonal sum rule.

The corresponding equations for ions with a d^2 or d^7 configuration in an octahedral field, or with a d^3 or d^8 configuration in a tetrahedral field, are given below.

For example, d^7 (octahedral field) where ν_2 is ${}^4T_{1g}(F) - {}^4A_{2g}$, and ν_3 is ${}^4T_{1g}(F) - {}^4T_{1g}(P)$,

$$340Dq^2 + 18(\nu_3 - 2\nu_2)Dq + \nu_2^2 - \nu_2\nu_3 = 0 \qquad (3)$$

$$B = \frac{\nu_3 - 2\nu_2 + 30Dq}{15} \qquad (4)$$

Table 1 records examples of Dq and B calculated using equations (1)–(4) together with those reported previously, for some octahedral and tetrahedral compounds of cobalt (II) and nickel (II).

Ultrasonic Absorption in Aqueous Solutions of Certain Inorganic Sulphates

It is well known[1] that for a salt solution the relationship between adiabatic compressibility, β, and molarity, c, is given by the expression:

$$\beta = A + B\,c + C\,c^{3/2}$$

Recently[2], the variation of compressibility with concentration, for aqueous solutions of various inorganic sulphates (lithium sulphate, magnesium sulphate, sodium sulphate, potassium sulphate, etc.), was reported; differences in the behaviour of each solution were related to differences in the cations—as the sulphate ion was common to all, the differences were considered to be due to differences in the ionic radius of the cations.

When the ionic radius increases, the compressibility decreases; if it is assumed that the hydration of the sulphate ion is the same in each solution for a given concentration, it would seem that a larger ionic radius would lead to greater solvation which would result in a lower compressibility.

Table 1

Magnesium sulphate in water		Mg^{++} (r = 0·65 Å)

0·5	1·0734	1·109	6·4651

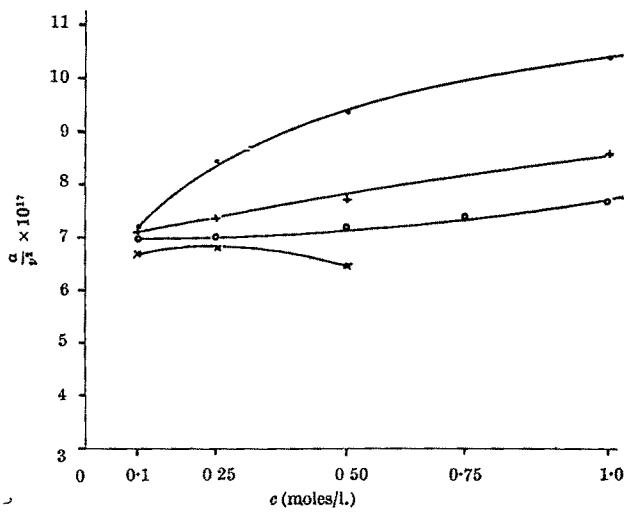

Fig. 1. Plot of ultrasonic absorption against molarity for the sulphates of magnesium (●), lithium (+), sodium (○) and potassium (×)

It is necessary to take into account the fact that the radius of Li^+ ions (r = 0·60 Å)[3] has a greater effect on compressibility in lithium sulphate than does the radius of the Mg^{++} ion (r = 0·65 Å) in magnesium sulphate.

It is possible that a larger number of water molecules is bound by the two Li^+ ions than by the single doubly charged Mg^{++} ion. We can obtain values for ultrasonic absorption $\left(\frac{\alpha}{\nu^2}\times 10^{17}\right)$ (ref. 4) from the expression:

$$\frac{\alpha}{\nu^2} = \frac{8}{3}\frac{\Pi^2}{\rho}\frac{\eta}{V^3}$$

where V is the ultrasonic velocity, ρ is the density (20° C), and η is the viscosity (Ostwald) 20° C.

In liquids, as we know, the contribution of the thermic conducibility to the ultrasonic absorption is negligible; thus, because $\alpha_{class} = \alpha_\eta + \alpha_{cond}$, $\alpha_{class} = \alpha_\eta$.

Table 1 gives $\frac{\alpha}{\nu^2}\times 10^{17}$ values, molarity, density and viscosity coefficient, and Fig. 1 a plot of ultrasonic absorption against molarity, for the sulphates of magnesium, lithium, sodium and potassium.

For a given value of concentration, we can see that $\frac{\alpha}{\nu^2}\times 10^{17}$ is largest for a solution of magnesium sulphate, and that it decreases in the order lithium sulphate, sodium sulphate, potassium sulphate.

Because dissociation of magnesium sulphate only results in one Mg^{++} ion (r = 0·65 Å), while dissociation of lithium sulphate, sodium sulphate and potassium sulphate results in two Li^+, Na^+ and K^+ ions, respectively, (the radii of which are 0·60, 0·90 and 1·33 Å, respectively), when ionic radium increases, the ultrasonic absorption decreases. It is thus necessary to take into account the fact that there is a lower effect for doubly charged Mg^{++} ion than for Li^+ and other ions. This could well confirm the hypothesis that the number of water molecules bound to ions in solution is responsible for the different behaviours of η, β, V in various solutions, that is, the larger the number of water molecules bound by ions of large ionic radius, the lower the value of ultrasonic absorption.

Metal Clusters in a New Mixed Halide of Molybdenum (IV) and (V)

SINCE 1963 there have been several reports of the existence of trimeric clusters of rhenium atoms in anionic and uncharged halogen compounds of rhenium (III)[1–5]. Recently, Dr. R. Colton and Prof. R. L. Martin have adduced magnetic and spectral evidence for the existence of trinuclear clusters in rhenium (IV) chloride[6] and also in molybdenum (III) chloride[7]. In an investigation of the reactions of molybdenum hexafluoride as outlined in the following paragraph, a new mixed halide of molybdenum has been isolated and characterized. Magnetic, spectral and conductance measurements indicate that this compound is ionic and contains the $(Mo^{IV}_3Cl_9)^{3+}$ cation, an entity which fits very well into the scheme proposed by Colton and Martin for stable clusters in molybdenum–chlorine compounds.

When molybdenum hexafluoride reacts at room temperature with chlorides such as phosphorus trichloride, carbon tetrachloride and silicon tetrachloride, the corresponding fluorides (PF_3, CF_4 and SiF_4) are identified among the products of reaction. However, in each of these cases and in many similar reactions[8] the product containing molybdenum was found to have the empirical formula $Mo_2Cl_3F_6$. This same orange compound, together with chlorine, is obtained as a result of mixing molybdenum hexafluoride and molybdenum pentachloride. When hydrogen fluoride was distilled on to molybdenum pentachloride, the same mixed halide was the only involatile product while hydrogen chloride and chlorine could be distilled from the reaction system.

Obviously this mixed halide of odd oxidation state is a compound of considerable stability. It appeared to sublime unchanged at 80° C, but on further heating it decomposed to molybdenum trichloride and molybdenum hexafluoride. It was found to react with water and with nitrobenzene, and to be virtually insoluble in carbon tetrachloride, in perfluoroheptane and in trifluoroacetic acid. However, it was readily soluble in acetonitrile.

The empirical formula suggested two possible structures. The first of these is a bridged structure with two molybdenum atoms, each surrounded by an octahedron of three chlorine atoms and three fluorine atoms. The two octahedra could share a face containing three chlorine atoms.

This type of structure has been reported for the $W_2Cl_9^{3-}$ anion[9]. An alternative formulation would be an ionic one, for example $(Mo^{IV}Cl_6)^{+}$ $(Mo^{V}F_6)^{-}$. The hexafluoromolybdate (V) anion is well known, but the $MoCl_3^{+}$ cation has not been previously reported.

Conductance measurements in acetonitrile favoured an ionic structure. A value of 80 ohm^{-1} cm^2 was obtained for the molar conductance at a concentration of $4{\cdot}35 \times 10^{-3}$ M based on the empirical formula $Mo_2Cl_3F_6$. Electrolysis of the brown solution in acetonitrile in a three-compartment cell resulted in a brown catholyte solution which gave a positive test for chloride and a negative test for fluoride, and a colourless anolyte which gave a positive fluoride test and a very weak chloride test. This observation was consistent with electrolysis of a compound containing the MoF_6^- anion and a cation containing molybdenum and chlorine.

Determination of the magnetic susceptibility over the temperature range 93°–290° K showed it to follow a Curie-Weiss plot with a value for θ of 155°, which is of the same magnitude as the values found for other compounds containing the MoF_6^- anion[10]. Using this correction, values for the magnetic moment of 1·67–1·73 Bohr magnetons (B.M.) per molybdenum atom were obtained over the temperature range studied. Solution measurements in acetonitrile also gave a value of 1·67 B.M. However, the formulation $(Mo^{IV}Cl_3)^{+}$ $(MoF_6)^{-}$ is at variance with these magnetic data. If 'spin-only' values are assumed for the d^1 (Mo^{V}) and d^2 (Mo^{IV}) configurations a value of 2·45 B.M. is obtained. Experimental figures can be reconciled with calculated values, however, if the suggestion is made that the cation is trimeric. The compound could then be formulated $(Mo^{IV}_3Cl_9)^{3+}$ $(Mo^{V}F_6)_3^{-}$.

We assume here that the core of the $(Mo_3Cl_9)^{3+}$ cation is similar to that found in the $Re_3Cl_{12}^{3-}$ and Re_3Cl_9 structures[1–4]. In this case the molecular orbital treatment[6] leads to a ground-state electronic configuration $(a_1')^2$ $(a_2'')^2$ $(e')^2$ with two unpaired electrons per trimer. This structure would be expected to give a moment of 1·64 B.M. per molybdenum atom, a value corresponding with two-thirds of an electron per molybdenum atom.

However, the magnetic moment of the anion cannot be neglected. It is assumed here that it contributes one unpaired electron per MoF_6^- anion to the measured moment. The magnetic moment calculated for the overall formulation $(Mo_3Cl_9)^{3+}$ $(MoF_6^-)_3$ then becomes 1·68 B.M. per molybdenum atom, a value in excellent agreement with the experimental one.

Examination of the spectrum of the compound in acetonitrile shows the presence of a peak in the infra-red region at 630 cm^{-1}. In spectra of mulls and disks absorption at 623 cm^{-1} has been reported[11] as being characteristic of the hexafluoromolybdate (V) anion in the well characterized compound $KMoF_6$.

An acetonitrile solution of the compound shows absorption maxima at 21,500 cm^{-1} and 14,100 cm^{-1}. The colourless MoF_6^- anion does not absorb appreciably in the visible region and the observed absorption bands are therefore attributed to the trimeric cation $Mo_3Cl_9^{3+}$. The spectra of some related trimeric transition metal chloride clusters are summarized in Table 1 and it is a striking feature that they all show two similar bands.

Table 1. SPECTRA OF SOME CHLORIDE CLUSTERS

Compound	Electron configuration	Positions of absorption maxima cm^{-1} (ϵ_{max})	Solvent	Reference
Re_3Cl_9	d^4	13,300 (410); 19,400 (1,610)	Acetone	4
Mo_3Cl_9	d^2	13,150; 19,100	Reflectance	7
$Mo_3Cl_9^{3+}$	d^2	14,100 (160); 21,500 (1,550)	Acetonitrile	This report
Mo_3Cl_{12}	d^2	13,330; 22,200	Acetonitrile	12
$W_3Cl_{12}^{3+}$	d^1	13,100; 22,200	Acetonitrile	12

Conductance measurements and electrolysis in acetonitrile suggest that the compound reported here is ionic and its insolubility in non-polar solvents further supports this. Spectra and magnetic measurements suggest a structure based on a trimeric cation and the MoF_6^- anion. It should be noted that if the molar conductance is calculated on the basis of the formula $(Mo_3Cl_9^{3+})$ $(MoF_6^-)_3$ a value of 240 ohm^{-1} cm^2 is obtained for the molar conductance at a concentration of $1{\cdot}45 \times 10^{-3}$ M. Measurement of the molar conductance as the solution is diluted indicates a limiting value of about 330 ohm^{-1} cm^2.

We thank Prof. R. L. Martin and Dr. R. Colton for helpful discussion.

Investigation of Steric Effects about the Amide Bond by Gas–Liquid Chromatography

THE steric requirements of molecules dominate the rates and equilibria of many reactions in organic and inorganic chemistry. It is still difficult to make precise calculations of steric effects, but in many cases the qualitative principles controlling steric requirements have become apparent. For example, in reactions that involve addition to an unsaturated function containing a double bond, the empirical 'rule of six' correctly states "the greater the number of atoms in the six position, the greater will be the steric effect"[1]. The rule of six has also been used to interpret conformations of polypeptides and proteins and to explain hydrolysis rates of di- and poly-peptides[2].

We have found that the separation of diastereoisomeric pairs using gas–liquid chromatography can be used to assess steric conditions about the amide bond and that here again the rule of six correctly predicts the steric effect. In particular, we chose α-chloro alkanoyl valine methyl esters, because they are readily prepared from the respective peptides; and we had already shown that α-chloro alkanoyl chlorides are excellent reagents for the quantitative chromatographic resolution of diastereoisomers[3]. Since the presence of neighbouring polar groups may greatly modify steric factors, we have restricted our work to those compounds, derived from amino-acids, which have no hetero-atom in the side-chain. Correlation of the six-number with the ratio of retention times of the diastereoisomeric pairs is summarized in Table 1. Examination of the data suggests that the number of atoms in the 5 and 7 position is unimportant for the assessment of steric effects, but that the most hindered α-chloro acids are those with the highest six-number. This explanation is consistent with the observation that 2-chloro-3-dimethylbutanoic acid is the best reagent for the gas–liquid chromatographic analysis of D,L-amino-acid esters.

Our results suggest that differences between the vapour pressures of the diastereoisomers are enhanced by increased crowding about the amide bond, as is shown by separations on a non-polar silicone gum rubber column (*SE*-30) (Table 2). In addition, a more polar liquid phase (*FFAP*) improves the resolution (Table 1). We interpret the latter result as being due to secondary bonding between the amide carbonyl and the polyester column substrate. Since the magnitude of this effect will also be dependent on configuration it will be different for each diastereoisomer and further enhance the separation.

Table 1. CORRELATION OF THE RULE OF SIX WITH RATIO OF RETENTION TIMES OF DIASTEREOISOMERS OF A SERIES OF *N*-CHLORALKANOYL VALINE

Comparison of Diffusion of Carbon Dioxide into Hydrocarbon Systems and Polymeric Solutions

METZNER recently reported diffusion coefficients of ethylene and carbon dioxide into polymeric and colloidal solutions[1]. We have measured absorption rates of carbon dioxide in mixtures of hydrocarbons of molecular weight 160–360. In this work, for a twenty-four-fold increase in viscosity the diffusion coefficients varied from $0{\cdot}73 \times 10^{-5}$ to $2{\cdot}50 \times 10^{-5}$ cm²/sec. These data can be interpreted by existing theories on diffusion[2]. The values quoted by Metzner for diffusion of carbon dioxide into dilute solutions of carbopol and carboxy methyl cellulose are all within this range ($1{\cdot}8$–$2{\cdot}4 \times 10^{-5}$ cm²/sec) although the apparent viscosities of these solutions will be very much greater than that of the highest molecular weight hydrocarbon investigated (25 centipoise).

As Astarita has shown[3], the values of the diffusion coefficients of carbon dioxide into polymeric solutions are very much higher than existing theories would predict. The fact that the diffusion coefficients are all of the same order as those for carbon dioxide into water and hydrocarbons suggests that, at the concentrations considered, the presence of the polymeric molecules has little effect on the molecular transport of the solute, although such molecules have a profound effect on the flow properties of the solution. At zero shear stress, the polymer molecules would not effect the diffusion of solute if they were spaced well apart in relation to the volume of the solute molecules. The increase of diffusion coefficients as the concentration of polymer molecules increases (apparent viscosity increasing) could then only be accomplished by ordering of the solvent around the polymer molecules, provided the intermolecular spacing between the polymer molecules was again very large.

BIOCHEMISTRY

Insensitivity of Phytochrome Decay *in vivo* to Respiratory Uncoupling by 2,4-Dinitrophenol

PHYTOCHROME, the red, far-red photo-reversible chromoprotein that controls much of higher plant growth and development, undergoes two changes in the dark following an initial red light exposure. One change, reversion, is the transformation of the far-red absorbing form, P_{FR}, into the red absorbing form P_R. A second change, which we will call decay, is the loss of total photo-reversible phytochrome as a result of the apparent destruction of P_{FR} (ref. 1). Since there is considerable indirect evidence that P_{FR} is the active form of phytochrome, the interactions between P_{FR} decay and metabolism may be of significance in elucidating the mechanism of phytochrome action.

Butler and Lane[2] have shown that decay in etiolated *Zea* (corn) seedlings is directly proportional to oxygen concentrations between 0 per cent and 10 per cent. They further demonstrated that cyanide, carbon monoxide and azide partially inhibit both respiration and P_{FR} decay, thus suggesting that respiration and decay are closely linked. Furuya *et al.*[3], however, have shown that in coleoptiles of etiolated *Avena* (oat) seedlings ethylenediamine tetraacetic acid (EDTA) stops decay at concentrations having no effect on oxygen uptake. This suggests that respiration and phytochrome decay are not necessarily related. We have now used 2,4-dinitrophenol (DNP), an uncoupler of the respiratory chain, as a further test of the possible relationship between these processes.

Since it is well established that the uncoupling action of DNP is accompanied by a surge of oxygen uptake[4], we first determined what concentrations of DNP cause a significant increase in respiration.

The material was taken from four-day-old seedlings of *Avena sativa* cultivar 'Clintland' grown at 26° C in darkness. Leafless coleoptile segments, 5 mm in length, were cut, randomized and then placed in groups of thirty in each of the Warburg-type flasks used in the experiment. The main chamber of the flasks contained, beside the tissue, a 0·02 M sodium–potassium phosphate buffer at *p*H 6·5 with 1·5 per cent sucrose[5]. The centre well contained 10 per cent potassium hydroxide, and the side arms held either DNP or water, as the case might be. Oxygen uptake was followed at 26° C in air with a '*GME*' differential respirometer (Gilson Medical Electronics, Middleton, Wisconsin). Once the initial respiratory rate of each flask was determined over 100 min, the contents of the side arms were tipped into the main vessel. The final rate was established over 120 min after a 30-min incubation period. All data were first normalized to the initial rates for each flask. These values were then averaged for the various DNP concentrations and for the controls. With the control values taken as 100 per cent, the means obtained in this way were used to compute the net DNP effect at various concentrations[3]. Several such experiments gave values of 114, 137, 143, 154 and 135 per cent of the control for 1, 2, 3, 5 and 10×10^{-5} M DNP, respectively. These values are close to those obtained for *Zea* (corn) coleoptiles under similar conditions by Beevers[6].

We then proceeded to test the effects of uncoupling concentrations of DNP on phytochrome decay. The same type of material prepared for the respirometer experiments was used here, except that all manipulations were carried out in the dark or under a dim green safelight[7]. The segments were then incubated for 30 min in the sucrose–phosphate buffer, either with or without added DNP. After the incubation period a 5-min red-light treatment[7] was given to the appropriate segments. At 0, 1 and 2 h after the red light, twenty-five segments were quickly packed into cuvettes, 3 mm in diameter, and placed on ice. The samples were then assayed for phytochrome by methods described elsewhere[7], using a two-filter difference spectrophotometer to measure total $\Delta(\Delta OD)$ values, which are taken as estimates of total phytochrome. Results of a typical experiment are presented in Table 1 and indicate that uncoupling concentrations of DNP have no effect on decay.

Table 1. LACK OF EFFECT OF 3×10^{-5} M DNP ON PHYTOCHROME DECAY IN *Avena* COLEOPTILE SEGMENTS

Each value is the mean of three samples

Treatment	Hours after red light	Phytochrome total $10^3\ \Delta(\Delta OD)$	Percentage remaining
Controls (buffer and sucrose only)	0	53·2	100
	1	32·8	62
	2	17·2	32
Plus DNP	0	51·8	100
	1	29·0	56
	2	17·0	34

Further experiments have shown that a much higher concentration of DNP, 10^{-3} M, prevents the loss of total phytochrome in both red-light-treated and dark samples. At the same time, 10^{-3} M DNP reduces the respiratory rate to about one-tenth of the control rate. These facts indicate that decay is dependent at least on an intact metabolism and also that DNP itself does not affect phytochrome absorbance.

In conclusion, our results demonstrate that respiratory chain energy conservation is not intimately related to phytochrome decay. This finding supports the view[3] that decay requires oxygen and metal activity, not as a function of the respiratory chain, but rather as a function of other, as yet unknown, reactions. The question of the physiological importance of phytochrome decay remains open.

This research was carried out at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission. We thank Rosemarie Dearing for technical assistance. Matthews O. Bradley was a participant of the Brookhaven Summer Student Program.

Activity of Amino-laevulinic Acid Synthetase in Normal and Porphyric Human Livers

ACUTE intermittent porphyria (AIP) is well known as an inborn error of porphyrin metabolism, clinically characterized by attacks of abdominal pains and frequently associated with the neurological and mental symptoms and signs. The excretion of the two kinds of porphyrin precursors, porphobilinogen (PBG) and delta-amino-laevulinic acid (ALA) in urine, suggesting the presence of a disturbance in the porphyrin metabolism, has been thought essential for the diagnosis of this disease.

Although a block in the conversion of PBG and ALA to porphyrins has been regarded as the explanation for the accumulation and urinary excretion of these compounds, Granick and Urata[1] reported a marked elevation of ALA synthetase activity in liver mitochondria in the experimental porphyria in guinea-pig induced by feeding of 3,5-dicarbethoxy-1,4-dihydrocollidine (DDC). Recently we have had an opportunity to perform a metabolic investigation on human porphyric liver.

The patient was a man 32 years old, with a history of attacks of abdominal pain and neurological symptoms such as weakness of arms and legs lasting for a month

Table 1. ENZYMATIC ACTIVITIES IN HUMAN PORPHYRIC LIVER

	ALA synthetase in washed mitochondria		ALA dehydrase in 10,000*g*-supernatant	PBGase in 10,000*g*-supernatant	Iron–protoporphyrin chelatase in mitochondria

* mpv, ml. packed volume.

3 years ago. He was hospitalized for re-examination, with the disease in remission. During his stay in hospital he continued to excrete about 200 μmoles of PBG and 80 μmoles of ALA in his urine every day without signs and symptoms of AIP. A biopsy of the liver was carried out surgically to remove 2 g of liver.

For the preparation of liver mitochondria and supernatant, 2·0 g of the fresh liver was homogenized for 1 min with 20 ml. of 0·25 M sucrose including 0·005 M sodium bicarbonate and 0·005 M potassium-phosphate-buffer (*p*H 8·0) in a Potter–Elvehjem glass homogenizer with a loose pestle, followed by centrifugation at 800*g* for 10 min. The supernatant was centrifuged at 10,000*g* for 10 min. The mitochondria portion was washed twice with sucrose solution. ALA synthetase activity was assayed by the method of Granick and Urata[1], ALA dehydrase and PBGase activity by the method of Granick and Mauzerall[2], and iron–protoporphyrin–chelatase activity by the method of Labbe[3].

As shown in Table 1, ALA synthetase activity is markedly greater in porphyric liver mitochondria than in the controls, and the ALA dehydrase activity is about twice that in the controls, while the PBGase and chelatase activity is nearly the same. The ability of porphyric liver to convert PBG to porphyrins, measured by an increase of optical density at 407 mμ in a Beckmann spectrophotometer, was about twice that of the control, although the activity of each enzyme is still under investigation.

This study indicates that overproduction of the porphyrin precursors, resulting from increased ALA synthetase activity in the liver mitochondria, is the principal feature of the disturbance of porphyrin metabolism in human acute intermittent porphyria.

Carbon-14 in Carboxyl Carbon of Fatty Acids formed by Platelets from Normal and Diabetic Subjects

WHEN platelets from diabetic patients are incubated with acetate carbon-14, a significantly smaller than normal percentage of fatty acid carbon-14 is found in myristic and palmitic acids. Formation of longer-chain fatty acids, particularly saturated and unsaturated 20-carbon fatty acids, is much less affected, resulting in an increased percentage of fatty acid carbon-14 in these fatty acids[1–3]. Platelets from comatose diabetics show the greatest abnormality[1], while those from non-ketotic insulin-dependent diabetics[2] and insulin-independent diabetics[3] show less marked but similar changes.

Harlan and Wakil[4] have shown that myristic (14 : 0), palmitic (16 : 0), and stearic acids (18 : 0) can be made in the supernatant fraction of rat liver by *de novo* synthesis via the malonyl CoA pathway. However, the mitochondrial fraction of rat liver makes both palmitic and stearic acids by chain lengthening of relatively non-radioactive shorter chain fatty acid precursors.

We have postulated that the abnormalities in fatty acid formation which we have demonstrated in platelets from diabetic patients result from decreased formation of fatty acids *de novo* with little or no impairment of fatty acid formation by chain lengthening.

We have, therefore, decarboxylated the fatty acids formed by normal platelets to determine if both *de novo* synthesis and chain lengthening occur. Since a decrease in carbon-14 myristic and palmitic acids could be due to formation of these fatty acids by chain lengthening in the diabetic, we have decarboxylated myristic and palmitic acids formed by platelets from diabetic subjects.

Platelet-rich plasma (5 ml.) was prepared by centrifugation of heparinized whole blood at 450*g*. All glassware was siliconized. After the initial centrifugation, the platelet-rich plasma was checked for leucocyte contamination. If the platelet suspensions contained more than 200 leucocytes per mm³, they were re-centrifuged for 2–3 min. In this way, platelet suspensions containing 0–200 leucocytes per mm³ could be obtained. In a previous investigation, we have calculated that this degree of leucocyte contamination could contribute no more than 3·5–4 per cent of the total fatty acid radioactivity[5]. Following centrifugation, the platelet suspensions in plasma were incubated with 5 μc. of 1-^{14}C acetate for 4 h at 37° C under 95 per cent oxygen and 5 per cent carbon dioxide. Lipids were extracted from the platelets and plasma[5]. After saponification and extraction[6] of the crude lipid extract, the fatty acid methyl esters[7] were then separated on a 20 per cent diethylene glycol succinate column.

Each peak and the areas between the peaks were trapped separately on siliconized cellulose acetate filters by a method developed in this laboratory[8]. Fatty acids were tentatively identified by their retention time in relation to known standard fatty acids. The radioactivity in each fatty acid was determined in a liquid scintillation spectrometer. The fatty acid methyl esters were then recovered from the scintillator by passing them through a silicic acid column in 2·5 per cent diethyl ether in hexane. They were decarboxylated by the Schmidt azide degradation technique as modified by Hajra and Radin[9].

All diabetics who required insulin to prevent ketosis were classified as insulin-dependent. All diabetics who had never developed ketosis or ketonuria and had never received insulin were classified as insulin-independent.

Myristic and palmitic acids appear to be formed *de novo* from acetate 1-^{14}C by the normal platelet, since one-seventh and one-eighth of the total radioactivity was found

in the carboxyl carbon. In contrast, stearic acid (18 : 0), oleic acid (18 : 1), arachidic acid (20 : 0), eicosenoic acid (20 : 1), and the mixture of fatty acids with retention time corresponding to 22 : 0 or more appear to be formed by addition of acetyl Co*A* to a relatively non-radioactive shorter chain fatty acid, since 51–100 per cent of the total fatty acid radioactivity is found in the carboxyl carbon. Lauric acid (12 : 0) may be formed by either mechanism since 12·9–34 per cent of the total carbon-14 was found in the carboxyl carbon (Table 1).

The percentage of carbon-14 found in the carboxyl carbon of myristic and palmitic acids formed by platelets from non-ketotic insulin-dependent or insulin-independent diabetics was similar to that of normal individuals (Table 1).

In contrast, in three of four experiments, the carboxyl carbon of palmitic acid formed by platelets from acidotic diabetics contained a much greater percentage of carbon-14 than normal. This was also true of myristic acid in two of four experiments (Table 1). Therefore, both palmitic and myristic acids may be formed abnormally in diabetic acidosis, apparently by chain lengthening. Decarboxylation of 18 and 20 carbon fatty acids formed by platelets from diabetics in acidosis showed that these fatty acids are made by chain lengthening (Table 1).

Coniglio and Cate[10] have shown that starvation may result in a shift in formation of palmitic acid from *de novo* synthesis to chain lengthening in both liver and carcass. Hollenberg and Douglas[11] have demonstrated similar findings with the rat epididymal fat pad. It appears that the platelet may respond to severe diabetic acidosis in a similar way. Fatty acid formation in the platelet may be regulated in much the same way as that in better-known tissues. Another aspect of these findings is of interest. Fatty acids containing 18 carbons are presumably formed by addition of acetyl Co*A* to palmityl Co*A*. If newly formed palmitic acid served as a precursor for stearic or oleic acid, only one-ninth of the carbon-14 in 18 : 0 and 18 : 1 should have been in the carboxyl carbon of these acids. However, a much greater percentage of the radioactivity was actually found. It seems apparent, therefore, that there are two pools of palmitate within the platelet which do not equilibrate during the time of investigation. We have shown in a previous report that newly formed myristic and palmitic acids are found primarily in non-esterified fatty acids of platelets, while newly formed longer chain saturated and unsaturated fatty acids are found primarily in phospholipids and glycerides[12]. It is therefore unlikely that non-esterified fatty acids serve as direct precursors for chain lengthening. It may be that the precursors for formation of 18-, 20- and 22-carbon fatty acids are present in an esterified form at the site where chain lengthening occurs.

The existence of pathways for *de novo* synthesis and chain lengthening within the same cell magnifies the difficulties involved in attempting to measure relative rates of synthesis of various fatty acids made by the cell. If, for example, 7 per cent of the total fatty acid radioactivity is in stearic acid, but all is present in the carboxyl carbon, while 24 per cent of total fatty acid radioactivity is present in palmitic acid, but distributed equally in each alternate carbon, there will be seven moles of stearic acid formed for each three moles of palmitic acid. Similarly, in diabetic acidosis, when 30 per cent of the carbon-14 in palmitate is in the carboxyl carbon, approximately two and a half times as much palmitate will be formed per unit amount of acetate 1-^{14}C incorporated. In this situation, a decrease in incorporation of acetate carbon-14 of more than 50 per cent could still maintain normal 'synthesis'. Perhaps, however, the site of formation and the function of palmitate would be quite different from normal.

We thank Mrs. Jean Jackson and Mrs. Maxine Adams for technical assistance. The research was supported by grants

Occurrence of Phytanic Acid in Rumen Bacteria

THE branched-chain fatty acid 3,7,11,15-tetramethylhexadecanoic acid (phytanic acid) has been isolated and identified in butterfat[1–4], sheep fat[5], ox fat[6], ox serum[7,8], crude petroleum[9] and also in the tissues, serum and urine of humans afflicted with the rare disease referred to as Refsum's syndrome[10–12] (heredopathia atactica polyneuritiformis). This communication reports the occurrence of trace quantities of this acid in the rumen bacteria from a fistulated cow fed clover-grass hay.

Phytanic acid has not hitherto been reported as a constituent of rumen lipids, although Keeney, Katz and Allison[13], in their quantitative studies on rumen digesta, detected C_{13}, C_{14}, C_{15}, C_{16} and C_{17} branched-chain fatty acids in rumen bacteria. In the investigation now reported, a concentrate of phytanic acid was prepared from the rumen bacterial lipids by low-temperature crystallization from acetone and mercuric acetate adduct formation followed by chromatographic separation on a 'Florisil' column[14]. The presence of the C_{20} multi-branched component was determined by gas–liquid chromatography, recognition of the chart peak being based on retention data previously established in this laboratory for the same acid isolated from butterfat[4] and from Refsum's syndrome tissues[12] and conclusively identified by techniques which included mass and infra-red spectrometry. The methyl ester of authentic phytanic acid isolated from ox fat[6] when added to the methyl esters of the phytanic acid concentrate extracted from rumen bacteria, co-chromatographed on columns impregnated with polydiethylene glycol adipate and 'Apiezon L', respectively.

The presence of branched-chain fatty acids in bacterial lipids is well established[15,16] but, whereas in some species of bacteria certain of these constituents—namely the C_{15} and C_{17} iso and ante-iso acids[17–20]—represent major proportions of the total lipids, in ruminant body and milk fats these acids occur in trace amounts only. Akashi and Saito[17] postulated that branched-chain acids of animal fats[21,22] were derived from bacterial lipids in the gut of the host, and this hypothesis is supported by the investigation of Keeney *et al.*[13] on the rumen contents of a lactating cow, by the studies of Kuzdzal-Savoie[23] and by this report.

The chemical structure of phytanic acid, as distinct from that of the iso and ante-iso acids, suggests a close relationship with the isoprenoid alcohol phytol which constitutes a substantial proportion of the chlorophyll molecule of green plant life. An examination of the lipids extracted from the clover-grass hay fed to the experimental cow did not, however, reveal phytanic acid. It seems probable, therefore, that rumen bacteria convert phytol to phytanic acid within their own tissues and that the presence of this C_{20} tetramethyl fatty acid in ruminant body and milk fats is due to assimilation of the lipids of these micro-organisms[4].

Effect of Boiling and Storing on Cycasin Content of *Cycas circinalis* L.

RECENTLY we described a quantitative chromatographic method[1], using the extraction procedure by Riggs and Korsch[2], for the specific estimation of cycasin in the kernel of *Cycas circinalis*. Matsumoto and Strong[3] have reported a chromotropic acid method which can be used for indirectly assessing cycasin from the quantity of formaldehyde liberated. Hydrolysis of cycasin by acid[4] or by its emulsin[5] is known to yield methanol, formaldehyde and nitrogen.

Our own method has been considerably simplified. First, the soaking and washing for 8 days through three changes of water (carried out initially to emulate the cooking procedure of the Guamanians)[6] has been dispensed with since this seems to remove the cycasin from the cycad nut[1,7]. Secondly, the Riggs and Korsch[2] procedure of extraction, which was followed initially and which involves boiling for 20 min, can also be dispensed with. The method now followed is reduced to: (1) cutting the cycad nuts into small slices; (2) drying the slices overnight in an oven at 40° C; (3) powdering of the dried slices; (4) extracting by stirring in 80 per cent ethanol for 15 min; (5) centrifuging at 3,000 r.p.m.; (6) directly spotting the clear supernate on Whatman No. 1 paper, using amounts equivalent to 25–50 mg of the original kernel; (7) unidirectional paper chromatography; (8) staining; and (9) colorimetric quantitation, as earlier. Recovery of known amounts of authentic cycasin is quite adequate with this method also.

Results obtained using this simplified procedure are given in Table 1, and compared with the cycasin content of the same specimen assessed by the chromotropic acid method. It is seen that on the whole the values obtained are comparable, especially in materials '*B*' and '*D*'. There appears to be a difference, however, in the values

Table 1. CYCASIN IN CYCAD NUT POWDERS DETERMINED BY THE SIMPLIFIED CHROMATOGRAPHIC METHOD AND THE CHROMOTROPIC ACID METHOD

	Material	No. of estimations	Chromatographic method (month of estimation)	No. of estimations	Chromotropic acid method (month of estimation)
			July '64 and July '65		July '65
A	Powder of dried chips of cycad (received from Guam)	5	Nil	2	0·080

* Riggs and Korsch extraction procedure (ref. 2).

obtained by these two methods in the case of unwashed cycad nut powder (material '*C*') received through the National Institutes of Health, and also for the 20-min extracts of unwashed nuts prepared here (Table 2, material '*C*' 2, 3, 4). In these samples formaldehyde liberation indicated a higher cycasin-level or showed some cycasin where none was detected by the chromatographic method. Since the latter is sensitive to as little as 5 μg of cycasin and specific for it, it appears possible that the formaldehyde reaction might be given by substances in the cycad nut other than cycasin itself, thereby perhaps producing higher values than those actually present. Even the pure enzyme emulsin, β-glucosidase (kindly provided by Dr. Marjorie Whiting and Dr. H. Matsumoto), which is present in the kernel of cycads[5] (a specific enzyme generally accompanying a plant glycoside[8]) is found to give a colour reaction identical to that of formaldehyde, on treatment with chromotropic acid.

Prolonged storage may have a significant effect on the cycad nut. As will be seen from item '*B*' 1 of Table 2, sample I of the cycad nut received in October 1962 was exceptional in showing cycasin in August 1964, even when the nut had been soaked and washed in water, while samples II and III revealed no cycasin under these conditions. It is possible that this was due to some internal change in the nut stored for a long period, because samples II and III had at that time only just been received. As expected, the extract of the 'unwashed' nut from this batch also showed a moderate quantity of cycasin (Table 2, '*C*' 1). An explanation for this was made possible by our subsequent observation on the effect of prolonged boiling on cycasin content of the nuts.

In view of the foregoing, and because the nuts of *C. revoluta* and *C. circinalis* contain the enzyme β-glucosidase which is known to destroy cycasin[5,9], it was decided to inactivate β-glucosidase and see if this resulted in a higher cycasin concentration being obtained. For the purpose of doing this the kernels were boiled for a prolonged period, since boiling for 20 min in the course of the preparation of the Riggs–Korsch extract was apparently inadequate to reveal cycasin (items '*C*' 2, 3 and 4 of Table 2). On the other hand, the effect of boiling for 80 min was striking and revealed 0·5–1·5 per cent cycasin, where none was evident before (Table 2 and Fig. 1). The absence of any difference between the 20 min and the 80 min extracts of cycads of batch I ('*B*' 1 and '*C*' 1 in Table 2) is due to the operation of the aforementioned factor of prolonged storage.

It was thought that the emulsin would be destroyed by boiling for 20 min as there is probably no enzyme which resists such treatment; however, the enzyme is located within the kernel in such a position that 20 min of boiling did not affect it. It is conceivable that emulsin and its substrate, cycasin, reside in different cells of the kernel, since such a state is known to subsist in glycosides[8]. The prolonged boiling probably breaks up the cell wall, exposing the enzyme which is then destroyed by the heat. Prolonged storing of the whole nut under inadequate refrigeration probably achieves the same result and under both these conditions a higher value of cycasin is obtained.

On the other hand, repeatedly washing and soaking the nuts for 8 days, as in our earlier experiments[6], probably liberates and activates the enzyme which destroys the cycasin which cannot afterwards be detected (Table 2, '*B*' 2 and 3). A similar procedure is carried out by the Guamanians, and cycad chips received from Guam also

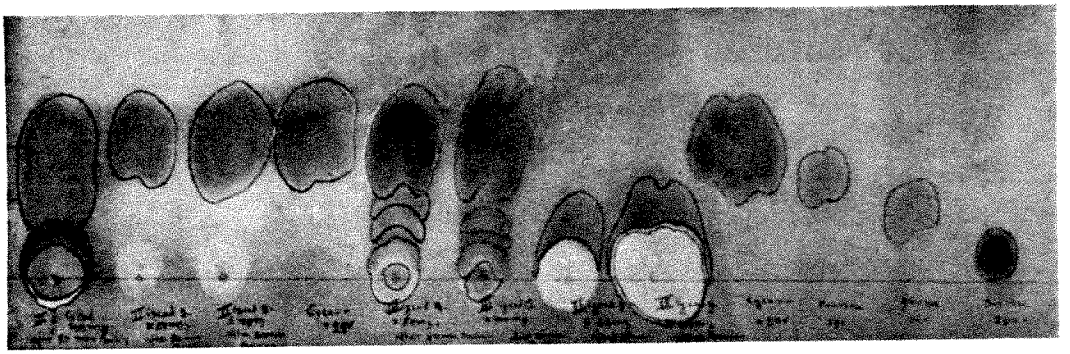

Fig. 1. Twelve spots of different preparations of various types of cycad nuts and of known sugars, as indicated below each spot. Note the effect of boiling on II cycad, spots 2 and 3 as compared with spots 7 and 8

failed to show cycasin (Table 2 *A*). Prolonged boiling did not reveal any cycasin as it had already been destroyed.

Further indirect confirmation of the foregoing observations, on the varying content of cycasin and the effect on it of boiling and storing, emerged from our long-term experiments on the feeding of various preparations of cycad nuts to different groups of monkeys. Two of three animals fed on the nut, after it had been intensely boiled, died of jaundice and hepato-toxicity while only one out of five monkeys fed on unwashed cycad suffered this fate (unpublished observations).

This investigation was supported in part by a grant from the National Multiple Sclerosis Society of America.

Red Fluorescence in Costo-vertebral Spot of Hamsters

DURING the course of experimental production of melanomata in hamsters[1,2] and the study of red fluorescence in tumours[3,4], we discovered, by chance, that the costo-vertebral spot of some of our normal hamsters showed a well-marked red fluorescence under ultra-violet radiation. Red fluorescence has been observed in the Harderian gland of hamsters and some other rodents[5], but its significance is obscure. Red fluorescence is also seen in many tumours[3,4]. In all these cases the red fluorescence is due to the presence of porphyrins.

Fifty males and fifty females from our colony of hamsters, in which the exact date of birth was known, were shaved in the region of costo-vertebral spots and examined under ultra-violet radiation. This was done in the autumn (23.10.64) when the animals were between 5 and 18 months old. Only one male showed red fluorescence in one of its costo-vertebral spots. Twenty-one males and twelve females from the same group of animals were shaved and re-examined in the following summer (19.5.65). (The remaining animals were not available because they had been used for other experiments.) The age of the animals used in this experiment ranged from 11 to 15 months. Of the females, only one animal showed a weak reddish fluorescence in one of the costo-vertebral spots, but sixteen males showed fluorescence in both spots, two in one spot, and three showed no red fluorescence. Even in males showing red fluorescence in both spots, one spot was usually more strongly fluorescent than the other.

Histological examination of cryostat prepared sections under ultra-violet radiation showed that the red fluorescence is mainly located in the necks of the hair follicles above the large sebaceous-type gland that occurs in this region. At times a faint patchy red fluorescence was also seen in the adjacent sebaceous glands themselves.

Red fluorescence in biological material is due to the presence of porphyrins. It would therefore appear that the male hamster in the summer season produces a secretion containing porphyrins from the glands in the costo-vertebral spot. It has been suggested that the secretion from the spot of the male hamster serves to mark territory[6], but that from the female has no such function. It is intriguing to speculate whether this difference is due to the presence of porphyrins. As yet, little is known about the fluorescence of the secretion of other territory-marking animals.

HAEMATOLOGY

Effect of Ferritin on Globin Synthesis

IN certain hypersideraemic anaemias the erythroid precursor cells in the bone marrow contain iron deposits. The iron overloaded mitochondria of these sideroblasts are not capable of synthesizing haem at a normal rate[1]. Iron-containing deposits are demonstrable not only in mitochondria, but also in other parts of the cytoplasm of these cells. It is, therefore, possible that iron overload also affects globin synthesis directly. In some of these hypersideraemic anaemias pyridoxine has been found to have a therapeutic effect which is likely to be due to the mobilization of the mitochondrial iron deposits[1]. In view of the amelioration of the anaemia of thalassaemia with pyridoxine[2], a direct influence of this vitamin on globin synthesis might also be assumed.

The effect of ferritin on globin synthesis was investigated in a cell-free system meant to imitate the conditions in sideroblasts. Reticulocytes, obtained from phenylhydrazine-treated rabbits, were lysed by short exposure to hypotonic *tris* chloride buffer containing magnesium chloride (ref. 3). The stroma, mitochondria, and intact leucocytes were removed by centrifugation at 15,000*g* for 15 min. Ribosomes and the enzyme fraction were then obtained and processed according to the method of Allen and Schweet[4] with the following exceptions: *s*RNA was not separated from the enzyme fraction; valine-1-^{14}C was used and the incubation period was 40 min. To some of the incubation mixtures (Table 1) commercial, 2x crystallized, cadmium-free ferritin was added which had been dialysed against 0·05 M *tris* chloride buffer, *p*H 7·5. Experiments were also done with the addition of buffered pyridoxal, pyridoxine, pyridoxamine, or deoxypyridoxine in concentrations from 10 mμg to 1 mg per tube.

After incubation the ribosomes and, when present, most of the ferritin were removed by centrifugation at 100,000*g* for 2 h. The supernate was freed of unincorporated valine-1-^{14}C by dialysis against running tap water for 36 h. Aliquots of the dialysed samples were then dissolved in hydroxide of hyamine and added to naphthalene-dioxane scintillation fluid[5]. Radioactivity was deter-

Table 1. THE EFFECT OF FERRITIN ON GLOBIN SYNTHESIS WITH VARIATIONS IN THE COMPOSITION OF THE INCUBATION MIXTURE

* 3 mg ribosomes; 5 mg enzyme; 1 μmole ATP; 120 μg pyruvate kinase; 10 μmoles phosphoenolpyruvate; 20 μmoles GSH; 50 μmoles potassium chloride; 5 μmoles magnesium chloride; 0·25 μmoles GTP; 0·05 ml. of amino-acid mixture (3); 10 μg D,L-valine-1-^{14}C; 50 μmoles *tris* chloride buffer, *p*H 7·5; total volume 1·45 ml.
† 2 μmoles ATP; 240 μg pyruvate kinase; 20 μmoles phosphoenolpyruvate.

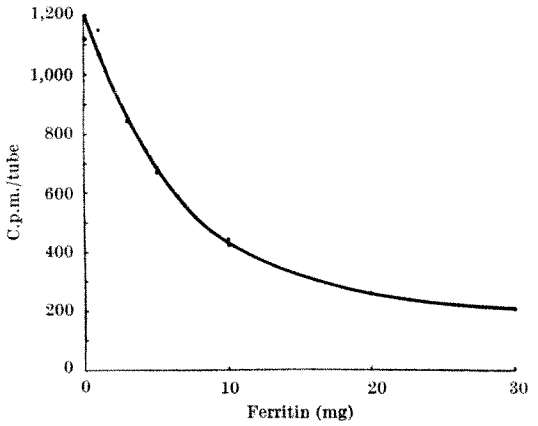

Fig. 1. The effect of increasing amounts of ferritin in the incubation mixture on the incorporation of valine-1-^{14}C

mined and adjusted for self-absorption by use of an internal standard. Incorporation was expressed in c.p.m. per incubation tube. Counts in duplicate tubes varied less than 5 per cent.

The amount of incorporated valine-1-^{14}C into the non-dialysable fraction was considered to be a measure of globin synthesis. The incorporation decreased in a hyperbolic manner with increasing concentrations of ferritin in the incubation mixture (Fig. 1). Ferritin had no effect when added to the mixture after incubation. The enzyme-*s*RNA fraction and the ribosome fraction were both rate-limiting at the concentrations employed. The inhibition by ferritin was completely abolished by doubling the concentration of glutathione (Table 1). This effect is possibly due to binding of ferritin iron by SH-groups. In the absence of ferritin a slight decrease in incorporated valine occurred following doubling of the concentration of the energy system. The mechanism of this effect is obscure as is the reason for the diminution of the inhibiting action of ferritin in the presence of doubled concentration of valine-1-^{14}C.

Pyridoxine, pyridoxal, or pyridoxamine in amounts up to 1 mg per tube neither enhanced globin synthesis in this system nor prevented the inhibition by ferritin. Deoxypyridoxine, a pyridoxine antimetabolite, was also ineffective.

The results of the described experiments suggest that ferritin inhibits globin synthesis. The fact that this inhibition is counteracted by excess glutathione in the incubation medium suggests that ferritin inactivates SH-enzymes required for the assembly of the polypeptide chains. It is possible that in thalassaemia the high ferritin content of the cytoplasm inhibits globin synthesis beyond the genetically determined limitation. Since in the incubation tube pyridoxine neither stimulated globin synthesis nor counteracted the effect of ferritin, it is likely that the slightly ameliorating effect of pyridoxine in this disease[2] is indirect through the action of pyridoxine on haem synthesis[1].

BIOLOGY

*p*H of Grasses in Relation to Genera

IN 1964 Birch *et al.*[1] reported that the low *p*H values found in aqueous extracts of the grass *Setaria sphacelata* did not occur in similarly prepared extracts of another grass *Brachiaria ruziziensis* or in those of legumes. We have now made a *p*H survey of many grasses to find out if *S. sphacelata* is a unique species in this respect.

The majority of the grasses were sampled from the Kitale nursery (6,200 ft.) and the remainder from Molo (9,200 ft.) and Mtwapa on the coast. Five sub-families and their associated tribes were represented as follows: Bambusiformis (Bambuseae); Phragmitiformis (Stipeae and Oryzeae); Festuciformis (Festuceae, Hordeae and Phalarideae); Eragrostiformis (Eragrosteae, Chlorideae and Sporoboleae); and Paniciformis (Paniceae, Arundinelleae, Andropogoneae and Maydeae). As might be expected in a tropical country the Paniceae contained the largest number of species and the Andropogoneae the second largest. In all, 112 samples were examined for *p*H: the determination was made electrometrically after shaking 0·4 g of the dried and ground sample with 50 ml. water for 30 min.

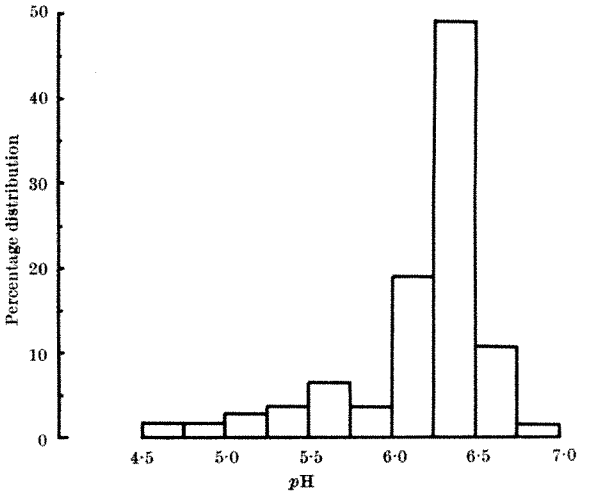

Fig. 1. Percentage distribution of *p*H in 112 samples of grass

As shown in Fig. 1, more than 80 per cent of the samples gave a *p*H value of more than 6; their mean value was 6·38. The remaining samples gave a mean *p*H value of 5·44 and they were composed as shown in Table 1.

Table 1. GRASSES WITH *p*H VALUES OF LESS THAN SIX

Genus	Species	No. of samples	*p*H range
Cenchrus	*C. ciliaris*	8	5·35–5·90
	C. setigerus	1	5·90
Pennisetum	*P. polystachyon*	1	4·75
	P. purpureum	1	5·70
	P. stramineum	1	5·15
Setaria	*S. sphacelata*	6	5·00–5·70
	S. splendida	2	4·75–5·00
	S. trinervia	1	5·45

It is apparent that *S. sphacelata* is not exceptional in its ability to produce low *p*H values in aqueous extracts, but it is remarkable that, of all the species examined, those which share this characteristic are confined to three closely related genera of the Paniceae.

Work is now in progress to see if the relationship between *p*H and ammonium accumulation as reported for *S. sphacelata* applies to these species.

Regeneration of Yeast Protoplasts prepared by Snail Enzyme

It has previously been shown[1,2] that yeast protoplasts prepared by autolysis of the cell wall may regenerate. The rate of regenerating protoplasts grown on the surface of solid media was very low (1–2 per cent). The cultivation of protoplasts embedded into high-percentage gelatine led to almost quantitative regeneration[3].

The regeneration ability of yeast protoplasts liberated by digestion of the cell wall with enzymes of the snail *Helix pomatia* has either not been demonstrated at all[4], or has been observed occasionally only[5,6]. We have been successful in achieving a high rate of regeneration of yeast protoplasts prepared by snail enzyme by embedding the protoplasts in nutrient media containing gelatine.

Cells of *Saccharomyces cerevisiae* Hansen, strain No. 7 (VULKP, Prague), were used. The protoplasts were prepared by the modified procedure of Eddy and Williamson[7]. Log phase cells were washed with distilled water and then incubated in the concentration of 10^7–10^8 with the following medium: citrate phosphate buffer (*p*H 5·4), 0·8 M mannitol and dried gut juice of *Helix pomatia* 10 mg/ml. After about 1 h of incubation at 28° C, 95–98 per cent of cells were converted into protoplasts. The enzyme was removed by washing the protoplasts with mineral nutrient medium. The protoplasts were then partly grown on the surface of agar films in moist microscopic chambers and partly embedded in mineral nutrient medium containing 30 per cent gelatine. The procedure of embedding has been described previously[3].

The character of growth of protoplasts prepared by snail enzyme on the surface of solid media was the same as that of those prepared by autolysis of the cell wall. Plasmatic formations that have already been described in both types of protoplasts arise[1,4]. The majority of these plasmatic formations died within 48 h and only a small proportion (about 1 per cent) regenerate into new yeast cells after 5 days of incubation. Both morphology and time lapse of regeneration is the same with protoplasts prepared by autolysis of the cell wall.

The protoplasts embedded into high percentage gelatine grow (their diameter increases 2–3 times), maintaining the spherical shape. After 10–14 h of incubation (at room temperature) the formations begin to bud on one or several sites simultaneously (Fig. 1). After 20–24 h, microcolonies of regenerated yeast cells can be found in the preparations. The rate of regenerating protoplasts may reach 80 per cent under optimal conditions. The morphology of the regeneration process of protoplasts prepared by snail enzyme is entirely the same as in that prepared by autolysis. The time lapse, however, or the appearance of morphological changes, respectively, is substantially shorter (by 10–15 h). This is based probably on the physiological state of protoplasts, as the preparation of protoplasts by autolysis uses the cells of stationary cultures.

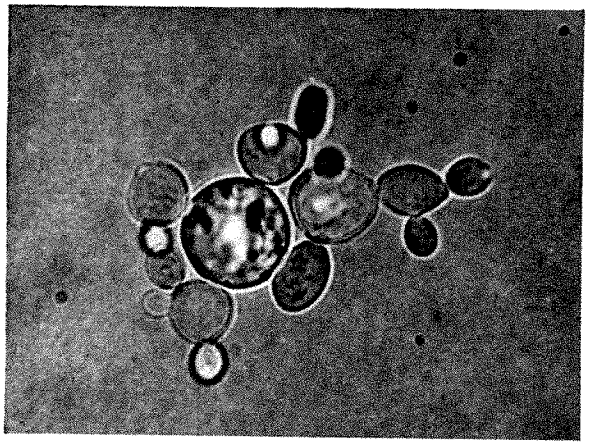

Fig. 1. Regenerating protoplast of *S. cerevisiae* after 24 h incubation in 30 per cent gelatine (× *c.* 1,133)

Formation of the cell wall also takes place in the same way in both the types of protoplasts. The fibrillar network representing the ground work of the new cell wall[8] is formed first and then the cement substances of the matrix. Just before the regeneration, the formation of a structurally and functionally complete cell wall is accomplished. The whole process of formation of the cell wall in protoplasts prepared by snail enzyme accordingly takes place faster.

In the course of further experiments, the protoplasts prepared by autolysis of the cell wall were treated with snail enzyme under the same conditions as the protoplasts prepared by snail enzyme. When embedding in gelatine medium, the regeneration rate as well as the morphology and time lapse of regeneration of these protoplasts was the same as those of controls.

The identity of protoplasts prepared by autolysis of the cell wall or by snail enzyme from the point of view of the regeneration ability has thus been confirmed. More detailed cytological aspects of the possible differences between these protoplasts prepared in different ways are under investigation at present.

An Arthropod Intermediate Host of a Pentastomid

The life cycles of pentastomids, or tongue worms, are little known although the biology of these creatures has been the subject of investigations since the pioneer studies of Rudolf Leuckart[1] in 1860. In the adult stage, pentastomids are almost exclusively parasites of reptiles, exceptions being species of *Linguatula* from carnivores and *Reighardia sternae* from gulls and terns. The immature stages of these parasites have hitherto been found only in vertebrate animals, ranging from fish to mammals. In every case in which life cycles have been either partially or totally elucidated the intermediate host has always proved to be a vertebrate. As Baer[2] says, "It is particularly interesting to record that no larval pentastomid has ever been found in an invertebrate and that, on the other hand, many species of warm-blooded animals can act as intermediate hosts of reptilian parasites". Our discovery recently of larval pentastomids in cockroaches in Singapore is therefore of unusual significance since it appears to be the first record of the finding of tongue worms in invertebrates.

During routine dissections of the American cockroach, *Periplaneta americana*, taken from a house in a well-to-do area of Singapore, a few cockroaches were discovered harbouring hundreds of pentastomid larvae. Subsequently, systematic examinations of *P. americana* from the same and from neighbouring localities revealed a high percentage of parasitized insects. 108 cockroaches were dissected and, of these, eleven contained larvae. Most of the infestations were light, numbering not more than twelve larvae per insect, but in the case of two cockroaches, infection was so heavy that the haemocoelic cavity gave the impression of being a writhing mass. In addition to

those captured in prosperous quarters of the city, cockroaches from poorer districts, including village (or kampong) areas, were also dissected and found to have pentastomid larvae.

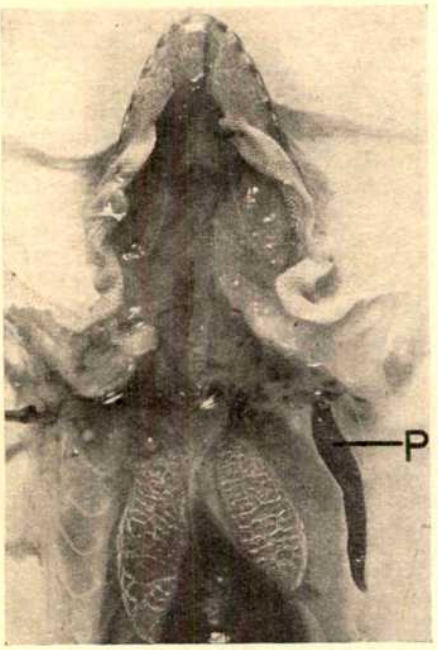
Since the definitive hosts of by far the great majority of pentastomids are to be found among reptiles, attention was focused on these animals in the search for the definitive host of the blattid pentastomid. Geckonid lizards occur commonly in houses in Singapore and we have found cockroach remains in their stomach contents.

100 geckoes taken in various parts of the city were examined and, of these, thirty-one were found infested with pentastomids. All the tongue worms we have collected so far from Singapore geckoes belong to a species of *Raillietiella*, tentatively identified as *R. hemidactyli* Hett 1934. *R. hemidactyli*, originally described from Burma, is widely distributed throughout South-east and Eastern Asia, where it occurs in various lizards[3–5]. It has also been recorded recently from Madagascar[6] and Puerto Rico[5].

We have found all stages of *R. hemidactyli* in the lungs of several species of geckoes, the lizards chiefly represented in our collections being *Hemidactylus frenatus* and *Platyurus platyurus*. The pentastomid material obtained ranges from advanced larvae (a little less than 1 mm in size) to adults (relatively large creatures measuring up to 100 mm and more), which may completely fill the lung cavity (see Fig. 1). Larvae are uncommon, most specimens being nymphs or adults.

Larval pentastomids, taken from the lungs of the geckonid *H. frenatus*, have been compared with those removed from the haemocoele of the cockroach, *P. americana*, and they are the same species (Fig. 2, *A* and *B*).

The life cycle of *R. hemidactyli* as we have deduced it from dissection and ecological data available is as follows: The adult female tongue worm in the lungs of the lizard liberates embryonated eggs into the trachea of the host. The eggs pass to the pharynx where they are swallowed and find their way to the exterior with the faeces of the gecko. Nymphal or adult cockroaches ingest the lizard faeces containing the pentastomid eggs. These hatch in the mid-gut of the insect. The hatched larvae penetrate the wall of the mid-gut and make their way into the haemocoele where they undergo further development. At least one moult to the second larval stage (?) takes place here.



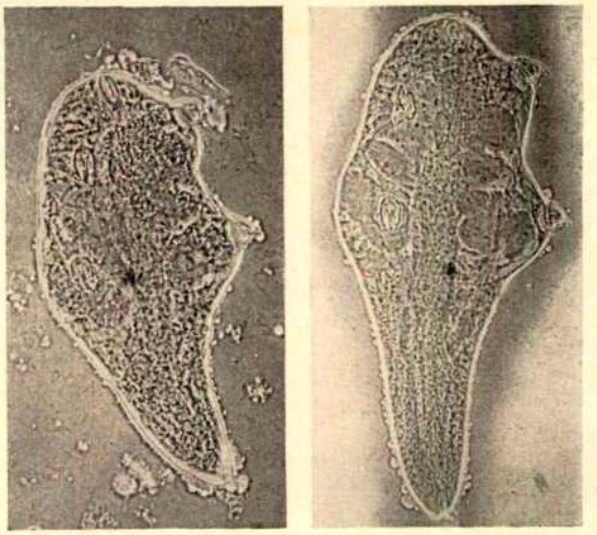


Fig. 1. Young adult female gecko (*Platyurus platyurus*) dissected so as to show the thoracic cavity. A tongue worm, *Raillietiella hemidactyli*, removed from the left lung of a lizard of about the same age is shown lying close to the left lung. The parasite (*P*), fixed in the extended state, measured 10·5 mm in length

A *B*

Fig. 2. Photomicrographs of unstained larvae of the tongue worm, *Raillietiella hemidactyli*. *A*, A larva, measuring 0·65 mm, removed from the haemocoele of the American cockroach, *Periplaneta americana*; and *B*, a larva, measuring 0·95 mm, obtained from the lung of a geckonid lizard, *Hemidactylus frenatus*

Infection of the definitive host takes place when the cockroach is eaten by a lizard. The larvae probably attach themselves to the mouth and the pharynx and migrate from there directly to the lungs. We believe that this is the route by which infection of the respiratory system takes place, since in numerous careful dissections we have never found pentastomids in the post-pharyngeal portion of the alimentary canal or neighbouring structures.

Our claim that the American cockroach, *Periplaneta americana*, is an intermediate host of *Raillietiella hemidactyli* of Singapore house geckoes is supported by experiments carried out in our laboratory. Mr. C. Rajamanickam has successfully infected cockroaches by allowing them to feed on lizard faeces containing pentastomid eggs. The repeated failure by previous workers to discover an intermediate host for certain pentastomids of insect-eating reptiles has led recent investigators to postulate that at least some species of tongue worms (including *Raillietiella* spp.) must have direct cycles[7]. The discovery of an invertebrate host for at least one species of *Raillietiella* now calls in question this postulate.

We thank Dr. Ralph Audy, director of the George Williams Hooper Foundation, for his encouragement and interest, and Mr. Yip Hoi Kee of the Department of Zoology for the photographs in Figs. 1 and 2. This work was supported by the U.S. Public Health Service.

Cytological Investigations on some Indian Diplopoda (Myriapoda)

THE class Myriapoda has received scant attention from cytologists, the order Diplopoda even less. Among the earlier contributions to this field of study, mention may be made of Oettinger[1], Sokoloff[2] and Bessiere[3]. Barring a recent contribution to the cytology of three South Indian species of Diplopoda by Natarajan[4], no attention has been devoted to chromosome studies in this group.

This note presents the chromosomal cytology of eight South Indian species of Diplopoda investigated for the first time; these were collected from different parts of the state of Mysore. The scheme of classification adopted here is based on the investigation of Attems[5].

Three species of the family Harpagophoridae (*Harpurostreptus* sp., *Ktenostreptus* sp. and *Thyropygus* sp.) reveal different diploid chromosome numbers of twelve, twenty and twenty-four respectively. The autosomal heteropycnosis in *Thyropygus* sp., regular 'Bouquet' formation in *Ktenostreptus* sp. in early meiotic prophase and tetraploidy in *Harpurostreptus* sp. are some of the significant observations made in the course of this investigation. *Chondromorpha mammifera* Attems is a member of the family Strongylosomidae. The diploid chromosome number is fourteen. Very extensive endopolyploidy has been observed in this form. *Strongylosoma* sp., a member of the same family, exhibits the diploid chromosome number of twenty-four.

The other three forms investigated are *Arthrosphaera zebraica* and two unidentified species of the genus *Arthrosphaera* belonging to the family Sphaerotheridae. They are commonly called pill-millipedes. They present the highest diploid chromosome numbers for the group: twenty-six, thirty and thirty respectively.

In addition to the variation in chromosome numbers, the cytology of diplopods offers many points of interest. In all the species studied all the chromosomes are acrocentrics. The sex-chromosome mechanism is of the *XY* type. The prereductional meiotic division and succession are a few of the characteristics of the sex-chromosomes. The occurrence of single chromatid bridges in the meiotic anaphase of one of these (*Arthrosphaera zebraica*) is a significant observation.

It is too early to evaluate the importance of cytological data based on the numerical relationships of the chromosomes of a few species, although it indicates the probable existence of a cytological basis for taxonomic purposes. It is hoped that the completion of the cytological analysis of large numbers of species will afford a clearer perspective of the evolutionary history and phylogeny of this ancient group.

I thank Dr. B. R. Seshachar of the University of Delhi for guidance, and Dr. D. MacFarlane of the Commonwealth Institute of Entomology and the British Museum (Natural History), London, and the Zoological Survey of India, Calcutta, for their kind attention in identifying the specimens used in the present investigation.

Ribonucleic Acid-storage Inclusions of Freshwater Sponge Archaeocytes

THE presence of RNA in the lenticular, metachromatic inclusions of freshwater sponge archaeocytes has been recently commented on by Ruthmann[1]. Typically, the RNA occurs in conjunction with a basic protein to form a combined structure of characteristic appearance (*RS* in Fig. 1).

In attempts to determine the ultrastructural organization of the RNA–protein complex, by means of RNase digestion techniques, Ruthmann was unable to determine conclusively whether the RNA was directly bound to fibrillar protein or was carried on ribosomes presumed present in the complex.

We have been examining the structure and functions of the archaeocyte inclusions of the Australian freshwater sponge, *Ephydatia multidentata*, with techniques very similar to Ruthmann's and, in general, have come to similar conclusions. However, we have also used an additional technique the results of which strongly suggest that a large proportion of RNA, if not all of it, is carried on ribosomes which are attached to the fibrillar protein of the inclusions. In this technique electron-microscope sections were prepared from archaeocyte inclusions fixed in veronal acetate buffered with 1 per cent osmium tetroxide (*p*H 7·3) for 2 h, followed by 1 per cent potassium permanganate solution for 30 min and treated with 2 per cent uranyl nitrate. Definite leaching out occurred in the ribonucleoprotein 'shell' material of the inclusions which assumed the appearance shown in Fig. 2, where the darker nucleoprotein region can be seen to be perforated with many small 'holes' the diameter of which is in the order of 40 mμ. Their arrangement is orderly and in some regions there is evidence of a lamination reminiscent of membranes or fibrils. Since potassium permanganate solutions are known to remove ribosomes from the endoplasmic reticulum, we consider that a similar event has occurred here, and the section may be interpreted to mean that the spaces and laminations have been caused to appear by the removal of ribosomes from the fibrillar protein matrix. Neither we, nor Ruthmann, have obtained so definite a picture with RNase-treated material, although a faint suggestion of it has sometimes been seen.

Ruthmann has also speculated on the source of deoxyribonucleotides for chromosomal replication during the initial phase of histogenesis. Many workers[3–6] have noted

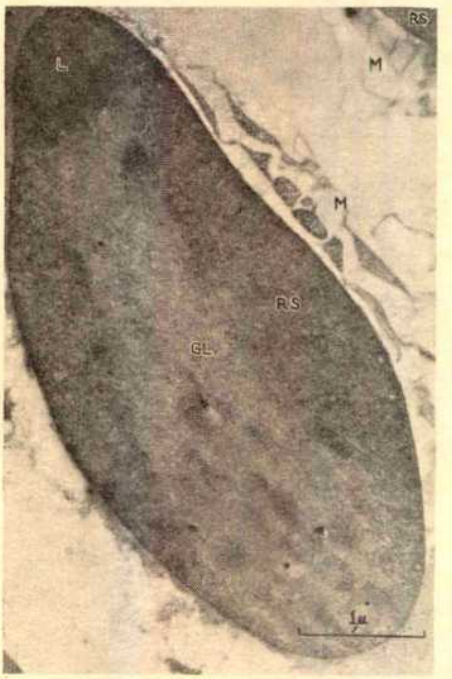

Fig. 1. Electron micrograph of an archaeocyte lenticular granule within the gemmule. Veronal acetate buffered 1 per cent osmium tetroxide, 2 h. 0·1 per cent uranyl acetate in absolute methanol, 1 h; *in toto*. *RS*, Ribonucleoprotein 'shell' material; *GL*, inner region of the granule composed mainly of acidophilic proteins and glycoprotein; *M*, phospholipid membrane surrounding granule; *L*, lipid droplet

the binucleate condition of the archaeocytes both within the gemmule and just prior to its formation. We have also noticed this in our material and agree that some early differentiation within the gemmule may be explained by a division of these binucleate cells without recourse to deoxyribonucleotide stores. Ruthmann considers, however, that it is very unlikely that morphogenesis begins with only twice the number of cells present in the gemmule since he observed mitosis within the gemmule. He therefore postulated that the deoxynucleotide precursors must have been present within the completely closed gemmule system. He considered the precursors could exist in the form of soluble mono- and di-nucleotides which had escaped detection by the histochemical tests used, or perhaps as cytoplasmic DNA, although he could provide no evidence for this.

We have repeatedly been impressed by peculiarities observed in Feulgen-treated archaeocytes taken from gemmulating *Ephydatia multidentata*. In many of these cells the DNA was all within the nucleus, showing up as numerous large granules. In many other archaeocytes, however, additional Feulgen-positive granules of a similar size were found outside the nucleus. In some cases there were no extra-nuclear granules, but the cytoplasm had localized areas which were tinged red and which could be explained by assuming the presence of small particles of DNA, the particle size being below the resolving power of the microscope. It is possible that these observations are of stages in which DNA becomes available in the cytoplasm and is broken down into sub-microscopic units and then into the soluble mono- and di-nucleotides as suggested by Ruthmann.

We should also like to draw attention to another possible source of nuclear material which can be seen in some archaeocyte inclusions. Fig. 2 was chosen because it includes, not only the evidence for the presence of ribosomes already discussed, but also a comparatively large electron-dense body the function of which is problematical. It has a double membrane and resembles a minute nucleus, but it is not Feulgen-positive nor is its appearance changed when digested with DNase or RNase. It is possible, however, that the interior substance may be deoxyribonucleotides.

Another suggestion introduced by Ruthmann is that these particular organisms possess enzymes capable of converting RNA to DNA. Although this hypothesis was initially suggested by Brachet[7,8], biochemical evidence

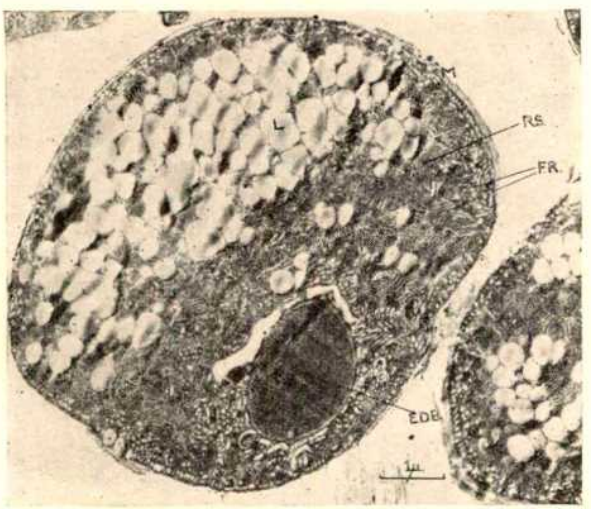

Fig. 2. Electron micrograph of an archaeocyte lenticular granule within the gemmule. Fig. 3. Electron micrograph of an archaeocyte lenticular granule within the gemmule. Revised Gomori acid phosphatase method. Veronal acetate buffered 1 per cent osmium tetroxide (*p*H 7·3), 2h; *in toto*. *L.S.*, Lead sulphide deposit indicating the site of acid phosphatase activity; *R.S.*, ribonucleoprotein 'shell' material; *S.*, space or lacuna

has not been forthcoming to support it. However, we have found that in our material acid phosphatase, at least, is present in these inclusions. This was established by performing a revised Gomori acid phosphatase test coupled with fixation in veronal acetate buffered 1 per cent osmium tetroxide for electron microscope analysis. The acid phosphatase was observed (Fig. 3) to be deposited as black lead sulphide, precipitated in such a way as to have shrunken away from the rest of the tissue. These deposits therefore seem to be surrounded by clear spaces or lacunae and in some cases have been removed by sectioning.

The acid phosphatase is localized within the lipid inclusions of the granule and it would seem, therefore, that the enzyme hydrolyses the phospholipid which is present, but this does not rule out the possibility that it may be involved with degradation of nucleic acids of the granule, perhaps in a way similar to that described by Schmidt and Laskowski[9] for acid phosphomonoesterase. Although no definite evidence for these more specific acid phosphatases was obtained, we have definitely established that these granules do incorporate at least one enzyme species.

Analysis of Reptilian Cortical Structure

THE evolution and organization of the reptilian cortical structures have long been a major problem to comparative neuroanatomists. Three major cortical layers are recognized[1]. In reptiles, these three regions (Fig. 1*A*) occupy the roof of the telencephalon and form distinct cellular masses which are named as follows in dorsomedial to dorsolateral succession: hippocampus (archipallium),

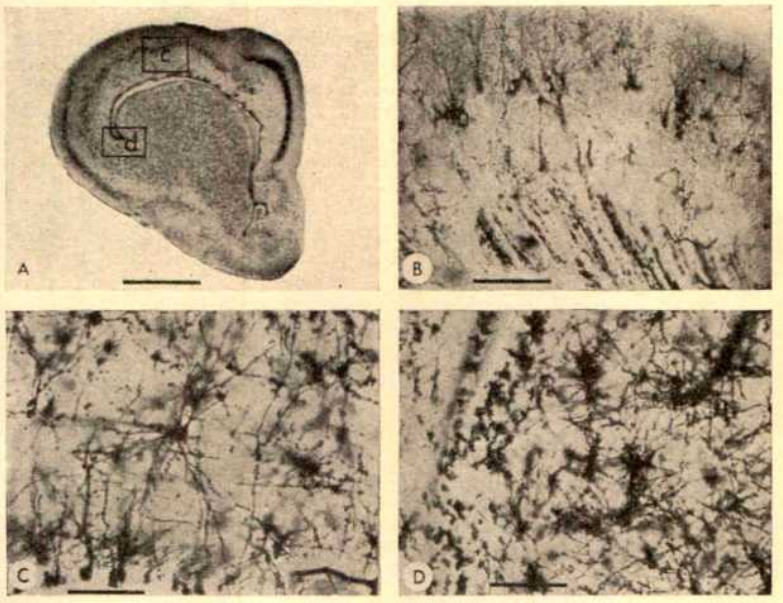

Fig. 1. Forebrain sections of *Iguana iguana*. *A*, Transverse section through the hemisphere showing nuclei and position of Figs. *C* and *D*. *B*, Golgi-Cox sagittal section through hemisphere showing dorsomedial cortex and alveus. *C*, Golgi-Cox transverse section through hemisphere showing projection neurones of dorsomedial cortex. *D*, Golgi-Cox transverse section through hemisphere showing association neurones of dorsolateral cortex. Bar scales indicate the following lengths: *A*, 17 mm; *B*, 250μ; *C*, 125μ; *D*, 166μ

general cortex (neopallium), and pyriform cortex (palaeopallium). In addition, a sub-pallial mass, the 'primordial general cortex'[2], is of pallial origin[3].

Recent electrophysiological work by Kruger and Berkowitz[4] confirms the basic organization of the pyriform and hippocampal cortices as proposed by earlier workers and suggests that these areas are true homologues of similarly named regions in the mammalian telencephalon. However, the data obtained by these workers suggest that the organization of the reptilian general cortex may not be along the lines of the mammalian neocortex.

With these facts in mind, I analysed the cortical areas of two *Alligator mississippiensis* and six *Iguana iguana* by use of the Golgi–Cox method. All animals were juveniles. The results of the analysis support Kruger and Berkowitz's statement with some modifications.

Crosby[2] in her analysis of the cortex of the alligator suggests that the axons of the large pyramidal cells of the general cortex pass ventrally into the alveus where they synapse with projection neurones of the primordial general cortex and neostriatum (dorso-lateral area of Crosby). Such a series of connexions would confirm homology with the extrapyramidal motor system in mammals and would suggest a basic organization similar to the mammalian condition. If such is the case, then the cells of this region should be of the pyramidal projection type with long axons visible extending into the underlying palaeostriatum.

The primordial general cortex in the alligator is not well developed and consists only of a slight infolding of the cortex in the rostral region of the telencephalon. The cell types of the general cortex are definitely projection cells and their axons do pass into the alveus. However, the neurones of the primordial general cortex appear to be intermediate between projection and associative neurones. No clear evidence can be obtained as to the projection of axons into the primordial general cortex. Resolution of this problem will require the use of experimental degenerative methods.

The cortex of the green iguana is more highly differentiated and offers a clearer solution to the problem. The general cortex is not continuous with the hippocampus or pyriform cortex as in the alligator. The primordial general cortex is highly developed and is located along the rostral one-third of the telencephalon. The general cortex (dorsomedial cortex) consists of large double pyramid neurones which receive their input along a highly branched dendritic tree oriented towards the superficial surface of the cortex. The axons of these cells pass into a deep alveus Fig. 1*C*).

Then neurones of the primordial general cortex (dorsolateral cortex) are not of the double pyramid type but are typical short-axon associative cells (Fig. 1*D*). Furthermore, the alveus does not extend ventrally into this region. The alvear axons pass toward the medial wall of the hemisphere, where they form the fornix complex and then fuse with the medial forebrain bundle (Fig. 1*B*).

It appears that the organization of the 'general cortex' in reptiles is fundamentally different from that of mammals. There are no direct thalamo-cortical afferent pathways to the 'general cortex'. The only observed connexions of the dorsal thalamus with the telencephalon appear to be thalamo-palaeostriatal fibres of the lateral forebrain bundle[4,5]. If the dorsolateral cortex (primordial general cortex) of the green iguana does not contain efferent cortical fibres, then it may be hypothesized on the basis of cell type that this region serves as an association area between the dorsomedial cortex and the striatal regions (Fig. 2). This is further substantiated since this is the only region of the lateral surface of the hemisphere where such connexions could be made with the dorsomedial cortex. Afferent connexions could occur via the medial forebrain bundle and alveus, but it appears that this system is primarily efferent in the region of the dorsomedial cortex.

The efferent pathway of the dorsomedial cortex does not pass into the striatal mass as in mammals but passes via the alveus to the medial forebrain bundle (Fig. 2). Analysis of these characters leaves little basis for homologizing the dorsomedial cortex of reptiles with the mammalian neocortex. Instead, this cell layer should be considered a part of the hippocampus or more likely

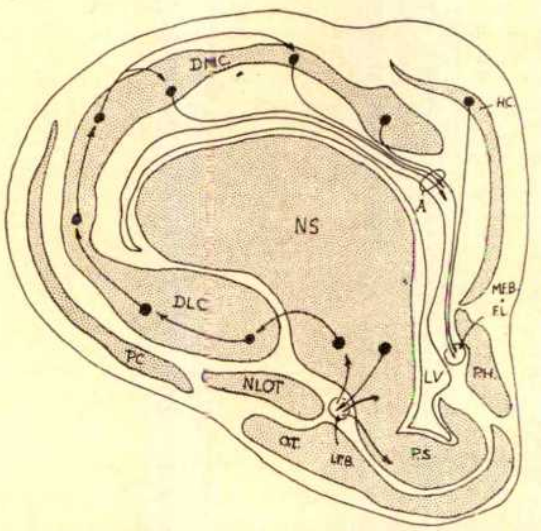

Fig. 2. Diagram of a transverse section through the hemisphere of *Iguana iguana*, at the level of the dorsolateral cortical infolding, showing major connexions. *A*, Alveus; *DLC*, dorsolateral cortex; *DMC*, dorsomedial cortex; *HC*, hippocampal cortex; *LFB*, lateral forebrain bundle; *LV*, lateral ventricle; *MFB+FL*, medial forebrain bundle and fornix longus; *NLOT*, nucleus of lateral olfactory tract; *NS*, neostriatum; *OT*, olfactory tubercle; *PC*, pyriform cortex; *PH*, primordial hippocampus; *PS*, palaeostriatum

transitional cortex (mesopallium) homologous with the subiculum or other similar mammalian cortical structures. Such a proposal was considered by Rose[6]. While the present analysis does not confirm the detailed description of Rose's work, the basic concept appears sound. This arrangement could account for the transition of evoked potentials on the dorsomedial surface of the hemisphere[4] and still satisfy the observed anatomical evidence for an efferent pathway via the alveus and medial forebrain bundle.

It seems that the dorsal cortex or pallium in tetrapods has evolved along two separate lines. Early in its evolutionary history, probably at the amphibian or very early reptilian level, selective forces of very different types acted on the primitive dorsal pallium to produce the mammalian neocortex and also quite independently the reptilian structures. The dorsomedial and dorsolateral cortices of the reptile may be considered homologous to the dorsal pallium in amphibians in the same manner that the mesopallium and neopallium of mammals are homologous to the amphibian dorsal pallium. The organization of the amphibian telencephalon would allow such an interpretation. The dorsal pallium is in contact with association fibres from both the hippocampus and striatum[7]. Based on anatomical organization, it should be possible to divide even this primitive dorsal pallium into presumptive evolutionary regions. A lateral component in theropsids would be free to expand into neocortex under striatal control with the increase in somatic input as would occur with increased complexity of locomotion. An increase in complexity is an acceptable corollary of the modifications occurring in the other body systems during the amphibian–reptilian transition of the theropsid line of evolution.

The sauropsid evolutionary line which gave rise to modern reptiles and birds did not evolve a neocortex. The amphibian lateral pallial component in these forms appears to have migrated towards the striatum. The dorsolateral cortical component in modern reptiles appears to be shifting ventrally and may mimic a stage in avian evolution in which the same homologous region fused to form, in part, the massive avian striatum.

A medial component already associated in amphibians with the hippocampus might continue its evolution in this direction in reptiles and mammals. A continued evolution would give rise to transitional cortical structures (mesopallium) important in functions involving both olfactory and somatic sensory integration. It now seems that modern reptiles and mammals share this trend.

I thank Drs. J. E. Heath and H. M. Smith for advice. The drawings were compiled by Mr. R. P. Barber.

The work was supported in part by N.S.F. summer fellowship, 1964, at the University of Illinois.

Evaluation of Nitrogen Fixation in Legumes by the Regression of Total Plant Nitrogen with Nodule Weight

THE relation of nitrogen fixation to nodulation is not yet well understood. Nodule position, nodule size, haemogoblin content and longevity of nodule tissues have been taken into consideration[1,2]. Chen and Thornton[3] showed, from considerations of the structure of effective and ineffective nodules of clover, pea and soybean, that differences in efficiency of nitrogen fixation were due to the volume of active bacterial tissue. Bowen[4] found a highly significant regression of dry weight of plants with nodule weight in *Centrosema pubescens*, inoculated with seventeen different *Rhizobium* strains. He suggested that *Rhizobium* strains have the same nitrogen fixing ability weight for weight of nodule tissue, and that differences in effectiveness resulted from the different amounts of nodule tissue formed.

In a number of greenhouse and field experiments, we found linear regressions of the logarithm of total plant nitrogen with nodule weight. The regressions have been a valuable tool in the investigation of nitrogen fixation under most conditions. Fig. 1 presents a typical example of such a regression.

In this experiment, in all treatments, total plant nitrogen was dependent on the amount of nodule tissue formed, its logarithm increasing linearly with the nodule weight. Following the equation for the linear regression $Y = a + b\,X$ we can calculate the amount of nitrogen fixed and that absorbed from seeds and soil. Y represents the logarithm of total plant nitrogen and X the corresponding nodule weight on each point of the regression line. a represents the point on the Y-axis where no nodules were formed, that is the logarithm of nitrogen absorbed from seeds and soil. Thus, logarithm of nitrogen fixed, $NF = Y - a$ and $Y = NF + a$. Substituting in the regression equation:

$$Y = a + b\,X$$
$$NF + a = a + b\,X$$
$$NF = b\,X$$

Thus, under the conditions of such an experiment, where nitrogen is the limiting factor of plant growth, the amount of nitrogen fixed can be calculated. It is dependent on the nodule weight and on the slope b of the regression of total plant nitrogen with nodule weight. Environmental effects which act on nodule number or size will increase the nodule weight but will not change the slope. It becomes possible to distinguish effects on nitrogen fixing efficiency, that is on the amount of nitrogen fixed per unit nodule tissue, because these effects will change the slope. Addition of nitrogen to the soil will increase the Y – intercept a and the amount of nitrogen actually absorbed from seeds and soil can be calculated as well.

These observations have been confirmed in a number of experiments. In a greenhouse experiment with soy-

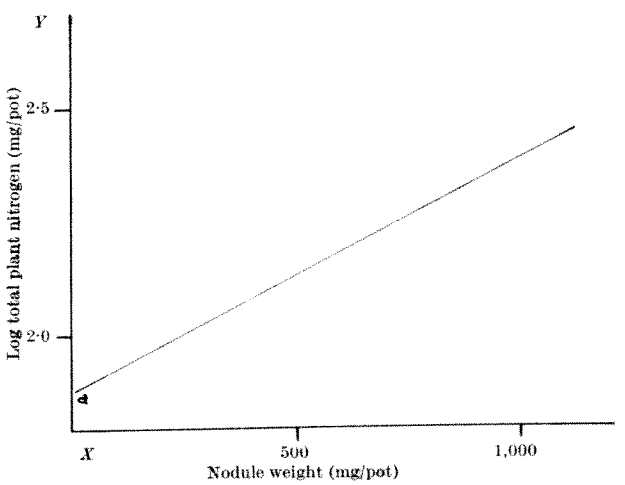

Fig. 1. Nitrogen fixation of soybeans. The greenhouse experiment included two *Rhizobium* strains, two soybean varieties and three lime treatments. It was conducted in a very poor, acid soil mixed with 1 per cent of rice straw and fertilized with *PK* and minor elements. a, log nitrogen absorbed from seeds and soil; b, regression coefficient, significant at $P = 0{\cdot}01$; NF, log nitrogen fixed. $a = 1{\cdot}88$; $b = 0{\cdot}000503$; $NF = 0{\cdot}000503X$

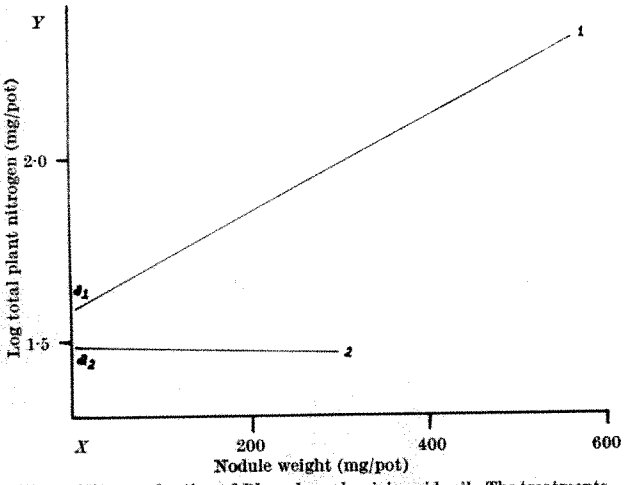

Fig. 2. Nitrogen fixation of *Phaseolus vulgaris* in acid soil. The treatments of the greenhouse experiment included six *Rhizobium* strains and three lime treatments. Line 1, five more or less effective *Rhizobium* strains; line 2, one ineffective *Rhizobium* strain; *a*, log nitrogen absorbed from soil and seeds; *b*, regression coefficient, significant at $P = 0{\cdot}01$; *NF*, log nitrogen fixed. $a_1 = 1{\cdot}58$; $b_1 = 0{\cdot}001331$; $NF_1 = 0{\cdot}001331X$; $a_2 = 1{\cdot}48$; $b_2 = 0{\cdot}000085$; $NF_2 = 0{\cdot}000085X$

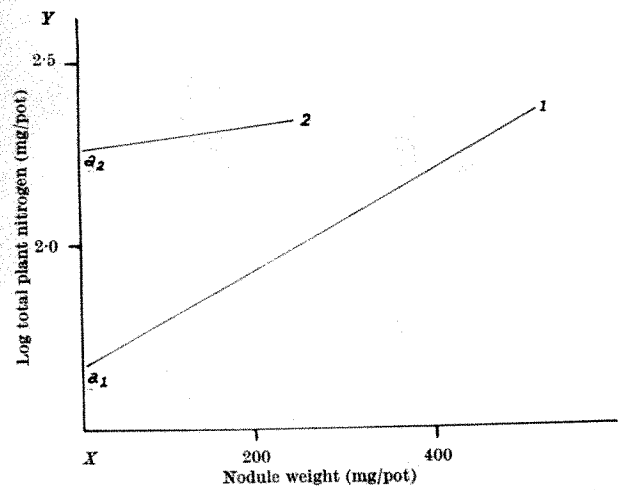

Fig. 3. Nitrogen fixation of *Phaseolus vulgaris*. The treatments of the greenhouse experiment included three fertilizers (*O*, *PK* or *NPK*) and four *p*H levels obtained by diluting an acid soil with sand. All pots were uniformly inoculated. Line 1, no mineral nitrogen added; line 2, 100 p.p.m. of nitrogen added; *a*, log nitrogen absorbed from seeds and soil; *b*, regression coefficient, significant at $P = 0{\cdot}01$; *NF*, log nitrogen fixed. $a_1 = 1{\cdot}66$; $b_1 = 0{\cdot}001386$; $NF_1 = 0{\cdot}001386X$; $a_2 = 2{\cdot}27$; $b_2 = 0{\cdot}000377$; $NF_2 = 0{\cdot}000377X$

beans, similar to that shown in Fig. 1, practically the same regression coefficient was obtained ($b = 0{\cdot}000501$ significant at $P = 0{\cdot}01$). Two field experiments with thirty soybean varieties showed similar regressions ($b = 0{\cdot}000678$, significant at $P = 0{\cdot}05$; and $b = 0{\cdot}000684$, significant at $P = 0{\cdot}01$ respectively).

In three greenhouse experiments with beans (*Phaseolus vulgaris*) it was shown that bean nodules, under similar conditions, were 2–3 times more efficient than soybean nodules, the regression coefficients being 0·001331, significant at $P = 0{\cdot}01$, 0·001386, significant at 0·01, and 0·001383, significant at $P = 0{\cdot}01$ respectively. The regressions of two of these experiments are shown in Figs. 2 and 3.

The results of the experiment presented in Fig. 2 were divided into two groups. One included five more or less effective *Rhizobium* strains at three lime treatments and the other included one ineffective strain at three lime treatments. The first group is presented in regression line 1, the second in line 2. As expected, the amount of nitrogen absorbed from seeds and soil (*a*) was similar in both groups. In group 1 the nitrogen fixation increased accordingly to the increase in nodule weight caused by the different *Rhizobium* strains or by the lime treatments. The increase in nodule weight of the plants inoculated with the completely ineffective strain did not bring about any nitrogen fixation.

The results of the experiment presented in Fig. 3 also form two distinct regressions. Here the data from the pots with mineral nitrogen form a different line. As expected, the amount of nitrogen absorbed from seeds and soil (*a*) is higher. It is almost as high as the amount needed for maximal plant growth under the given conditions, and the regression coefficient is not significant. The addition of 100 p.p.m. of nitrogen as ammonium nitrate almost paralysed nitrogen fixation, even in the presence of nodules. The regression of the data from the pots without mineral nitrogen was practically identical with that obtained in the previous experiment (Fig. 2).

Fig. 4 shows the results of a greenhouse experiment with *Centrosema pubescens*. Nodules of this plant were, under the given conditions, still more efficient than bean nodules. In this experiment the added nitrogen (50 p.p.m. nitrogen) was not enough for maximal plant growth and there was some nitrogen fixation even in these pots. The nitrogen-fixing efficiency of these nodules, however, was lower than that in the pots without mineral nitrogen and the slopes of the two regressions were significantly different.

Details of the experiments mentioned in this paper have been published elsewhere[5–7]. The treatments included the use of different *Rhizobium* strains, and different plant varieties, lime-pelleted seeds, lime and fertilizer treatments, *p*H levels and two soil temperatures. Most of these treatments increased nitrogen fixation, but few of them affected the regression coefficient (*b*) of total plant nitrogen with nodule weight. *b* is, therefore, an index of nitrogen-fixing efficiency which seems to be surprisingly constant for each plant species and appears to be independent of most environmental effects, *Rhizobium* strains and plant varieties. This confirms Bowen's[4] suggestion that differences in the nitrogen fixation of *Rhizobium* strains are generally due to differences in the numbers or sizes of the nodules produced. The fact that none of the different calcium treatments affected efficiency in nitrogen fixation per unit nodule tissue supports Andrew and Norris's[8] suggestion that calcium is essential for the meristematic activity of nodules.

The calculation of nitrogen fixation and of the amount of nitrogen absorbed from seeds and soil as well as the

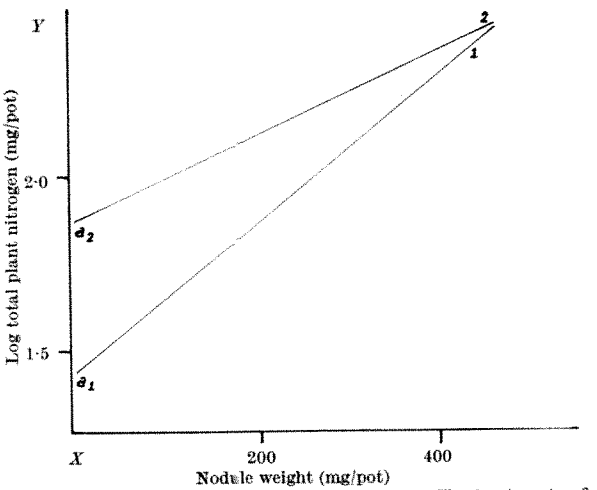

Fig. 4. Nitrogen fixation of *Centrosema pubescens*. The treatments of the greenhouse experiment included two soil temperatures, three lime treatments and two nitrogen levels (0 and 50 p.p.m.). There was one check treatment without inoculation for each nitrogen level, all other pots were uniformly inoculated. Line 1, no mineral nitrogen added; line 2, 50 p.p.m. of nitrogen added; *a*, log nitrogen absorbed from seeds and soil; *b*, regression coefficient, b_1 and b_2 significant at $P = 0{\cdot}01$, difference between b_1 and b_2 significant at $P = 0{\cdot}05$; *NF*, log nitrogen fixed. $a_1 = 1{\cdot}45$; $b_1 = 0{\cdot}00202$; $NF_1 = 0{\cdot}00202X$; $a_2 = 1{\cdot}87$; $b_2 = 0{\cdot}00110$; $NF_2 = 0{\cdot}00110X$

possibility of distinguishing efficiency of nitrogen fixation per unit nodule tissue might become of considerable help for nutrition studies in legumes, under field and greenhouse conditions. Complete results will be published elsewhere.

Anisopus Larvae (Diptera) in Cases of Intestinal and Urino-genital Myiasis

ZUMPT[1] in his comprehensive work on myiasis in the Old World includes *Anisopus* (Anisopodidae) under intestinal myiasis. James[2], writing on myiasis from the New World, also includes *Anisopus* (as *Sylvicola*) in the same category. Smart[3] states that there are records of *Anisopus* larvae in cases of intestinal and urino-genital myiasis. Many of the early text-books of medical entomology do not include the genus.

There appears to be only one published record of intestinal myiasis involving larvae of *Anisopus fenestralis* (Scop.): this is the one reported by Shrewsbury[4]. In this case a 3-year-old girl, after an attack of vomiting, developed a mild enteritis which lasted for some 2 weeks. On two separate occasions a single larva was found in her motions and in the third week of her illness two more larvae were found in her chamber-pot immediately after urination. There was no urethral or vaginal irritation in this case, as would be expected if larvae had been present in the urino-genital system, and it is therefore assumed that the larvae were passed *per anum*. There appear to be no published records of urino-genital myiasis involving *Anisopus*, and Dr. Smart informs us that his statement was based on an unpublished case which he dealt with when on the staff of the British Museum (Natural History).

We can now record a case of urino-genital myiasis involving larvae of *Anisopus fenestralis* brought to us by Dr. H. H. Johnston, of the Public Health Laboratory, Oxford, in 1962.

The patient was a pregnant woman, of reasonable intelligence. Larvae had been passed in the urine for up to a month when she directed her private doctor's attention to them. He then sent a urine sample to the Public Health Laboratory for investigation. The sample, which was brown in colour, contained about half a dozen larvae one of which was sent to the Hope Department of Entomology, Oxford, for identification. This larva was determined by us as *Anisopus fenestralis* in the second instar (10 mm long).

Of the seventy or so species of Anisopodidae (=Rhyphidae) known, only *Anisopus fenestralis* has been accused of causing myiasis. Keilin and Tate[5] give a detailed description and figures of the third instar larva, which is 12–14 mm long. It may be that records of *Anisopus* have been overlooked, and for convenience the larva of *A. fenestralis* is illustrated here. The most important diagnostic character of *Anisopus* is a shield-like thickening, lined by very large hypodermal cells, which surrounds the anus, the shape of this structure varying with the species.

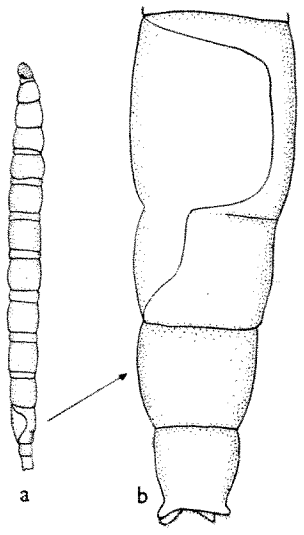

Fig. 1. *a*, Third instar larva of *Anisopus fenestralis* (L.); *b*, same showing enlarged view of anal 'shield'

Shrewsbury[4] suggested that with the intestinal myiasis case, the patient had swallowed eggs which hatched in the intestine. Zumpt[1], after considering the possibility that the larvae were already in an advanced stage when swallowed or that eggs were deposited near the anus, favours Shrewsbury's view because of the small number of larvae recovered. Smart[3] suggests that in these cases eggs may be laid directly in the pubic region.

The larvae of *Anisopus* have been recorded from various habitats such as slime flux exuding from tree wounds, decaying leaves in tree rot-holes, decaying roots of angelica and burdock, honeycombs, rotting potatoes, mouldy decaying cardboard and sewage filter beds. Edwards[6] records a remarkable case of *Anisopus* breeding in liver that had been in formalin for 7 years. The eggs are enclosed in a large gelatinous mass when laid and a gravid female will probably oviposit on any suitable moist surface. It is therefore probable that infection of the urino-genital tract by larvae of *Anisopus* is purely fortuitous.

Lichens with Bitunicate Asci

THE division of the class Ascomycetes into the two sub-classes Ascomycetes and Loculoascomycetes in accordance with the ideas of Nannfeldt[1] is now generally accepted. Characteristic of the sub-class Ascomycetes are the unitunicate ascus and true paraphyses, of the sub-class Loculoascomycetes the bitunicate ascus and paraphysoid filaments. Two British species belonging to genera the ascocarps of which were of unknown type are now found to belong to the Loculoascomycetes. They are *Pyrenula nitida* (Weig.) Ach. and *Anthracothecium pyrenuloides* (Mont.) Müll. Arg. These two species, typical of

their genera, are notable for their brown thick-walled spores and are highly characteristic members of the Pyrenulaceae, a family which apart from these and closely related genera has been somewhat variously constituted by Zahlbruckner[2], Watson[3], and Hale[4].

Observation of the branched and occasionally anastomotic structure of the paraphysoid filaments of *P. nitida* and *A. pyrenuloides* suggested that their asci might be bitunicate, but examination of dried herbarium specimens by the method of Richardson and Morgan-Jones[5] produced negative or, in one case, equivocal results. The reason for this is that in some genera, notably those with more or less cylindrical rather than ovate or saccate asci, proliferation of the asci can be induced only in fresh material. This is worth emphasizing because no difficulty is experienced with dried specimens in most genera, especially *Arthopyrenia* and those morphologically close to it such as *Dermatina*, *Mycoporellum* and *Microthelia*.

A visit to Ireland in August 1965 was therefore made the occasion to collect young fresh specimens of *P. nitida* and *A. pyrenuloides*. The former is abundant everywhere and was obtained from West Cork (*V.C. H3*), Glengarriff, altitude *c.* 100 ft., on smooth bark of *Sorbus aucuparia* (rowan). Material of the latter was collected from North Kerry (*V.C. H2*), Torc Mountain, altitude *c.* 500 ft., on smooth bark of *Corylus avellana* (hazel). This region in the neighbourhood of Killarney is the only locality for *A. pyrenuloides* in Europe. The specimens were kept for 8 days in the humid, but not wet, environment of a plastic bag open at one end. Before they were examined, a few drops of water were added to the bag and its mouth was closed for 48 h. The result was to provide specimens with a few undoubtedly proliferated asci (see Fig. 1). In both species caps consisting of the upper part of the outer tunic of the ascus were formed. Hodgetts[6], Cain[7], and Butler[8] considered that these may be an abnormality produced in water mounts. The results obtained by Richardson and Morgan-Jones[5], who refer to this opinion, appear to confirm my own conclusion drawn from the study of asci in a variety of genera that, though the cap may be an abnormality, it is especially characteristic of plants with more or less cylindrical asci. The genus *Microglaena* as reconstituted by Morgan-Jones and Swinscow[9] is also notable for its cylindrical asci and the formation of caps.

The finding that *Pyrenula nitida* and *Anthracothecium pyrenuloides* have pseudothecia rather than true perithecia for ascocarps means that they must be placed in the Loculoascomycetes. Moreover, the family Pyrenulaceae, of which these genera are characteristic members, needs to be revised to exclude from it genera with unitunicate asci.

Electron Microscope Observations of Pancreatic Islet Cells of the Early Chick Embryo

VILLAMIL[1] reported that the islet cells in chick embryo pancreas are formed from the primitive pancreatic cells at the eighth day of incubation. He observed these cells through a light microscope.

I have used an electron microscope to observe the fine structure of islet cells in the chick embryo. The pancreas was removed from the embryo at the eighth day of incubation, cut into small pieces, fixed in phosphate-buffered 1 per cent osmic acid solution for 1 h, embedded in 'epoxy' resin[2] and sectioned with a Porter–Blum ultramicrotome. Ultra-thin sections were stained with lead citrate[3] and observed using an *HU* 11*A* electron microscope.

The pancreas from a chick embryo at the eighth day of incubation is composed of a mass of parenchymal cells, some of which form an incomplete acinus and a few acinar lumens dilate into an irregular shape[4]. Among these parenchymal cells, well-differentiated α- (Fig. 1) and β-cells (Fig. 2) can be discerned. In the cytoplasm of islet cell, the rough-surfaced endoplasmic reticulum and Golgi apparatus are not so well developed, but the Golgi apparatus obviously plays a part in synthesizing

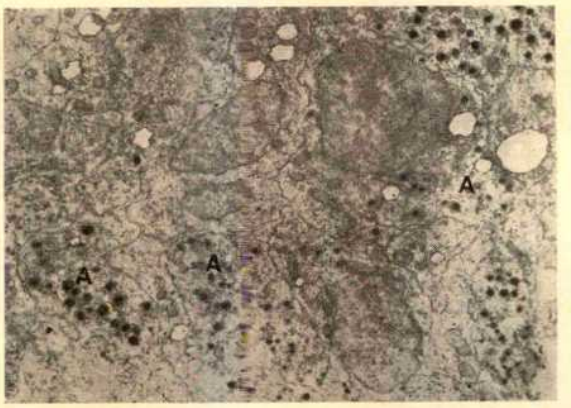

Fig. 1. Electron micrograph of chick embryo pancreas at the eighth day of incubation. Well-differentiated α-cells (*A*) can be seen among the mass of parenchymal cells. They are distinguished by a mass of spherical dense secretory granules in the cytoplasm. (× 3,100)

the secretory granules (Fig. 3). Abundant ribosomes and a few thin mitochondria are preserved in the cytoplasmic matrix. α-Cells contain many spherical dense granules enveloped in a limiting membrane, and these granules are 50–500 mμ in diameter; however, they vary considerably in density. Between the granule and the limiting membrane there is often a clear space resembling a hood. β-Cells have dense crystals enveloped in a membrane. These crystals are mostly needle-shaped or rectangular and are frequently gathered into a sheaf-like form. Therefore, depending on the direction of sectioning, the granules of β-cells have varied outlines. β-Granules are less dense than α-granules. The α- and β-granules are thought to be identical with those of chicken previously reported[5–7]. At the eighth day of incubation only a narrow intercellular space is observed between the islet cells and the undifferentiated parenchymal cells or primitive exocrine cells. Between the islet cells and the endothelial cells the basement membrane, exhibiting a low density, and connective tissue are sometimes observed.

The active secretion of hormone in the islet cells of the chick embryo is supposed to begin after the eleventh day of incubation[8–11]. Some granules appear in islet cells, however, close to the cytoplasmic membrane at the eighth day of incubation. Fig. 4 reveals two α-granules secreted into the intercellular space. This suggests that secretory granules can be passed out through any part of cytoplasmic membrane to the extracellular space even at the eighth day of incubation: the process responsible for this action is termed emiocytosis and is similar to that exhibited by merocrine glands[5,7,12–17].

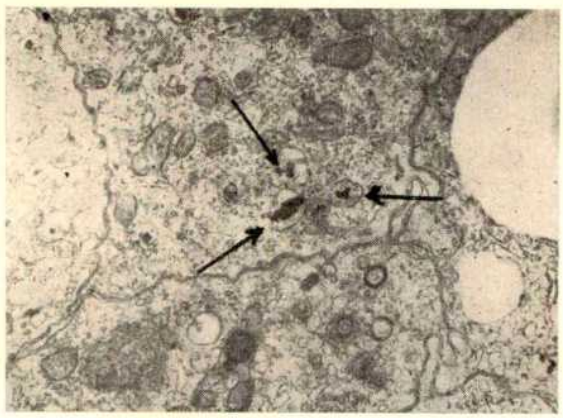

Fig. 2. Electron micrograph of chick embryo pancreas at the eighth day of incubation. In the cytoplasm of β-cell, crystal-like secretory granules can be seen with a limiting membrane (arrows). (× 9,300)

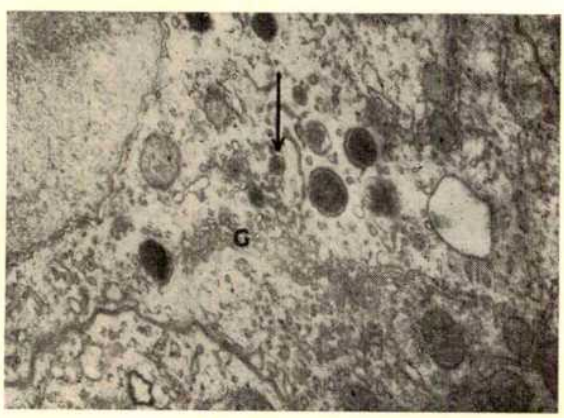

Fig. 3. Electron micrograph of chick embryo pancreas at the eighth day of incubation. The Golgi apparatus (*G*), which is composed of vesicles and small tubules, is forming α-granules (arrow). (× 15,000)

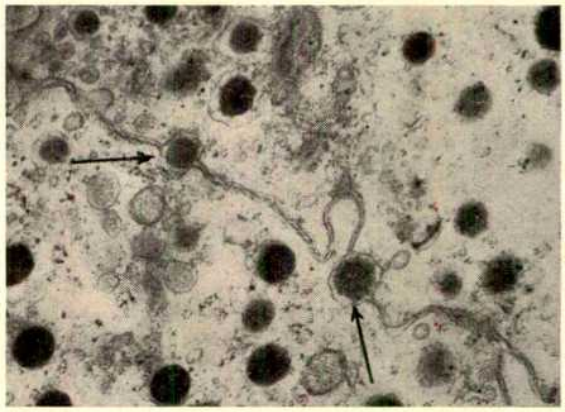

Fig. 4. Electron micrograph of chick embryo pancreas at the eighth day of incubation. Two α-granules in the intercellular space (arrows) may have been secreted from the α-cells by emiocytosis or merocrine type of secretion. (× 37,000)

Glycogen deposits have been observed in the liver of chick embryo between the seventh and the ninth days of incubation[18]. The finding at the eighth day of incubation that secretion occurs from the islet cells, and the presence of glycogen deposits in the liver, suggest that the two phenomena are related[1].

PHYSIOLOGY

Measurement of 'Core' Temperature in the Rat

IN investigations involving changes in body temperature in the rat[1–3] we have noted discrepancies, in the control levels and changes in response to given doses of drugs such as morphine, chlorpromazine and reserpine, between our own data and those quoted for comparable situations in the literature. Although a wide variety of techniques for measuring body temperature have been used, the most commonly used method in the conscious animal is the intermittent or chronic insertion of a thermosensitive device into the rectum. Few authors state the distance to which the thermometer is inserted but, where the measurement is given, it is generally, in the rat, of the order of 3·0–5·0 cm.

Using a thermistor probe, 3·5 mm in diameter, and a tele-thermometer with which the temperature can be read to 0·1° C, the temperature was recorded at various distances from the anal sphincter of six rats weighing

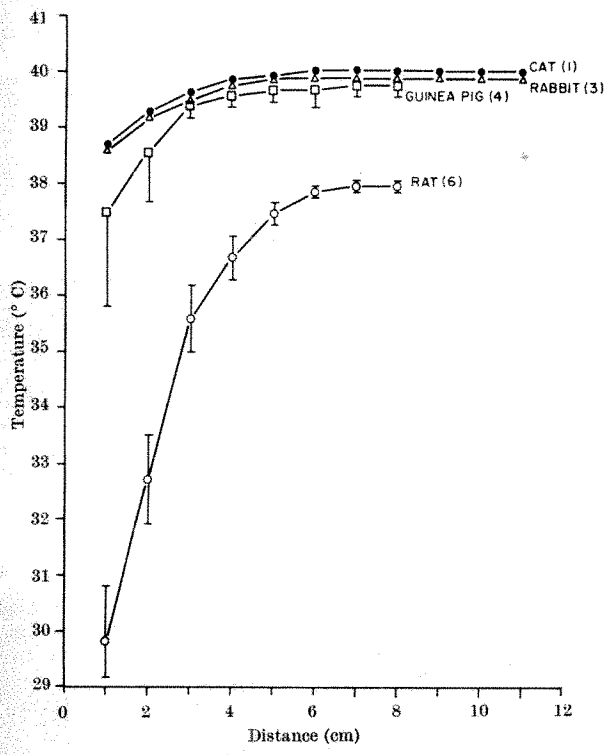

Fig. 1. Mean temperatures recorded at various distances from the anal sphincter. Numbers refer to number of animals. Vertical bars represent standard errors of the means

between 200 and 300 g (Fig. 1). The record assumes a plateau between 6 and 8 cm to give a mean of 38·0 ± 0·1° C, and it can be seen that the readings fall off rapidly at distances of less than 5 cm. If the readings were to be taken by repeated introduction of the probe to a distance of around 3 cm, a slight variation in position could produce a considerable error in the readings, and this could easily be of greater magnitude than the changes being investigated.

A more serious source of error is apparent from Fig. 2, where the fall in body temperature at the time of maximum effect of a systemic dose of 35 mg/kg of morphine sulphate

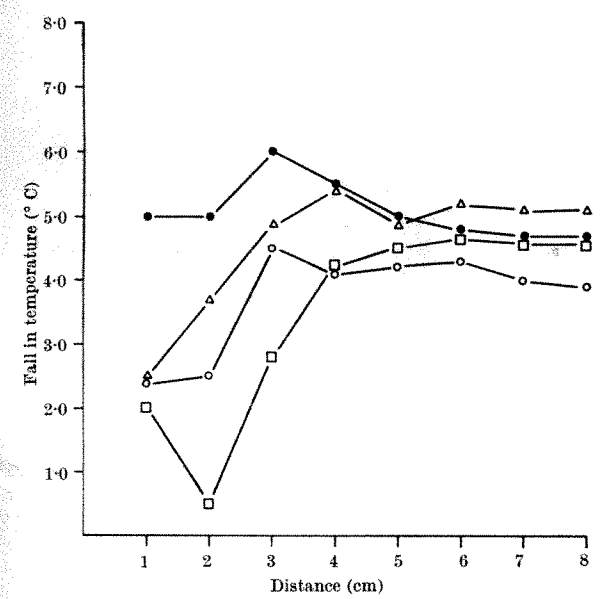

Fig. 2. Fall in temperature recorded at different distances from the anal sphincter in four rats at time of maximum hypothermia following intraperitoneal injection of 35 mg/kg of morphine sulphate

is recorded at different distances in four animals. Measurements at less than 5 cm would indicate a considerable variation in response and possibly obscure significant effects.

With a rat weighing from 200 to 300 g the maximum distance to which the probe can be inserted is approximately 8·0 cm, and post-mortem examination shows that, at this distance, the tip of the thermistor is lying behind the liver and close to the diaphragm.

Temperature measurements at various sites throughout the body of the calf and the rabbit, by insertion of thermocouples directly into the organs, reveal that the liver is at the highest temperature[4]. The temperatures of the liver and the mesentery around the portal vein are essentially the same in the rat and are the highest temperatures in the abdominal cavity[5]. Although higher temperatures may be recorded in specialized tissues such as the anterior hypothalamus[1] or brown adipose tissue during cold-induced thermogenesis[6] in the rat, it would seem that the temperature of the liver represents the best approximation to the body core temperature. Measurement of temperature at more distal points in the gastro-intestinal tract will reflect changes in core temperature but will be also variably affected by changes in local blood flow.

A similar increase in recorded temperature is seen in the guinea-pig (Fig. 1); there is appreciable variation from animal to animal at less than 3 cm (using animals of 600 g). Records for the rabbit and the cat are almost identical with the temperature reaching a steady level from 6 cm onwards.

It is concluded from these investigations that the most simple, accurate and reliable method of recording core temperature in the conscious rat is by means of a probe inserted at least 6 cm into the rectum and left in position throughout the experiment.

Sensitivity to Acetylcholine in Rat Slow Muscle

IN normal muscle fibres from the rat diaphragm, the depolarizing action of acetylcholine (ACh) is restricted to the region of the neuromuscular junction and its immediate surrounding[1,2]. The diaphragm is a 'fast' contracting muscle and it was interesting to determine if a similar pattern of ACh-sensitivity exists in a 'slow' muscle.

As an example of a slow muscle, we used the soleus of adult rats. The muscle was isolated and placed in oxygenated solution at room temperature. ACh was applied ionophoretically to different regions of the muscle fibres and the potentials were recorded with intracellular electrodes. The local ACh-sensitivity was taken as the ratio of depolarization (mV) to the quantity of charge ($C \times 10^{-9}$) which flows through the pipette[3]. The smallest detectable sensitivity was about 10^{-4} mV/nC.

The end-plate region of the muscle fibres is located about midway along the fibre; and its position can be identified by the presence of spontaneous miniature end-plate potentials[4]. The mean frequency of these potentials

in thirty soleus fibres was 1·3/sec (range 0·3–3·0/sec) which is within the values found in rat diaphragm muscle fibres.

The entire length of practically all the fibres in the soleus muscle is responsive to ACh, although the sensitivity is not uniformly distributed. There is a peak of sensitivity which coincides with the end-plate region. The ACh-sensitivity falls rapidly to either side of the end-plate and remains at a low level (10^{-1}–10^{-3} mV/nC) throughout the rest of the fibre. At the muscle-tendon junction there is again an increase in sensitivity; but the maximal sensitivity at myotendinous junctions is still a few hundred times less than at the myoneural junction. The profile of ACh-sensitivity along soleus fibres resembles that found by Katz and Miledi[5] in some fibres in the frog sartorius.

Since the diaphragm may not be a typical fast muscle, we decided to examine the distribution of ACh-sensitivity in a fast leg muscle to make the observations more comparable with those in the soleus. In preliminary experiments, we have found that the distribution of ACh-reactive sites in the fast extensor digitorum longus is similar to that in the diaphragm: the only region of detectable sensitivity is the end-plate and its immediate surroundings.

It would seem, therefore, that in rat fast muscle fibres the ACh-sensitivity is restricted to a small part of the cell surface; while in slow soleus fibres the entire surface is usually sensitive to ACh. An interesting possibility is that the ACh-sensitivity of a muscle is determined by the type of innervation it receives, a possibility which we are testing by cross-innervating fast and slow muscle.

Anaerobic Glycolysis in Parts of the Giant Axon of Squid

THE giant axon of the squid, *Loligo pealii*, after careful dissection and removal of auxiliary fibres, can be separated into mitochondrion-poor axoplasm and the relatively mitochondrion-rich envelope[1] (axonal membrane plus Schwann cell plus associated cell-wall material) by the simple mechanical operation of extruding the axoplasm by rolling[2,3].

Recently, the oxidative system as measured by the metabolism of ^{14}C-glucose to $^{14}CO_2$ by this preparation has been found to be limited to the envelope, whereas the axoplasm has been found to be totally devoid of such metabolic activity[3]. The use of specifically labelled glucose has also permitted a qualitative affirmation of a functioning pentose phosphate pathway in squid axon as had previously been shown in lobster axons and in the electric organ of *Electrophorus electricus*[4,5], although it might still be expected that Embden–Meyerhof glycolysis would represent the major route[6,7]. Because of the marked compartmentation of oxidative activity, it appeared of interest to examine the extent and possible localization of glycolysis in squid axons.

Anaerobic glycolysis was measured manometrically using conditions similar to those previously used in this laboratory[4,8]. Three procedures were used for these determinations: (1) cleanly dissected axons were weighed and homogenized in the desired amount of bicarbonate glycolysis buffer[8], and aliquots of the homogenate were added to the main compartments of prepared iced Warburg vessels; (2) cleanly dissected axons were freed of axoplasm by thorough rolling and flattening on a glass plate under sea-water with a small tygon-coated roller[2,3] and were later treated as the whole axons in (1); (3) axoplasm was extruded from crudely dissected axons by light rolling, weighed and added directly to Warburg vessels, where it dispersed in the aqueous medium without the necessity of homogenization. A typical Warburg vessel used in these experiments contained in the main compartment (where all components were placed), 1·08 ml. of glycolysis medium[8]; 0·12 ml. of co-factor solution such that final concentrations of ADP and ATP were 0·00033 M each, and DPN was 0·0002 M; 0·12 ml. of substrate such that the final concentrations of glucose, glucose-1-phosphate, glucose-6-phosphate and fructose-1,6-diphosphate were 0·002 M each; 0·48 ml. of 0·02 M potassium bicarbonate containing 48 mg of axonal material. Substrates and co-factors were either purchased as the potassium salts or converted to that form; gas phase was 95 per cent nitrogen–5 per cent carbon dioxide; temperature, 30° C. Ninety minutes after commencement of readings there was an 80-mm increase in manometer fluid height. A control vessel (0·12-ml. buffer in place of substrate) gave a 7-mm increase. All vessels, including the thermobarometer, were run in duplicate; vessel constants were about 0·7.

Fig. 1 shows that whole axon and axoplasm have high rates of anaerobic glycolysis compared with that for the isolated axonal envelope. In terms of μl. carbon dioxide per gram fresh tissue and hour, the glycolytic activities of whole axon, axoplasm and envelope are in the ratio 780 : 950 : 130. This is a relatively high glycolytic rate, about one-fifth of that for rat brain under similar conditions[9], a most actively glycolysing system. Other published rates[10] under other conditions may not be a suitable basis for comparison, although such comparison would make the relative squid axonal rate appear even greater. Because the envelope represents about one-tenth the weight of the whole cleanly dissected axon, the anaerobic glycolysis rate of envelope is a small fraction of the glycolysis rate for whole axon, of the order of 2 per cent. Even the small but significant production of carbon dioxide in the absence of added substrate is probably also glycolysis as indicated by the total inhibition of carbon dioxide evolution in the presence of 0·005 M iodoacetate, also shown in Fig. 1.

The question may be asked what function the high level of glycolytic activity would perform. The inward passage of nutrients, the outward passage of products, and the synthesis and subsequent hydrolysis of ATP, metabolic events probably coupled to the maintenance of ionic gradients in cellular systems[11,12], almost certainly are dependent on glycolysis as well as on oxidative metabolism. It may be speculated that, since far less ATP is formed per mole of substrate glycolysed than is formed in the subsequent corresponding oxidative cycle, the high level of glycolytic activity would represent the greater means of ATP formation. As for the matter of supplying intermediates for oxidative metabolism, it need only to be noted that previous[3] and present results indicate that, at the maximum, squid envelope can oxidize 0·15 μmoles glucose to carbon dioxide per gram and hour. The extra glycolytic activity, especially of the axoplasm, is probably more a reflexion of enzyme concentrations than of actual metabolic functioning, since, due to the Pasteur effect, the glycolysis rate under aerobic conditions may be expected to be markedly lower than that reported here. The high glycolytic enzyme-levels may supply intermediates for the continuing synthesis of cellular components. The production of such intermediates by the axoplasm, and the production of TPNH by way of the pentose phosphate pathway metabolism by the axonal envelope, may represent a means of metabolic function and control in nerve tissue.

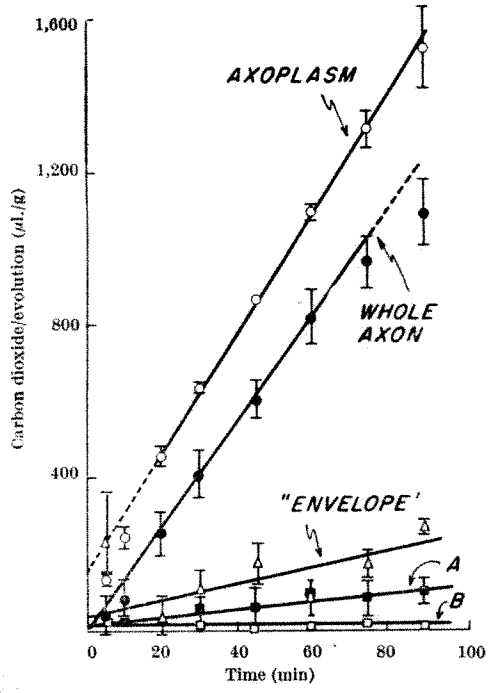

Fig. 1. Anaerobic glycolysis by whole squid axon, by axoplasm, and by envelope, that is, membrane plus Schwann cell plus associated cell wall material. *A*, Average endogenous reaction (control) for all preparations in the absence of substrate. *B*, Whole axon in the presence of added substrate and 0·005 M iodoacetate. Vertical bars, standard deviation

Absorption by the Mouse and Rat Urinary Bladder of Glycine, Tryptophan and Glucose

THE passage of drugs, dyes and inorganic ions through the mammalian urinary bladder has been the subject of many investigations[1,2]. However, few attempts have been made to ascertain if the mammalian bladder absorbs normally occurring, physiological components of urine, for example, amino-acids and sugars. It was observed[3] during the course of investigations of the bladder carcinogenicity[4] of certain urinary metabolites of the essential amino-acid, L-tryptophan, that nearly 90 per cent of the carbon-14 present in an aqueous solution of carbon-14-labelled 3-hydroxy-L-kynurenine or 3-hydroxyanthranilic acid, instilled directly into the mouse urinary bladder, was recovered after 24 h in the respiratory carbon dioxide, carcass, and faeces. These data suggested that other normally occurring urinary substances might also be absorbed by the bladder.

To investigate this hypothesis, an aqueous solution (*p*H 5·6) of glycine-1-^{14}C (0·1 μM, 0·7 μc., 0·05 ml.), L-tryptophan-3-^{14}C (0·04 μM, 1·0 μc., 0·05 ml.), or D-glucose-1-^{14}C (0·1 μM, 0·4 μc., 0·05 ml.) was instilled, through a needle placed into the urethra under direct vision, into the urinary bladders of four female Swiss mice. To prevent possible reflux into the kidney and to avoid dilution of the label by urine, the ureters were ligated midway between the bladder and the kidneys. After ligation of the urethra[3], the mice were placed individually into a closed metabolism chamber. Respiratory carbon dioxide was collected as described[3] during the period 0–1 h, 1–6 h, 6–18 h and 18–24 h. After 24 h, the mice were killed and the urinary bladder, bladder contents, carcass and faeces were prepared[3]. The carbon dioxide samples, precipitated as barium carbonate, and aliquots of the homogenized tissue and faecal samples were placed on tared planchets and the radioactivity was measured in a Nuclear-Chicago thin-window, automatic gas-flow counter, with a background of 1·5 c.p.m. To obtain a comparative evaluation of the absorptive capacity of the urinary bladder, carbon-14-labelled glycine, L-tryptophan, or D-glucose were injected intraperitoneally into four mice, using the same conditions and dose-levels as were utilized for the instillation into the urinary bladder. Respiratory carbon dioxide was collected for the same time intervals, and all samples of carbon dioxide, tissues, faeces and urine were collected, prepared, and analysed for radioactivity[3]. As the total carbon-14 present in the animal and its faeces, urine, bladder contents, and respiratory carbon dioxide was measured, the percentage of carbon-14 present in each sample was calculated from the c.p.m. of carbon-14 recovered.

Following direct bladder instillation of glycine, $^{14}CO_2$ was detected in the breath after 1 h (Fig. 1*A*). At the end of 24 h, 51 ± 7 (*S.D.*) per cent of recovered carbon-14 was present in carbon dioxide, 47 ± 7 per cent was in the carcass and faeces, 1·1 ± 0·7 per cent was in the bladder, and only 0·2 ± 0·1 per cent was recovered from the bladder contents. Compared with the distribution of carbon-14 following intraperitoneal injection of glycine (Fig. 1*D*), the only statistically significant differences noted were in the percentage of $^{14}CO_2$ found at the end of 1 h (25 ± 3 intraperitoneal; 7 ± 3 intravesical; $P < 0·01$), and in the percentage of carbon-14 in the bladder (0·05 ± 0·03 intraperitoneal; 1·1 ± 0·7 intravesical; $0·02 > P > 0·01$). After the intravesical injection of L-tryptophan, $^{14}CO_2$ was present in the breath after 1 h (Fig. 1*B*). At the conclusion of the experimental period, 29 ± 4 per cent of the recovered carbon-14 was present in the carbon dioxide, 68 ± 4 per cent was in the carcass and faeces, 1·8 ± 0·9 per cent was in the bladder, and only 1·6 ± 1·4 per cent was recovered from the bladder contents. The only statistically significant difference in the distribution of carbon-14, in comparison with that observed following intraperitoneal injection of L-tryptophan (Fig. 1*E*), was the greater quantity of carbon-14 present in the bladder following intravesical instillation ($P < 0·01$), and the greater quantity of carbon-14 present in the urine (compared with the bladder contents) following intraperitoneal injection ($P < 0·01$). After direct bladder instillation of D-glucose, 6 ± 4 per cent was present as $^{14}CO_2$ after 1 h (Fig. 1*C*), and 77 ± 3 per cent was found in the carbon dioxide after 24 h. The carcass and faeces contained 23 ± 3 per cent, while the bladder and bladder contents contained lesser quantities of carbon-14. Compared with the distribution of carbon-14 following the intraperitoneal instillation of D-glucose (Fig. 1*F*), significantly greater

Table 1. COMPARISON OF THE DISTRIBUTION OF CARBON-14 IN SPRAGUE-DAWLEY RATS INJECTED INTRAVESICALLY OR INTRAPERITONEALLY WITH AN AQUEOUS SOLUTION OF L-TRYPTOPHAN-3-^{14}C

Sample	Intravesical injection (per cent)	Intraperitoneal injection (per cent)	*P*-value
$^{14}CO_2$			
0–1 h	0·5 ± 0·4	5 ± 4	N.S.
0–6 h	7·0 ± 3·0	22 ± 1	< 0·01
0–18 h	12 ± 6·0	28 ± 1	0·05 > *P* > 0·02
0–24 h	15 ± 8·0	32 ± 1	N.S.
Carcass and faeces	77 ± 4·0	65 ± 2	0·05 > *P* > 0·02
Bladder	8·0 ± 4·0	0·01	N.S.
Bladder contents or urine	0	4 ± 1	< 0·01

The solution used was at *p*H 5·6; and 0·1 ml., containing 0·08 μM and 2·0 μc. of L-tryptophan, were injected. The instillation into the bladder through a needle placed into the urethra, the collection and processing of the samples and tissues, and the measurement of the radioactivity were as described for the mice. The percentage of carbon-14 was calculated from the carbon-14 recovered. Three rats, weighing 150–200 g, were used for the intravesical study, and two rats of the same size were used for the intraperitoneal investigation. The values represent the mean ± 1 standard deviation.

($P < 0·01$) quantities of carbon-14 were present in the carbon dioxide at all time periods and in the urine (compared with the bladder contents) after intraperitoneal injection, while a significantly greater ($P < 0·01$) amount of carbon-14 was present in the carcass and faeces after intravesical instillation.

At the end of the experimental period, the urinary bladders were intact and of normal colour. In one experiment, the vascular supply at the base of the bladder was ligated intentionally, and at the end of 1 h, the bladder was soft and dark in colour. Unlabelled glycine, L-tryptophan and D-glucose in the same concentration and volume as used in the experiments with carbon-14 were instilled individually into the bladders of mice and the urethras were ligated[3]. The mice were killed after 1, 6, 18 and 24 h, the bladders were fixed with Bouin's solution, and histological sections were prepared[4]. The integrity of the bladder throughout the experimental period could be ascertained, for the mucosa, submucosa and musculature of the bladder were intact. When compared with a normal mouse bladder, no histological differences could be detected.

The absorption and distribution of carbon-14-labelled L-tryptophan after intravesical instillation into the bladder of the rat were compared with that observed following intraperitoneal injection (Table 1). After 24 h, following intravesical administration, all the carbon-14 was present outside of the lumen of the bladder. The rat bladder permitted the passage of this compound as readily as did the mouse bladder.

Though the passage of drugs, dyes and inorganic ions through the mammalian bladder has been demonstrated[1,2], the bladder has been thought of primarily as a storage receptacle for urine, and an organ of evacuation. These data suggest that the mammalian urinary bladder may play an active part in the conservation of substances essential for the nutrition of an animal. Because the functional capacity of the transitional cell epithelium lining the ureters, bladder and urethra is not known, it is possible that (1) the bladder mucosa, by absorbing amino-acids and sugars from the urine, may receive many essential nutrients in this way; (2) the bladder may function as an important regulator of metabolism through the absorption of physiological substances from the urine; or (3) the bladder may retain a vestigial absorbing function that permitted those species capable of conserving essential nutrients in this manner a better chance of evolutionary survival. The mechanism of absorption of these compounds is not known.

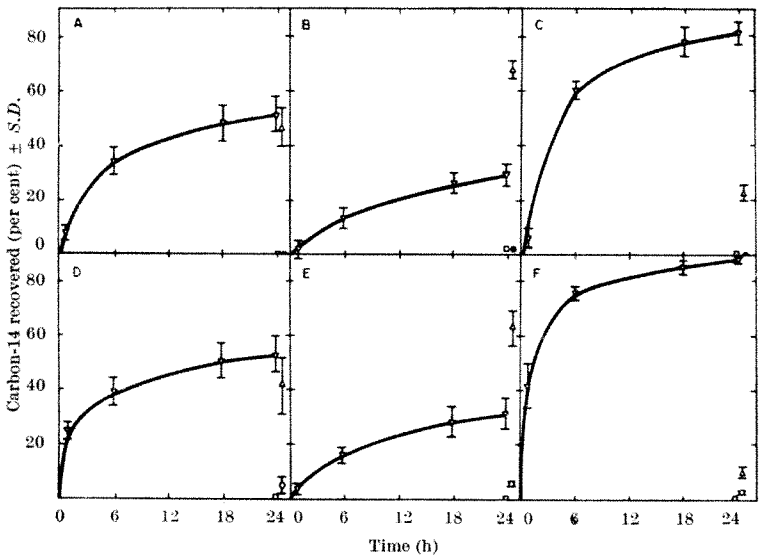

Fig. 1. Comparison of the distribution of carbon-14 in mice injected intravesically or intraperitoneally with an aqueous solution of carbon-14-labelled glycine, L-tryptophan, or D-glucose. The intravesical instillation of (*A*) glycine, (*B*) L-tryptophan, and (*C*) D-glucose is compared with the intraperitoneal administration of (*D*) glycine, (*E*) L-tryptophan, and (*F*) D-glucose. The inverted open triangles represent cumulative carbon-14 over the periods 0–1 h, 0–6 h, 0–18 h, and 0–24 h; upright open triangles the carbon-14 present in the carcass and faeces; open squares the carbon-14 present in the washed bladder; closed circles the carbon-14 remaining in the bladder lumen; and open circles the carbon-14 present in the urine

Acetylcholine and Choline Acetylase in Squid Giant Axon, Ganglia and Retina

THE giant axon of the squid stellar nerve and giant synapse of the stellate ganglia have frequently been used as test objects during investigations of the electrophysiological properties of nerve conduction and junctional transmission[1–3]. Other investigations in which these preparations have proved useful have concerned the chemical and molecular basis of nerve activity and the role of acetylcholine (ACh) in conduction[4–12].

A prerequisite for assuming an essential role of ACh in the conducting mechanism of any preparation is the presence of the ACh system: choline acetylase (ChAc), ACh itself, choline esterase (ChE), and ACh-receptor[4,5]. ChE was found in both preparations a long time ago[4], and recently by means of highly refined techniques it has been shown to be present in the envelope and axoplasm of carefully cleaned axons and in squid stellate ganglia[11,12]. Recent investigations have indicated that ACh receptor is present in the axon[9,10] as well as in the ganglia[11].

It appeared desirable to obtain more complete information by testing for the presence of ACh and ChAc. For purposes of comparison, similar determinations were made with the squid fin nerve with a bundle of axons, which lies adjacent to the stellar nerve, and with the axons from the walking leg of lobster. The last-mentioned preparation is of special interest, as ACh and related compounds directly affect conduction[13,14], and thus indicate that the permeability barrier is smaller than in the squid axon.

The squid retina was included in the present investigations as it has been reported

that this tissue has no ChAc activity[15]. This was surprising since the retinae of dog, rabbit and guinea-pig, for example, have high activities[16].

Samples of tissue were rapidly removed from the squid and lobster. The giant axons from the squid (*Loligo pealii*) were carefully cleaned of all adhering small nerve fibres and as much connective tissue as possible. Either the entire stellate ganglia was assayed or it was carefully divided into an outer portion, which contained mainly the ganglion cells of the first stellar nerve together with some of the proximal synapses, and an inner portion, which contained mainly the giant or distal synapses[17,18]. These will be referred to as the proximal and distal synaptic regions. The entire nerve bundles from the first two pairs of lobster walking legs were used.

Tissues intended for ChAc assay were placed in a refrigerator until ready for use, while those used for the direct measurement of ACh were immediately homogenized in 5 ml. of frog Ringer's solution[19] containing about 1×10^{-4} M physostigmine sulphate—except for the control samples, which were homogenized in Ringer's solution free of physostigmine.

Choline acetylase was determined as previously described[19], except that the phosphotransacetylase was purchased from Calbiochem; after incubation, the 1-ml. sample was diluted with frog Ringer's solution to at least 200 ml. This dilution avoids any interference in the bioassay from the ingredients of the incubation mixture. Control incubation tubes, both with and without boiled tissue, were always run as controls.

The ACh in the tissue, or that formed during a 1-h period of incubation in the ChAc assay, was determined by bioassay on the frog rectus abdominis muscle[19]. The following amounts of tissue were used: 50–90 mg giant axon (ten to fourteen axons); 100–140 mg fin nerve; 50–90 mg stellate ganglia (four whole ganglia); 15–30 mg proximal or distal synaptic regions (from three ganglia); 100–300 mg retina; 40–100 mg lobster axons. ($T = 18°–22°$ C.) The following tests were performed in order to ascertain that the material causing contraction of the frog rectus muscle was ACh or a choline ester: (1) tissue homogenate without physostigmine was added to the muscle; (2) the effect of acid and alkaline heating of extracts was sometimes tested. Except for the squid giant axon (see later), all contractions appeared to be exclusively due to ACh or to an ACh-like compound.

The results obtained are summarized in Table 1. In a few experiments the axoplasm of the giant axons was extruded[10], and attempts were made to determine ACh separately in the axoplasm and envelope. In order to obtain reliable quantitative results, however, it would have been necessary, based on the ACh content of the whole axon, to have at least 50 mg of axoplasm and envelope. Although as many as twenty axons were extruded for a single determination, we were unable to obtain sufficient tissue for quantitative data. The results obtained, however, seem to indicate that ACh is present in both axoplasm and envelope; the two values combined probably amount to about the same concentration found in whole axon. Investigations with a more sensitive bioassay technique may give a more exact quantitative relationship.

In the presence of physostigmine, the contraction of the rectus muscle produced by the homogenized suspension of the giant axon corresponded to an ACh concentration of 4·2 μg/g; however, in the absence of physostigmine, there was a mean contraction corresponding to 1·3 μg/g. This value was subtracted from the 4·2 to give the value of 2·9 shown in Table 1. The small contraction in the absence of physostigmine was probably due to the potassium contained in the axoplasm of the axons, as 60 mg of axoplasm contains sufficient potassium approximately to double the normal concentration of potassium (2·5 mM) in 5 ml. of frog Ringer's solution. In the absence of physostigmine, homogenates of the other tissues gave no contraction.

Table 1. ACETYLCHOLINE (ACh) AND CHOLINE ACETYLASE (ChAc) ACTIVITY OF SQUID GIANT AXON, RETINA, FIN NERVE, STELLATE GANGLIA AND PROXIMAL AND DISTAL SYNAPTIC REGIONS OF GANGLIA

Tissue	No. expts.	ACh* (μg/g)	No. expts.	ChAc* (μg/g/h)
Giant axon	7	2·9 ± 0·5†	4	263 ± 33†
Fin nerve	4	1·1 ± 0·2	4	481 ± 32
Stellate ganglia	4	11·3 ± 3·0	4	5,257 ± 235
Proximal synaptic region	3	2·7 ± 0·2	3	1,448 ± 521
Distal synaptic region	3	26·8 ± 5·5	6	8,753 ± 578
Retina	8	6·3 ± 1·0	6	887 ± 174
Lobster axons‡	13	11·3 ± 0·9	5	1,056 ± 43

* The ACh content of tissues is expressed as μg ACh/g fresh weight, and the ChAc activity as μg ACh formed/g fresh weight/h.
† Results are presented as means ± standard deviation of the mean (standard error).
‡ The lobster axons were taken from the walking legs.

The fin nerve exhibits higher ChAc activity than the giant axon but it has less free ACh. The amount of ACh in the fin nerve is about equal to that found in rabbit sciatic[20]. The giant or distal synaptic region has much higher ACh and ChAc than the proximal region, and has also been found to have more ChE[11]. The ChAc activity in the giant synaptic region is almost as great as that in the squid head ganglia, which has the highest concentration and is one of the best sources of ChAc[4]. Our values for ChAc in the walking leg of lobster are about twice as great as those recently reported[21], and indicate that the amount of ACh formed is sufficient for 800,000 impulses/h.

The relatively high ChAc activity which we found in the squid retina is in marked contrast to an earlier report by Feldberg *et al.*[15]. At the time of their investigations, however, the procedures used for determining ChAc activity were inadequate as the activity of this enzyme depended on an adequate supply of acetyl-CoA provided by another enzyme. By the addition of phosphotransacetylase to the incubation media, acetyl-CoA is produced and this source of error is eliminated.

The experiments were carried out at the Marine Biological Laboratory, Woods Hole, Massachusetts, and we are grateful for the facilities made available to us. We thank Prof. David Nachmansohn for his advice and Miss R. Spencer, Miss J. Rubinstein and Miss L. S. Ardwin for technical assistance.

Gluconeogenesis following Hypothalamic Stimulation

In previous experiments[1,2], a rise in serum glucose, and increased endogenous gluconeogenesis in liver slices, was found 5 min after the injection of 50–100 mg of 2-deoxy-glucose (2 DG), an inhibitor of glucose utilization, into fasting rats. 2 h after administration of 2 DG, an accumulation of liver glycogen was observed. There was a constant rise in urea excretion during the first 24 h. Adrenalectomy inhibited the response to 2 DG, and no effect was observed when 2 DG was injected together with glucose or insulin.

The changes due to 2 DG were not observed in animals anaesthetized with ether or pentobarbital. This suggested that stimulation of gluconeogenesis at least in these experiments originated in the central nervous sytem, possibly in the hypothalamus. The actual stimulus in the hypothalamus may be cellular glucopenia due to inhibition of glucose utilization caused by 2 DG. Previous observations in both experimental animals[1] and man[3] support the concept that 2 DG acts on the hypothalamus. If this hypothesis is correct an electrical stimulation of the hypothalamus may induce gluconeogenesis, and the present communication reports the results of such experiments. The stimulation was carried out in the following manner.

A bipolar stainless steel electrode—insulated except for its tip—was implanted, with the aid of a 'Krieg' stereotaxic instrument, into the posterior hypothalamus or caudate nucleus of male albino rats weighing between 200 and 300 g. One week after the surgical procedure the rats were deprived of food overnight and then stimulated with a 'Grass' stimulator with pulses of 10 msec duration and at a frequency of 20/sec. The current and duration of stimulation are shown in Table 1. Other animals which were similarly treated on the same day and kept exactly under the same conditions served as controls. Within 30 min of the end of the stimulation the animals were anaesthetized and killed by bleeding. Hepatic gluconeogenesis and glycogen content were determined. The brains were removed, fixed in formalin, cut at 80μ and examined for confirmation of the position of the stimulating electrodes (Fig. 1).

It was found that electrical stimulation of the hypothalamus increased the serum glucose level and the rate of hepatic gluconeogenesis. After 3 h, a 10–20-fold rise in liver glycogen was found. The stimulation was effective with a current as low as 0·06 m.amp.

Electrical stimulation at a different area in the central nervous system, namely, the caudate nucleus, had no effect on the measured parameters.

As in the case of 2 DG, adrenalectomized rats did not show an increased rate of gluconeogenesis after electrical stimulation.

These results and our earlier observation that anaesthesia inhibits the onset of gluconeogenesis indicate the important role of the central nervous system in the regulation of gluconeogenesis and consequently of the blood glucose level. It seems that both electrical stimulation and 2 DG cause a discharge of adrenocorticotrophic hormone releasing factor, thus activating the adrenal cortex.

Table 1. Effect of Electrical Stimulation of the Hypothalamus on Gluconeogenesis in Rats

Implantation	Current (m. amp)	Duration of stimulus (h)	Serum glucose (mg%) E	Serum glucose (mg%) C	Gluconeogenesis in liver slices (μmole glucose/100 mg wet tissue/2 h) E	Gluconeogenesis in liver slices (μmole glucose/100 mg wet tissue/2 h) C	Glycogen in liver (γ/100 mg wet tissue) E	Glycogen in liver (γ/100 mg wet tissue) C
Posterior hypothalamus	1·80	3	175 ± 14·7 (7)*	101 ± 13·0 (5)	2·96 ± 0·01	1·32 ± 0·03	300 ± 36	24 ± 2

* No. of animals indicated in brackets.

The livers were removed, chilled in cold saline, sliced with a 'Stadie Riggs' slicer and weighed. 100-mg liver slices were suspended in 1 ml. Krebs Ringer bicarbonate medium (ref. 4), aerated with 95 per cent oxygen and 5 per cent carbon dioxide. Incubation was carried out in a metabolic incubator at 37° C for 2 h. The glycogen content of the liver was determined by the anthrone method (ref. 5) and glucose after deproteinization (ref. 6) by the glucose oxidase method (ref. 7).

Endogenous gluconeogenesis was estimated by subtracting the amount of glycogen that disappeared from the liver slices during incubation from the amount of glucose found in the medium at the end of the incubation.

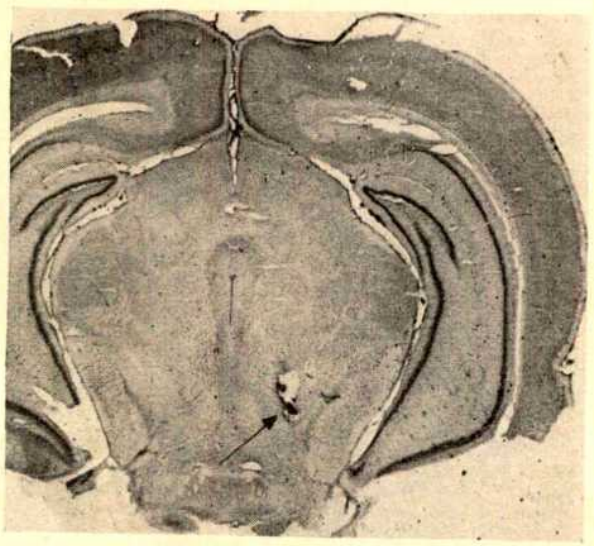

Fig. 1. Histological section of the posterior hypothalamus showing position of stimulating electrode

The fact that the hormones of the adrenal cortex are essential for the normal gluconeogenetic response is well known[8]. But it is probable that their effect in this process of gluconeogenesis is permissive. This problem is discussed elsewhere[1].

To sum up, electrical stimulation of the posterior hypothalamus in rats fasted overnight resulted in increased endogenous hepatic gluconeogenesis, hyperglycaemia and accumulation of liver glycogen. These changes did not occur in animals stimulated in the caudate nucleus. In adrenalectomized rats the effect could not be observed.

pH Decline in the Two Layers of the Panniculus Adiposus

THE post-mortem *p*H decline in a tissue has been accepted as an indication of the underlying, concomitant physical and chemical changes[1,2]. The relationship of this acidity development to subsequent tissue processing and organoleptic properties has also been established[3,4]. Although such investigations with muscle tissue have received considerable attention[5–9], similar investigations have not been undertaken with adipose tissue. Consequently, this investigation was conducted to determine the rate and extent of *p*H decline, if any, in adipose tissue.

Ten experimental animals (*Sus domesticus*), averaging 120 kg and similar in genetic and nutritional backgrounds, were used in this investigation. Samples of the panniculus adiposus were excised from the lumbar region of the right side of the carcass immediately after exsanguination and at 30 min, 1, 2, 3, 4 and 24 h *post mortem*. The *p*H values of the outer and inner layers of this subcutaneous adipose tissue were measured with a Beckman 'Zeromatic' *p*H meter equipped with a combination probe-electrode. The *T*-test of significance and the simple correlation coefficients were calculated by the methods outlined in Steel and Torrie[10].

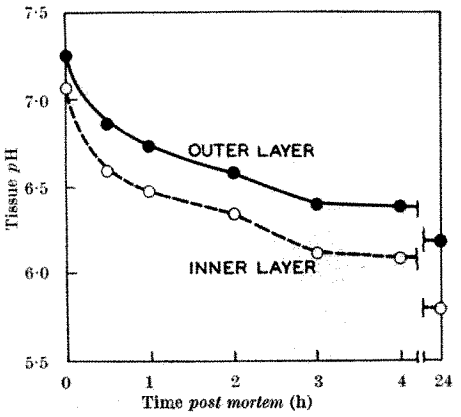

Fig. 1. Post-mortem changes in the *p*H of the outer and inner tissue layers of the panniculus adiposus

The results in Fig. 1 show the features of the post-mortem *p*H decline in the outer and inner layers of the panniculus adiposus. These data demonstrate that a gradual acidification does occur in adipose tissue following death. Further (Table 1), the two layers of this tissue are noted to differ significantly in *p*H values.

The outer layer of the panniculus adiposus always exhibited a higher *p*H regardless of the time *post mortem* at which it was measured. It can also be observed (Table 1) that the rate of *p*H decline (in 24 h) and its extent (ultimate *p*H) were more marked in the inner than in the outer layer.

Table 1. POST-MORTEM *p*H AND HYDROGEN ION CONCENTRATION (MOLES $\times 10^{-7}$) CHANGES IN THE OUTER AND INNER TISSUE LAYERS OF THE PANNICULUS ADIPOSUS

Panniculus adiposus layer	Initial (0-h)		Ultimate (24-h)		Difference	
	*p*H	H^+	*p*H	H^+	*p*H	H^+
Outer layer	7·25	0·62	6·18	8·99	1·07	8·37
Inner layer	7·07	0·92	5·79	17·53	1·28	16·60
Difference	0·18*	0·30*	0·39†	8·54*	0·15	8·23*

* $P < 0·05$.
† $P < 0·01$.

Table 2. CORRELATION COEFFICIENTS BETWEEN THE POST-MORTEM *p*H MEASUREMENTS IN THE OUTER AND INNER TISSUE LAYERS OF THE PANNICULUS ADIPOSUS

Inner tissue layer / Tissue measurement	Outer tissue layer: 0-h *p*H	0·5-h *p*H	1-h *p*H	2-h *p*H	3-h *p*H	4-h *p*H	24-h *p*H
0-h *p*H	0·95†	0·84†	0·63*	0·64*	0·54	0·49	0·54
0·5-h *p*H	0·93†	0·97†	0·93†	0·83†	0·84†	0·80†	0·64*
1-h *p*H	0·79†	0·84†	0·97†	0·71*	0·83†	0·80†	0·61
2-h *p*H	0·53	0·51	0·62	0·84†	0·85†	0·84†	0·53
3-h *p*H	0·37	0·47	0·64*	0·57	0·86†	0·88†	0·39
4-h *p*H	0·24	0·39	0·57	0·53	0·84†	0·86†	0·34
24-h *p*H	0·35	0·18	0·09	0·18	0·20	0·20	0·48

* $P < 0·05$.
† $P < 0·01$.

Although these data demonstrate the *p*H differences between the two layers of the panniculus adiposus, the simple correlation coefficients (Table 2) suggest a metabolic relationship in the development of post-mortem acidity in this adipose tissue.

The problem remains to relate these observations to the actual physical and chemical events occurring in the tissue.

Studies on Spermatozoa and Fluid collected directly from the Testis of the Conscious Ram

RAM spermatozoa require 12 to 15 days to traverse the epididymis[1] and during this time undergo changes which have been called maturation. In order to investigate these a technique has been developed for the continuous collection of spermatozoa before they enter the epididymis so that their *in vitro* metabolism may be compared with that of ejaculated spermatozoa from the same ram. The technique has also enabled a continuous collection of the fluid which is secreted by the testis and in which testicular spermatozoa are carried to the head of the epididymis. To our knowledge this investigation represents the first evaluation of testicular fluid and spermatozoa collected from conscious animals.

Nine adult merino rams kept in a climate room at 21° C were used. Under general anaesthesia and aseptic precautions, the head of the epididymis was dissected off the tunica albuginea and raised until the efferent ducts were located and severed. A ring of silicone rubber, with a plug fitting into the top, was sewn to the tunica albuginea so that it included the cut efferent ducts in the space so formed. The fluid from the efferent ducts flowed into this space, then down one of two tubes sealed into the wall of the ring, and was collected in a receptacle attached to the scrotum; samples for chemical analysis were collected into a receptacle surrounded by solid carbon dioxide. The other tube was occluded and used for daily flushing (Fig. 1).

The testicular fluid obtained was turbid and flowed at a rate of $1·0 \pm 0·11$ ml./h/100 g of testis (range 0·76–1·45; five rams) or at a rate of about 50 ml./day from a testis of average size. Spermatozoa were present at a concentration of $67·2 \pm 17·8 \times 10^6$/ml. (range $14–123 \times 10^6$; five rams). The total daily production was $1·6 \pm 0·43 \times 10^9$ spermatozoa/100 g of testis or $3·3 \times 10^9$ spermatozoa from an average-size testis. These figures agree with the calculated sperm production of Ile-de-France[2] and Suffolk rams[3].

Freshly collected testicular spermatozoa showed prominent kinoplasmic droplets and exhibited only feeble oscillating movements. The spermatozoa became more active in fluid with a higher alkalinity, as observed previously[4], or after storage at +3° C overnight in the fluid in which they were secreted. The catheters remained patent for up to 7 days.

The initial *p*H of testicular fluid was 7·1 but rose to 8·6 several hours after collection. Cell-free testicular fluid contained very little protein (0·1–0·5 g/100 ml.), about 3 per cent of plasma values. This is in marked contrast to the high protein concentration previously described for testicular lymph collected from rams[5,6]. The fluid was either isosmotic or hypotonic with a mean osmolarity of 283 ± 8·3 mOsm/kg (six rams) compared with the plasma osmolarity of 299 ± 1·7 mOsm/kg. The mean concentration of sodium in the fluid was 134 ± 1·7 m.equiv./l., and that of potassium was 11·4 ± 0·8 m.equiv./l. These were lower than those reported for the fluid collected from rams at slaughter[7,8], but similar to those recently obtained *post mortem* from bulls[9]. Only traces of glucose and fructose were found in testicular fluid, but lactic acid was present at a concentration of 58 ± 2·6 μg/ml., which is about 10 per cent of the values obtained for slaughterhouse material[8].

The fluid collected from seven rams contained variable amounts of testosterone ranging from 0·6 to 8·8 (mean 3·4) μg/100 ml., whereas in two other rams there was no testosterone detectable (< 0·5 μg/100 ml.). When present, therefore, testosterone appeared in testicular fluid at a concentration similar to that found in testicular lymph[5] and in the lower range of that found in plasma from the internal spermatic veins[5,10], but it was not correlated with protein concentrations eliminating possible contamination with lymph. Thus the testicular spermatozoa and developing cells inside the seminiferous tubules are exposed to testosterone which has been suggested as playing an important part in the maintenance of spermatogenesis[11] and sperm survival in the epididymis[12].

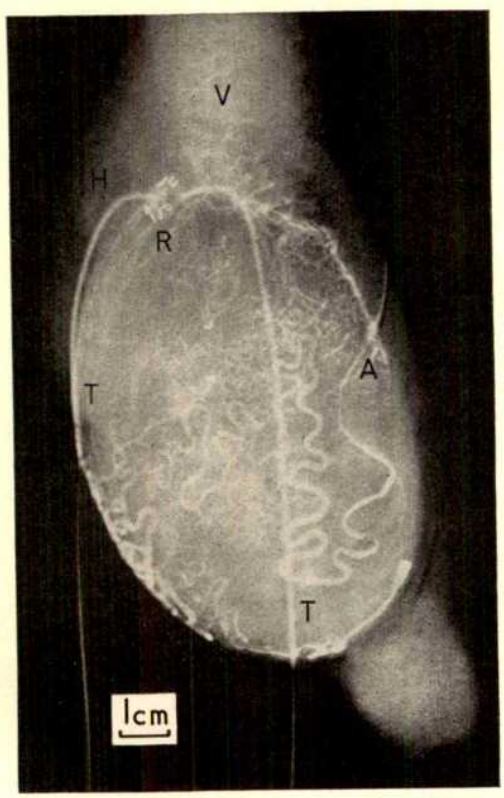

Fig. 1. Radiograph showing the ring (*R*) and tubes (*T*) of the testicular catheter in relation to the head of the epididymis (*H*) and vascular cone (*V*). *R*, 5 mm internal diameter, 8 mm outer diameter, 5 mm high; plug 2 mm thick; *T*, 1 mm internal diameter, 1·8 mm outer diameter. Sutures are attached to the stainless steel loops on the ring. Testicular catheter here filled with radio-opaque material ('Urografin', Schering *A.G.*), *A*, Catheter in testicular artery for injection of 'Urografin' to show the vessels and the vascular cone

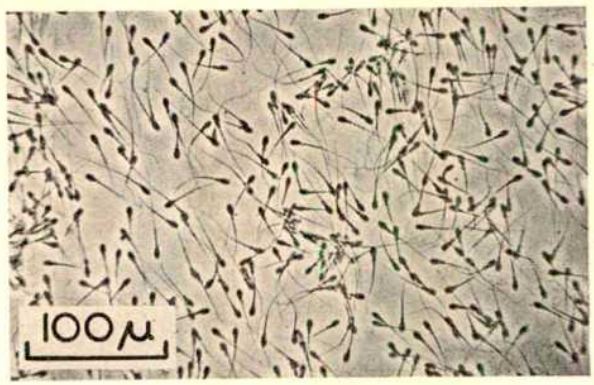

Fig. 2. Photomicrograph of washed testicular spermatozoa collected by the testicular catheter (phase contrast)

For metabolic studies the testicular spermatozoa were centrifuged (about 400 *g* for 5 min) from the testicular fluid, and were compared with spermatozoa obtained by electro-ejaculation. The spermatozoa were washed twice and resuspended in a phosphate buffer diluent with and without substrates[13]. Fig. 2 is a sample of the washed testicular spermatozoa used. The sperm suspensions were incubated in Warburg flasks under aerobic and anaerobic conditions at 37° C, usually for 3 h. Oxygen uptake, the utilization of glucose, fructose, an equimolar mixture of both and the production of lactic acid were measured[14–16].

A direct comparison of the metabolism of ejaculated and testicular spermatozoa from the same two rams is given in Table 1. The endogenous respiration of ejaculated and testicular spermatozoa was similar. The addition of a substrate stimulated the respiration of both types of cells, but to a greater extent in testicular spermatozoa. Fig. 3 shows the pattern of the oxygen uptake of testicular and ejaculated spermatozoa in the presence of a substrate. The initial rate of respiration was similar but thereafter decreased progressively in ejaculated spermatozoa. The oxygen uptake of testicular spermatozoa remained linear throughout.

In the presence of oxygen, the substrate utilization of ejaculated spermatozoa tended to be higher and also the lactic acid production was higher than that of testicular spermatozoa, but the values were not affected by substituting fructose for glucose. By contrast, under anaerobic conditions the rate of glucolysis by testicular spermatozoa was higher than by ejaculated spermatozoa. Thus although both types of spermatozoa showed a Pasteur effect—an increase in substrate utilization and lactic acid production under anaerobic conditions—it was greater in testicular spermatozoa. Both types of cells used glucose in preference to fructose when both sugars

Table 1. METABOLISM OF EJACULATED AND TESTICULAR SPERMATOZOA OF THE RAM
(Change/10^8 cells in 3 h)

Added substrate		Oxygen uptake (μl.) Ejac. sp.	Oxygen uptake (μl.) Test. sp.	Substrate utilization (μg) Ejac. sp.	Substrate utilization (μg) Test. sp.	Lactic acid production (μg) Ejac. sp.	Lactic acid production (μg) Test. sp.

	Anaerobic	—	—	G360 F119	G430* F154	400	397

The means of six observations on two rams are given. Similar values were obtained in six other rams, but because complete data were not obtained they have not been included.
Significance of differences between ejaculated and testicular spermatozoa:
* = $P < 0.05$ † = $P < 0.01$ ‡ = $P < 0.001$.
G and F: glucose and fructose utilization respectively from an equimolar mixture.

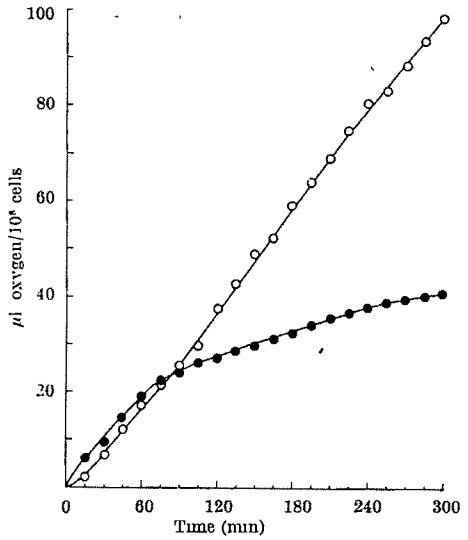

Fig. 3. A characteristic pattern of the oxygen uptake of washed testicular (○) and ejaculated (●) ram spermatozoa in a phosphate buffer diluent with glucose (0 005 M) as a substrate

were present and under both aerobic and anaerobic conditions, thus demonstrating the fructose-sparing effect previously described for ejaculated spermatozoa[17]. The lactate production by testicular spermatozoa under anaerobic conditions was not sufficient to account for the glucose utilized. Other metabolites may have accumulated in the medium and we have also shown that glucose is incorporated into lipid by testicular spermatozoa (unpublished observations).

The most striking differences found in the metabolic pattern between ejaculated and testicular spermatozoa were the greater oxygen uptake and lower lactic acid production of the latter. Differences have been observed in the metabolic pattern and enzymatic activities between ejaculated and epididymal spermatozoa from the ram and the bull, but these were only minor[18–20]. The present investigations have demonstrated that there are metabolic differences between testicular and ejaculated spermatozoa that may be the result of the process of 'maturation'.

We thank Dr. B. D. Stacy for the electrolyte and osmotic pressure measurements and Mr. N. T. Hinks for testosterone determinations.

VETERINARY SCIENCE

Blood Adenine Nucleotide Levels in the Normal and the Acetonaemic Dairy Cow

In man, various diseases cause the concentration of the adenine nucleotides in the blood to deviate from the values found in normal circumstances[1]. Determination of the levels of the adenine nucleotides in the blood thus provides information on the state of health and the metabolic condition of the patient.

It might be expected that, in the cow, variations of the levels of these nucleotides in the blood would also give some indication of the metabolic condition of the animal. However, although the concentrations of the adenine nucleotides in human blood appear to be well documented (for example, Laudahn[1]), there are few values available for bovine blood. Consequently, in connexion with a study of metabolic changes occasioned by the disease of bovine ketosis, the levels of the adenine nucleotides in the blood of the normal dairy cow were determined, and compared with those found in ketosis. Spontaneous primary bovine ketosis, also termed acetonaemia, is a disease which can affect dairy cows in the early stages of lactation, causing a decline in milk yield, and which can therefore be of considerable economic importance.

The concentrations of ATP, ADP and AMP in blood samples taken from dairy cows were estimated using the 'Test Kits' supplied by C. F. Boehringer und Soehne *G.m.b.H.*, Mannheim, West Germany. Blood was withdrawn from the jugular vein and collected directly in ice-cold 0·6 M perchloric acid solution and the mixture shaken vigorously. Afterwards, the blood proteins were removed by centrifugation and the levels of the nucleotides were estimated in the clear supernatant either directly (ATP) or after neutralization (ADP and AMP). ATP estimations were always carried out on the day the animal was bled. ADP and AMP estimations were performed on either the same or the following day. In the latter case, the neutralized samples were stored frozen. All manipulations before assay were performed at 0°–2° C.

Table 1. Adenine Nucleotide Concentrations in the Blood of Normal Cows and of a Cow Suffering from Spontaneous Primary Ketosis

	Day	Acetoacetate mg%)	ATP (mg%)	ADP (mg%)	AMP (mg%)
Mean of 12 normal cows	—	—	6 65	1 51	0·460
± *S.E.*			±0 46	±0 15	±0 024
Acetonaemic cow	1	5 96	6·42	2 16	0·478
	2	5·17	7·59	1 28	0 622
	3	6 11	5 55	1 17	0 368
	4	4 80	6 73	1·05	0 542
	14	0 71	6 75	Not determined	
	22	0·83	7·69	Not determined	
Mean	—	—	6·79	1 42	0 503
± *S.E.*			±0·32	±0 25	±0 053

The days on which blood samples were taken from the acetonaemic cow are numbered from the day on which the disease was first apparent. Samples were taken during the height of the disease and during the recovery period as indicated by the blood acetoacetate levels measured concurrently.

Table 1 shows the mean values for the concentration of the three nucleotides in the blood of twelve apparently normal animals. The standard error of the mean for each nucleotide is also given. It is clear from these figures that in the dairy cow the blood concentrations of the nucleotides are uniformly at the lower end of the range of values for human blood[1]. In Table 2, the values for individual animals are recorded. The cows were either of the Ayrshire or Friesian breeds, and were being used in a nutritional experiment involving different ratios of carbohydrate to protein in the diet. Of the twelve animals, all but one were in milk. Inspection of Table 2 indicates that these differences did not appear to cause a significant unidirectional alteration in the concentration of any of the nucleotides. Apart from this, a rather wide variation in the levels of all three nucleotides was observed (3·98—9·40 mg per cent

Table 2. ADENINE NUCLEOTIDE CONCENTRATIONS IN THE BLOOD OF NORMAL COWS

for ATP, 0·74–2·24 mg per cent for ADP, and 0·302–0·592 mg per cent for AMP).

Considerable evidence exists that, in acetonaemia, tricarboxylic acid cycle activity is depressed[2,3]. It might be expected that this would lead to lower ATP concentrations, and higher ADP concentrations, in the tissues and in the blood of the animal suffering from the disease, unless other energy-generating reactions (for example, fatty acid oxidation) were stimulated to compensate for decreased cycle activity. The occurrence of a case of spontaneous bovine ketosis at this institute provided an opportunity to determine whether the blood levels of ATP, ADP and AMP were altered during acetonaemia. Table 1 shows the levels of these nucleotides found in the blood of the animal while acetonaemic. Furthermore, the levels of ATP are also shown during the recovery of the animal, which is indicated by the decline of acetoacetate concentration in the blood.

It is evident from Table 1 that the mean values for the concentrations of the three nucleotides in the blood of the acetonaemic animal were similar to the mean values for these concentrations in the normal animal. Moreover, no significant change in the concentration of ATP occurred during recovery from acetonaemia, as measured by the decline in acetoacetate. Although some acetoacetate was still present at the 14th and 22nd days, this does not mean that the animal was still acetonaemic. Using the enzyme D(−)-β-hydroxybutyrate dehydrogenase for estimation of acetoacetate[4], up to 1·0 mg per cent of this substance has been found in the blood of apparently normal cows at Compton. Acetoacetate thus appears to be a normal constituent of cow's blood in these small quantities.

In summary, the levels of the three adenine nucleotides have been determined in the blood of apparently normal cows. Values within the normal range were found in a cow suffering from spontaneous primary ketosis. If tricarboxylic acid cycle activity is depressed in the acetonaemic cow, then the level of ATP may be maintained by other oxidative reactions. Alternatively, it is possible that in the cow the levels of the adenine nucleotides in the blood may not be representative of alterations in the tissues. It is hoped, therefore, to supplement this investigation with a study of adenine nucleotide levels in the tissues of the acetonaemic dairy cow.

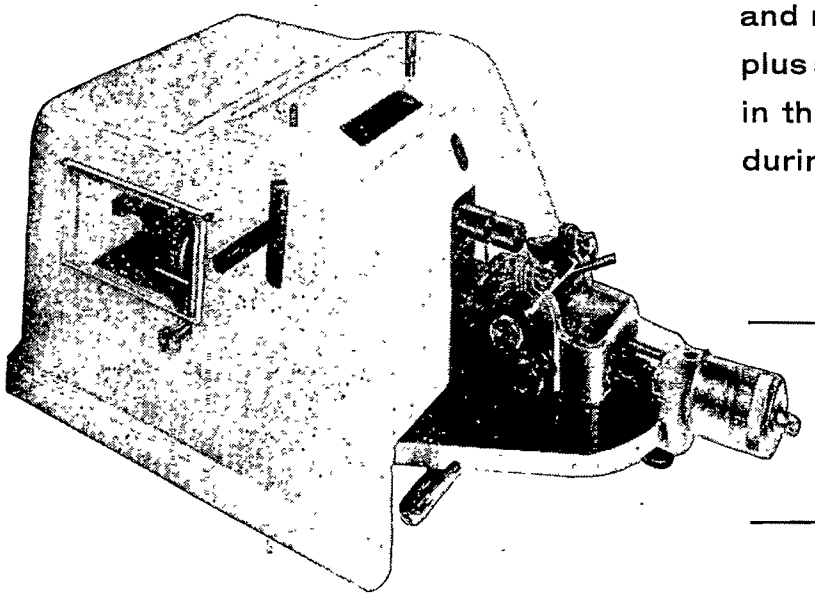
PHARMACOLOGY

Effect of Amphetamine and Catecholamines on Startle Response and General Motor Activity of Albino Rats

THE reactions of the mammalian organisms to external stimuli are affected, according to Hess[1], by a subcortical system co-ordinating visceral, somatic and psychic functions. This system consists of two separate and antagonistic divisions: ergotrophic and trophotrophic. The former produces a generalized increase in sympathetic activity with increased skeletal muscle tone, arousal and increased response to external stimuli. This is contrasted with the trophotrophic system which serves a recuperative and protective role and is characterized by an increase in parasympathetic activity, decreased muscle tone, sleep and decreased response to external stimuli. Brodie[2] has cited evidence that norepinephrine and serotonin may qualify as neurohormones for the two divisions respectively and claims that further evidence for norepinephrine as the ergotrophic hormone is that dopa (amino-acid precursor of norepinephrine) induces typical ergotrophic effects. It is felt by Brodie and associates that many of the lipid soluble congeners of norepinephrine easily penetrate the blood-brain barrier to stimulate the central adrenergic receptors of Hess.

In support of Brodie's position, the awakening effects of the phenylamines (specifically *m*-tyrosine and dopa) following administration of reserpine have been said to be due to their eventual transformation to catecholamines[3,4] (recalling that the sequence of steps in epinephrine formation is: tyrosine, dopa, dopamine, norepinephrine, epinephrine). However, recent work by Lee, Cho and Dobkin raised doubts as to the validity of the idea that lipid soluble precursors of epinephrine easily penetrate the blood-brain barrier and lead to the same kind of stimulation in the central adrenergic receptors of Hess's ergotrophic division. Using fairly large dose levels of catecholamines, these workers found that the norepinephrine–epinephrine precursors did not produce similar activity in their animals. Furthermore, tyrosine, tyramine and dopamine "seemed to produce a peculiar sedative state characterized by . . . the general appearance of sleep". In addition, they also noted a lack of dose-response relationships following administration of these drugs. It was felt by these investigators that if these phenylethylamines exert an effect on the ergotrophic system similar to that of norepinephrine and epinephrine (a result expected because of their structural similarity, comparable lipid solubilities and ability to undergo a stepwise transformation toward catecholamines), then they should produce a more obvious and essentially similar activity[5]. They found, furthermore, that the effect of the catecholamine precursors combined with the short-acting hypnotic, methohexital, definitely prolonged maintenance time of anaesthesia.



It was the purpose of this project to investigate the effect of small dose levels of the norepinephrine precursors with respect to (*a*) spontaneous motor activity, and (*b*) response to auditory stimulation. The latter parameter was selected to provide an additional means of evaluation of these drugs to determine if drug effect as measured by one means (enhancement or depression of observed activity) may be different when compared with effect on response to startle stimulation.

Because of the close structural similarity between amphetamine and the catecholamines, it was included in this experiment. It is believed to act centrally by releasing dopamine, and it appears to prevent the uptake of circulating norepinephrine by the tissues[6,7].

Subjects were eighty-four Charles River albino male rats ranging in weight from 75 to 130 g. Physical activity of the rat was measured as mm deflexion of a pen recorder through conversion of mechanical input (that is, the

Highly Successful ULTRA-MICROTOME

The outstanding success of this microtome for electron microscopy has resulted in rapidly-increasing sales to discriminating users, in both the New and Old Worlds and the instrument is right at the top of its class. This is due to its unsophisticated design, simplicity and reliability in operation, plus skill and workmanship in the Cambridge tradition during manufacture.

Some of the outstanding advantages:

- Strip hinge suspension—no friction or backlash
- Mechanical specimen advance—accurate calibration of section thickness
- Fine adjustment of automatic advance—steps of 5mμ from zero to 150mμ
- Full range of knife adjustments—tilt, traverse, rotation and micrometer advance
- Large specimen travel 0.1 mm by automatic advance
- Large specimen area—cuts 3 x 4 mm if needed

The Cambridge Ultra-Microtome is gravity-operated, and has no motor to cause vibration.

Send for List 344N. For future publications, ask for Mailing Form N/21/5/66

EH5

activity of the rat) by a force displacement transducer. Each subject was placed individually in an enclosed wire cage (8 in. × 8 in. × 7 in.) which was positioned on the floating platform of a mechanical scale. Attached to this platform was an 18-gauge needle which was led through the wire loop of an independently suspended force displacement transducer. Movement of the platform was thus measured as alteration in voltage which in turn was recorded as pen deflexion on the polygraph.

The noise stimulus was produced by a Grason–Stadler white noise generator, amplified by a white amplifier to 52 dB (absolute reference scale). A Gerbrands tape timer programmed noise generation for a duration of 1 sec every 4 min.

Drugs employed were DL-tyrosine, DL-3-4-dihydroxyphenylalanine (dopa), 3-hydroxytyramine-HCl (dopamine), and amphetamine sulphate. Tyrosine and dopa were dissolved in 0·1 N sodium hydroxide saline solution and *p*H adjusted to 10; dopamine and amphetamine were dissolved in 0·9 per cent saline. Dosages used were 0·5, 3 and 10 mg/kg for each drug.

Eighty-four subjects were divided into 14 groups, with six subjects per group. Each of the twelve groups was injected with one of the three dose levels of a particular drug. The concentration of each solution was adjusted to enable a constant volume (0·1 ml.) of drug to be injected into each rat. One group of six subjects was injected with 0·1 ml. of saline as control for dopamine and amphetamine and a second group of six subjects with 0·1 ml. sodium hydroxide saline solution (*p*H 10) as control for tyrosine and dopa.

Each of six rats per dose per drug was subjected to three white noise stimuli of 52 dB, duration of 1 sec, at 4-min intervals. Ten minutes were allowed for absorption of the intraperitoneally administered drug before the first noise stimulus was applied. Pen sensitivity was adjusted such that maximum deflexion would record 45 mm above base line. The response to each stimulus was recorded and the average response for each group of six subjects was determined.

Though the response to noise stimulation was quantitated and subjected to statistical analysis, evaluation of the animal's bodily motor activity was subjectively made by direct observation. Also, the tracings revealed any subject movement made, and these permitted further evaluation of this parameter. General motor activity of any one group was graded as 0, 1 and 2, plus or minus units above or below, respectively, the activity of the control for that group of subjects. Types of behaviour on which grading was made included judgments of the subject's level of excitement or depression by his walking, sniffing, climbing with forepaws up side of cage, etc. Observations were recorded over a 12-min period, beginning 10 min after injection of the drug. The startle response data were evaluated by a simple analysis of variance and subsequent comparisons were carried out by the Newman–Keuls procedure between groups. In no case was the response to any one noise stimulus significantly different ($P > 0·10$) from the response to the other two within any particular group. Thus, for each group, responses to the three stimuli were summed and the average used in comparisons between groups. Results for each group are shown in Table 1.

As may be seen from Table 1, 0·5 mg/kg dopa exerted a quieting effect on general motor activity as compared with control, while at 10 mg/kg no appreciable difference was noted. Lee, Cho and Dobkin observed an excitation with a dose level of 600 mg/kg (ref. 5). Response to noise stimulation of the 3 mg/kg group was significantly less ($P < 0·05$) than the response of both the lower and higher dosage groups.

The sedative effect of tyrosine as observed by Lee *et al.* at a dose level of 100 mg/kg was also noted in this experiment at dose levels of 3 and 10 mg/kg. However, the 0·5 mg/kg group showed mild excitement. The results of noise stimulation for the tyrosine group were not significantly different between groups ($P > 0·05$) although qualitative differences were noted. The startle responses of the 3 and 10 mg/kg groups were slightly greater than control, while the response of the lowest dosage group was comparable to that of control. The effects of the two highest dose levels of tyrosine were different from the two parameters of measurement used; that is, in one case (startle) a greater response was elicited as compared with control, where with general motor activity a decrease from control obtained.

Table 1. RESPONSE OF NAIVE RATS TO WHITE NOISE

Drug	Dose* (mg/kg)	S.E.	Startle response† (mm pen deflexion)	Spontaneous activity

	10·0	2·26	38	2
Control	—	4·04	24	—

* Six animals per dose per drug.
† Each indicated pen deflexion represents the mean value of 18 deflexions per group (6 rats × 3 stimuli per animal).

Dopamine at the three dose levels used had no influence on general motor activity, a result comparable with the findings of Lee *et al.* However, response to noise of the 3 and 10 mg/kg groups was greater than that of the lowest dosage group and control though results were not statistically significant ($P > 0·05$).

In the case of amphetamine, the degree of startle response varied directly with the dose. At 0·5 mg/kg this response was observed to be less than control. Both the 3 and 10 mg/kg groups had responses greater than control, with the latter significantly greater ($P < 0·01$) than the others. An increase in spontaneous activity was observed only in the highest dosage group.

In summary, the testing of catecholamines at these low dosage levels revealed variations in effect which were dependent on (*a*) dose, and (*b*) the particular parameter selected for observation. In one case, the measurement of response by one method was just the opposite of that as measured by the second method. Furthermore, changes in dose level caused a redistribution of observed effects, which were not necessarily proportional to dose alteration. The response to some injections was not what might have been expected of truly ergotrophic drugs and epinephrine precursors. Though many observations seem to support the view that catecholamine levels in the brain are involved in the control of psychomotor activity, results obtained in this experiment with low dose levels support evidence that psychomotor effects of the catecholamine precursors cannot be considered in the same category as epinephrine.

IMMUNOLOGY

A γ-Globulin Genetic Factor related to Gm(a) but localized to a Different Portion of the same Heavy Chains

PREVIOUS investigations have indicated that Gm(a)* and Gm(f)* are genetic characters localized in various areas of the major heavy chain class[1-3] of human γG globulins. These determinants, detected as antigens, segregate in most populations, as if controlled by allelic genes, and occur independently in myeloma proteins from Caucasians. A previous report indicated that specific reagents for the human genetic factors can be produced by immunizing rabbits with myeloma proteins[4]. In order to analyse in a more satisfactory way the genetic control of different portions of the heavy chains, it seemed desirable deliberately to immunize with critical protein fragments in order to disclose additional genetic sites believed to be present but not detected by available antisera.

The Fab portion of Gm(a+) myeloma proteins lacks any detectable genetic factor[5,6] and this was used as the antigen for rabbits. The antisera obtained were absorbed with normal human serum of various phenotypes and were then tested for differential agglutination against a battery of incomplete anti-D coats on human red blood cells. Antisera which appeared specific were investigated further by inhibition with selected proteins[5,6]. In this way a new factor, tentatively called Gm(z)*, was detected.

The Gm(z) genetic factor was found in the Fab portion of papain split FII γ-globulin, while Gm(a) was detected in the Fc portion as previously described[5,6]. All Gm(a+) myeloma proteins from Caucasians and Negroes were also Gm(z+) (Table 1). Papain splitting of these doubly positive myeloma proteins showed the Gm(z) determinant in the Fab peak separated by zone electrophoresis, while the Gm(a) factor was present in the faster migrating Fc peak. Pepsin treatment destroyed the Gm(a) determinant and left intact the Gm(z). Inhibition at a concentration as low as 0·008 mg/ml. was obtained for the active fragments. Isolated light chains failed to inhibit even at 2 mg/ml. All preparations of heavy chains from FII and myeloma proteins were inhibitory, but to a lesser degree than the intact protein and Fab fragments. Parallel investigations with Gm(f) indicated that Gm(z) and Gm(f), although on different myeloma proteins, behaved very similarly in the aforementioned experiments and were localized to the Fd portion of the heavy chains. Gm(z) was found only in myeloma proteins of the We(γ_{2b}) sub-group—as was the case for Gm(f).

The phenotype frequencies of various populations are shown in Table 1. In the Caucasian, Negro and Japanese groups, Gm(a) and (z) are concordant, but there are many discordant Gm(a+z−) sera in the Chinese and Easter Islanders. The latter groups affirm the non-identity of genetic factors Gm(a) and (z). Further evidence for this difference was obtained from the study of a Chinese myeloma protein which was previously shown to be Gm(a+f+) in striking contrast to all Caucasian and Negro myeloma proteins. This protein was Gm(z−).

The data from these investigations are consistent with the possibility that Gm(z) and (f) segregate as co-dominant alleles. They are the only genetic factors found so far on the Fd portion of the heavy chain[2,3]. None of the more than 300 sera tested were negative for both (z) and (f). A significant finding is that in all the groups investigated (Table 1) the frequencies of both factors and the proportion of heterozygotes are compatible with such allelism—assuming different gene frequencies for Gm(f) and (z). In the Chinese, where the frequency of (f) is high, as would be predicted, (z) is low, whereas in the Negro and Japanese populations the reverse is true. Family investigations of 42 Caucasian and 26 Easter Island progeny support the behaviour of Gm(f) and (z) as alleles.

* Only myeloma proteins of the We(γ_{2b}) class are shown.
† Easter Islanders.

The accumulated evidence indicates that in Caucasians the genes controlling the We-type heavy chain would be Gm^{az} and $Gm^{a\text{-}f}$. In Negroes the predominant gene would be Gm^{az}. On the other hand, in Chinese and the Easter Islanders, the gene Gm^{af} as well as Gm^{az} must be postulated to account for the large number of discordancies between Gm(a) and (z), their phenotype distributions, and the Chinese myeloma protein. The previous suggestion that the Gm^{af} gene arose by an intragenic cross-over[7] is compatible with the present observations, as the association of Gm(z) with Gm(a) disappears when Gm(f) becomes associated with Gm(a).

Two genetic factors are therefore now available which seem to be present on the same heavy chains, but in different areas readily separated by papain splitting. There has been considerable speculation on the possibility that the heavy chains of γ-globulin actually represent two chains under independent genetic control[8]. Some evidence regarding this point has been obtained from the present investigations. Gm(z) located on the Fd fragment seems to be controlled by the same gene as Gm(a) on the Fc fragment. The exact position of Gm(z) on the Fd fragment remains to be determined and the possibility is not ruled out that a separate unit could still exist in another portion of the fragment.

This investigation was supported by the U.S. Public Health Service. We thank Dr. L. Mårtensson for the Japanese sera and the Chinese myeloma protein.

PATHOLOGY

Cure of Mice bearing Advanced Plasma Cell Tumours with Aniline Mustard: the Relationship between Glucuronidase Activity and Tumour Sensitivity

THE unique action of aniline mustard (I) and closely related analogues in curing mice bearing advanced plasma cell tumours (up to 8 g in weight) was recently described[1]. From an investigation of a series of derivatives related to aniline mustard it was postulated that this compound was hydroxylated in the liver to form the highly toxic *p*-hydroxyaniline mustard (II), and then detoxified by conversion to the glucuronide or sulphate. A high glucuronidase or sulphatase activity of the tumour would result in the selective release in the tumour of the toxic *p*-hydroxy derivative:

I II

The levels of the enzymes β-glucuronidase and aryl sulphatase have been determined in two plasma cell tumours (*ADJ/PC5* and *ADJ/PC6A*), both very sensitive to treatment with aniline mustard, and compared with the levels of these two enzymes in two other solid transplanted tumours (sarcoma 180 and *NK* lymphoma) which, although growing in the same strain of mouse (*BALB/c-*), are quite refractory to treatment with aniline mustard when well established. β-Glucuronidase was assayed in whole tumour homogenates by the method of Talalay *et al.*[2], except that incubations were carried out at *p*H 7 and 10 per cent sulphosalicylic acid (SSA) was used to precipitate proteins at the end of the incubation period. While giving a clear supernatant SSA had the disadvantage that it also caused precipitation of some of the released phenolphthalein, the amount of phenolphthalein lost being directly related to the protein concentration of the homogenate. It was found that tissue homogenized in ten times its weight of isotonic potassium chloride provided the best conditions for the assay. At this protein concentration there was only a small loss of phenolphthalein on precipitation with SSA and sufficient enzyme was present to release a suitable amount of phenolphthalein during the 1 h incubation period. Errors due to loss of phenolphthalein were allowed for by setting up internal phenolphthalein standards with each experiment, and ensuring the protein concentration of each homogenate was similar. An aliquot of the homogenate was used for estimation of protein content and results were expressed as μg phenolphthalein released per mg protein per hour. Each value recorded in Table 1 is the mean of at least six independent determinations. Sulphatase was assayed as described by Dodgson and Spencer[3]. Internal *p*-nitrophenol standards were used and the results were expressed as μg *p*-nitrophenol released per mg protein per hour. Tumours were taken when about 1–2 g in weight and non-necrotic areas were selected.

Table 1

Tissue	Aryl sulphatase (μg *p*-nitrophenol/mg protein/h)	β-Glucuronidase (μg phenolphthalein/mg protein/h)	Established tumour regressions† (%)

* In the *BALB/c*+ mouse.

† Percentage of complete regressions of established tumours (1–2 g in weight) after treatment with the maximum tolerated dose of aniline mustard.

Table 1 shows the sulphatase and glucuronidase activities of established tumours (1–2 g in weight) and their response to treatment with maximum tolerated doses of aniline mustard. A direct relationship can be seen between β-glucuronidase activity and sensitivity to the nitrogen mustard. The two plasma cell tumours with levels five times higher than liver regress completely on treatment, while the two tumours with enzyme-levels of the same order as liver are insensitive to treatment. No such correlation applies between sulphatase-level and sensitivity. Liver and spleen are two tissues rich in β-glucuronidase[2] and all the tumours studied had levels at least as high, which is in agreement with the observation that tumours have a high level of β-glucuronidase. The two plasma cell tumours are outstanding in that their glucuronidase-level is five times higher than those tissues normally considered to be rich in β-glucuronidase. In both liver and *ADJ/PC5* plasma cell tumour the *p*H optimum of the β-glucuronidase was about 5·0 (Fig. 1). Since tumours are claimed to have a lower intracellular *p*H than other tissues[4,5] then, *in vivo*, the difference in β-glucuronidase activity between liver and tumour may be even greater

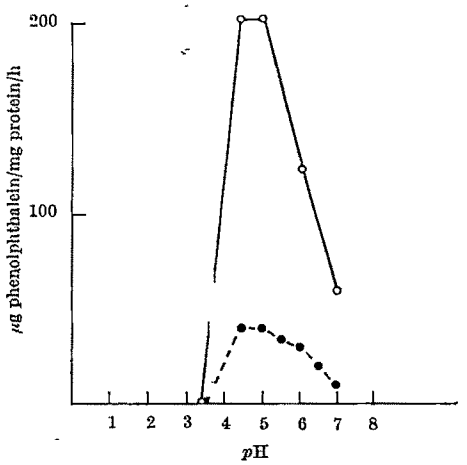

Fig. 1. β-Glucuronidase activities of homogenates of liver and *PC5* plasma cell tumour at different *p*H. ○, *ADJ/PC5* plasma cell tumour; ●, mouse liver

than indicated by the values in Table 1. In both tissues the glucuronidase was equally inhibited by 1 : 4 saccharolactone. Whether the intracellular location of β-glucuronidase differs between liver and the *PC5* tumour is not certain, although in both tissues addition of 'Triton *X*', which destroys lysosomes, before incubation gives a 50 per cent increase in enzyme activity. The enzyme uridine diphosphoglucuronyl transferase, which can be taken as a measure of the ability of the tissue to carry out glucuronide formation, was present in liver homogenate but not in *PC5* tumour homogenate when measured by the method of Storey[6].

These findings add support to the hypothesis that the extreme sensitivity of the two plasma cell tumours to aniline mustard is a consequence of glucuronide formation in the liver followed by breakdown of the glucuronide in the tumour leading to the formation of a toxic derivative. If these findings are confirmed, for example, by synthesis of the glucuronide of *p*-hydroxyaniline mustard and demonstration of its selective action against plasma cell tumours, then they may be exploited in a number of ways: (*a*) Assays of biopsy specimens of human tumours may reveal tumours which have levels of β-glucuronidase much higher than liver and which may be expected to be particularly sensitive to aniline mustard. (*b*) In tumours with high β-glucuronidase levels, this may be exploited by using not only aniline mustard glucuronide but also the glucuronides of other cytotoxic compounds which should be released selectively in the tumour. (*c*) Analogously, if tumours are found with exceptionally high sulphatase- or phosphatase-levels, the sulphate or phosphate of *p*-hydroxyaniline mustard may be used with advantage.

We thank Miss P. Finn and Miss G. Howard for technical assistance. VIROLOGY

Rapid Method for demonstrating Intracellular Pleuropneumonia-like Organisms in a Strain of Hamster Kidney Cells (*BHK* 21 *C*13)

THERE is as yet no ideal method for demonstrating pleuropneumonia-like organisms (PPLO) in tissue culture. Isolation of an infecting strain, particularly if this is intracellular, is frequently technically difficult and is always time-consuming. Cytological examination of monolayer cultures for evidence of PPLO infection is rapid, but staining artefacts may give rise to difficulty in interpretation. Indirect evidence of infection by transmission to susceptible 'indicator cultures'[1] is only valid if these can be maintained free from accidental contamination by PPLO.

We became acutely aware of these problems when PPLO were isolated from a strain of hamster kidney cells (*BHK* 21 *C*13)[2] in use in this laboratory. Two factors led us to believe that infection was intracellular. PPLO could rarely be isolated from the supernatant medium from cell cultures grown in the absence of antibiotics, but could readily be isolated when the cells were mechanically disrupted in a Griffiths tube and the cell debris plated on a suitable medium (Difco PPLO agar with 20 per cent inactivated horse serum and 5 per cent fresh yeast extract) which was then incubated anaerobically at 37° C for 5 days. In addition, PPLO could still be isolated from disrupted cells even after continuous cell culture for 3 weeks in medium containing kanamycin sulphate ('Kannasyn') in a concentration of 500 μg/ml., although the organism, when tested *in vitro*, was sensitive to a dose of 25 μg/ml.

Since PPLO are known to contain deoxyribonucleic acid (DNA), a modification of the fluorescent Feulgen staining technique[3] was developed which demonstrated the presence of abnormal foci of extranuclear DNA in infected cells. Subsequent investigations showed that these contained PPLO antigens.

Monolayer cultures of *BHK* 21 *C*13 cells infected with PPLO were grown in coverslips until a semi-confluent monolayer was obtained. Cultures of *BHK* 21 *C*13 cells from which PPLO had never been isolated served as a control. These preparations were washed twice in phosphate buffered saline (*p*H 7·2) and fixed for 10 min in formaldehyde saline (4 per cent) at room temperature. Preparations were then processed as follows. (Unless specifically stated otherwise, all procedures were carried out at room temperature.)

(1) Washed twice in distilled water (5 min each). (2) Immersed in 1·0 N hydrochloric acid at 60° C for 10 min to hydrolyse cell ribonucleic acid (RNA). (3) Hydrolysis stopped by plunging preparation into ice-cold water. (4) Washed twice in distilled water (5 min each). (5) Stained for 20 min in acriflavine–Schiff solution (acriflavine hydrochloride, 250 mg; potassium metabisulphite, 500 mg; 0·1 N hydrochloric acid, 50 ml.). (6) Washed twice in distilled water (5 min each). (7) Brought to 70 per cent ethyl alcohol by successive immersion in 20, 40 and 70 per cent ethanol. (8) Rinsed twice for 10 min in acid alcohol (0·1 N hydrochloric acid, 30 ml.; absolute ethanol, 70 ml.). (9) Rehydrated by immersion successively in 40 per cent and 20 per cent ethanol; mounted in buffered glycerol (glycerol, 90 ml.; phosphate buffered saline, *p*H 7·2, 10 ml.) and sealed with paraffin wax.

The preparations were then examined microscopically in short wave-length light (approximately 400 mμ: light source '*HBO* 200' mercury vapour lamp: Schott exciter filters *BG* 38/2·5, *BG* 12/4, Schott barrier filters 53/44).

In infected and in control preparations, cell nuclei fluoresced orange against a background of very pale yellow cytoplasmic fluorescence. Orange fluorescent foci were observed in the perinuclear region of 15–80 per cent of cells in infected preparations. The number of foci varied from one to one hundred per cell. The majority of cells had more than ten foci. In control preparations of uninfected cells, fewer than 3 per cent showed fluorescent foci. No cell had more than one focus. In both infected and control cells foci were still seen after treatment with ribonuclease (recrystallized five times; 100 μg for 8 h) but were not seen in cells which had been treated with deoxyribonuclease (recrystallized once; 100 μg/ml. for 8 h).

A comparison was made between cultural methods and fluorescent Feulgen staining as a means of detecting PPLO in cultures of *BHK* 21 *C*13 cells. Culture and cytological examination were carried out independently. The results are shown in Table 1.

Table 1. COMPARISON BETWEEN CULTURE AND FLUORESCENT FEULGEN STAINING AS A MEANS OF DETECTING PLEUROPNEUMONIA-LIKE ORGANISMS (PPLO) IN STRAINS OF HAMSTER KIDNEY CELLS (*BHK* 21 *C*13)

No. of specimens from which PPLO were isolated	Percentage of cells showing fluorescent foci	No. of specimens from which PPLO were not isolated	Percentage of cells showing fluorescent foci
22	15–84 (average, 30)	10	0·5–1·9 (average 1·0)

The agreement between the results of culture and of fluorescent Feulgen staining is good, and it is suggested that fluorescent Feulgen staining is a reliable, quick method for detecting intracellular PPLO.

The likelihood that the majority of fluorescent Feulgen-positive foci in infected cells might represent sites of PPLO multiplication was increased when it was found that they fluoresced specifically when infected cell preparations were exposed to rabbit prepared antiserum against *Mycoplasma hominis* followed by sheep anti-rabbit serum conjugated with fluorescein isothiocyanate. Control uninfected preparations when examined by this technique showed no specific fluorescence. It was concluded that the fluorescent Feulgen-positive foci observed in a small preparation of these cells are probably micronuclei.

AGRICULTURE

Absence of Bitterness in Navel Oranges from Rooted Cuttings

MOST Washington Navel oranges yield a juice which eventually becomes unacceptably bitter. The bitterness, which develops slowly on standing or rapidly on heating, is due to limonoid compounds, principally limonin, present in the fragments of albedo and segment walls incorporated into the juice during extraction. As the fruit ripens, the bitterness becomes less evident, and the rate at which bitterness decreases during ripening is affected markedly by the rootstock on which the tree is grown. Thus, Marsh[1] in California and Kefford and Chandler[2] in Australia showed that some rootstocks (for example, trifoliate orange) promoted early disappearance of bitterness, while others (for example, rough lemon) encouraged high levels of bitterness at and beyond normal harvesting maturity. In the latter work, organoleptic tests were supported by the yields of crude limonin extracted from the peel of the oranges used in preparation of the juice.

When an unidentified Navel cutting was used as a rootstock for a Washington Navel scion the fruit showed

no bitterness late in the season[1]. We now report negligible bitterness and low limonin contents in juices from Washington Navel fruits taken from trees grown as cuttings on their own roots. Qualitative observations on the absence of bitterness made on glasshouse fruit in 1962 were extended to field fruit in the 1963 and 1964 seasons and confirmed by assays of the limonin content of the juice[2].

The cuttings were taken from Washington Navel trees growing on rough lemon rootstock, and were propagated by the method of Gates, Bouma and Groenewegen[4]. After two months the rooted cuttings were either planted into the field not far from the mother trees or grown in a glasshouse in clean river sand treated with nutrients and trace elements. The plants grew vigorously in the field and in the glasshouse and have remained healthy and productive throughout the 2–6 years since they were propagated.

Fruit was taken for analyses from the first crop produced by the glasshouse cuttings, from the fourth and fifth crops from the field cuttings, and also from mature trees growing on rough lemon, sweet orange and trifoliate orange rootstocks, including trees in the same field experiment as the mother trees. The juices were extracted and processed by standard procedures[2], and were stored for 2 weeks at 0° C before examination for soluble solids, citric acid, limonin and bitterness. The results are recorded in Table 1.

Table 1. JUICE CHARACTERISTICS OF WASHINGTON NAVEL ORANGES FROM TREES ON OWN ROOTS AND ON ROOTSTOCKS

Root system	Age of tree (months)	Date of pick	Soluble solids (per cent)	Citric acid (per cent)	Limonin (p.p.m.)	Bitterness
Own roots	18*	30.6.63	9·2	0 82	3·5	None
Own roots	18*	30.6 63	10·1	0·88	3·0	None
Own roots	50	30.6.63	8 7	1·15	7 5	None
Own roots	50	18.7.63	11·2	1·18	4 5	None
Sweet orange	276	9 7.63	11·0	1·31	16·0	Strong
Rough lemon†	276	9.7.63	8·8	1 29	24·0	Extreme
Own roots	19*	27 7.64	11·2	1·13	3·0	None
Own roots	63	27.7.64	9·7	1·18	7·5	Doubtful
Trifoliate orange	60	21.7.64	12·0	1·15	8 0	Slight
Sweet orange	60	21 7.64	10·1	1·13	11·0	Moderate
Rough lemon	60	21.7.64	9·6	1·07	17·0	Strong
Own roots	64	4.9 64	12·2	0·99	6·5	None
Rough lemon†	290	4.9.64	11·6	1 02	11 5	Moderate

* Grown in glasshouse; other trees grown in field.
† Similar scion-rootstock relationship to mother trees.

The relationship between bitterness and limonin content agrees with our observations[3] that orange juices containing less than 6 p.p.m. of limonin are not bitter, those containing more than 9 p.p.m. are bitter, and those containing 24–30 p.p.m. are extremely bitter. The low limonin contents of the juices given by fruits from rooted cuttings point to a direct influence of the root system of Washington Navel trees on the amount of the bitter principle present in the fruit. At the same time, oranges from rooted cuttings were normal in composition and general quality, and gave juices of satisfactory flavour, both before and after processing. The practical application of these observations will depend on the health and productivity of rooted cuttings as commercial orchard trees.

Effect of Calcium and Strontium on the Preferential Formation of an Adenosine Triphosphatase in Wheat Roots

THERE are a number of factors which may induce the formation of a specific enzyme in living tissue homogenates[1]. In keeping within the definition established in ref. 1, the prefix 'induced' restricts the type of enzyme formation to one in which a specific inducer molecule is shown to be necessary in the formation of a particular enzyme. The present communication concerns the effects of the inorganic cations calcium and strontium on the selective formation of an adenosine triphosphatase (ATPase) of wheat roots. To distinguish this type of rather indirect effect, the term 'preferential' enzyme formation will be used.

Wheat roots were germinated in the dark and allowed to grow into solutions containing only the individual calcium or strontium salts. After 7 days the roots were excised and ground in the cold in a 0·05 M *tris*-(hydroxymethyl)-aminomethane buffer at *p*H 7·5 containing 0·005 M sodium ethylenediamine tetra-acetate (EDTA). A solution volume : root weight ratio of 2 was used in grinding. After removal of the cell debris, the mitochondria were separated by centrifugation at 20,000*g* for 15 min. The pellet was resuspended in the original volume of buffer and dialysed for 24 h in 0·001 M *tris* at *p*H 7·5. Separation in this manner undoubtedly resulted in the mitochondria being broken[2] and incapable of oxidative phosphorylation.

Table 1. EFFECTS OF CALCIUM AND STRONTIUM CONCENTRATION ON ROOT GROWTH AND ATPASE ACTIVITY

Growth treatment	Root weights (g/50 plants)	Cation added to assay*	ATPase activity†
H_2O	4 70	—	5 6
		Ca	15 2
		Sr	2·4
10^{-4} M calcium chloride	8·20	—	23·2
		Ca	47·7
		Sr	5 8
10^{-2} M calcium chloride	7·60	—	20 8
		Ca	42·6
		Sr	5·0
10^{-4} M strontium chloride	6·40	—	13·0
		Ca	26 3
		Sr	4·2
10^{-2} M strontium chloride	2·70	—	6·6
		Ca	15·3
		Sr	2·3

* 5 μmoles per tube, added as chloride salts.
† Expressed as μmoles P_i released per mg protein in 30 min.
Other conditions as presented in the text.

The ATPase activity was measured by determination of inorganic phosphate liberated from adenosine triphosphate (ATP) with an assay procedure similar to that used with spinach chloroplasts[3]. The basic reaction mixture contained 0·05 M *tris*-maleate buffer at *p*H 5·5, 5 μmoles ATP and an appropriate portion of the particulate enzyme preparation in a total volume of 2 ml. The incubation was conducted at 30° C for 30 min and reaction stopped by the addition of 4 ml. of cold 10 per cent trichloroacetic acid. Protein content was estimated from an aliquot of the enzyme preparation by the Folin-Ciocalteau method[4].

In an investigation undertaken to determine the possible involvement of an ATPase from wheat roots in ion uptake[5], it was noted that the specific activity of the ATPase varied with the calcium level of the root growth medium. The addition of calcium to the enzyme reaction mixture considerably enhanced the ATPase activity, whereas the chemically similar ion strontium inhibited the enzyme activity[5] (see also Table 1). The effects of varying concentrations of these two cations on root growth and synthesis of the ATPase are presented in Table 1. Root growth was increased in the two higher-level calcium treatments and in the 10^{-4} M strontium solution, but was reduced with 10^{-2} M strontium. The specific activity of the ATPase associated with the par-

ticulate fraction was sharply increased by all the calcium and the 10^{-4} M strontium growth treatments (Table 1, column 4). The ATPase activity of the 10^{-2} M strontium treatment was similar to that of the control, even though root growth definitely was impeded. It is re-emphasized that the results are expressed per unit of protein, thus indicating preferential formation of the enzyme. When the divalent cations calcium and strontium were added to the enzyme reaction mixture, however, two opposite effects were always noted as indicated previously. This observation is quite vital as it provides evidence that the properties of the enzyme are not altered by calcium and strontium levels of the root growth medium. Thus the actual quantity of the enzyme must be changed by their presence in the growth medium.

The results of an experiment in which the strontium concentration of the growth medium was varied over a wider range are presented in Fig. 1. The values for specific activity of the ATPase are those with calcium added to the reaction mixture and the weights are for fresh roots of ten representative plants from each treatment. At 10^{-5} M strontium the specific ATPase activity was greatly enhanced, thus indicating preferential enzyme formation. In contrast to the previous experiment, no increase in specific activity of the ATPase was obtained at 10^{-4} M strontium. Our inability to define precisely the effective strontium concentration was probably due to failure in maintaining constant strontium levels in the dilute solutions throughout the growth period.

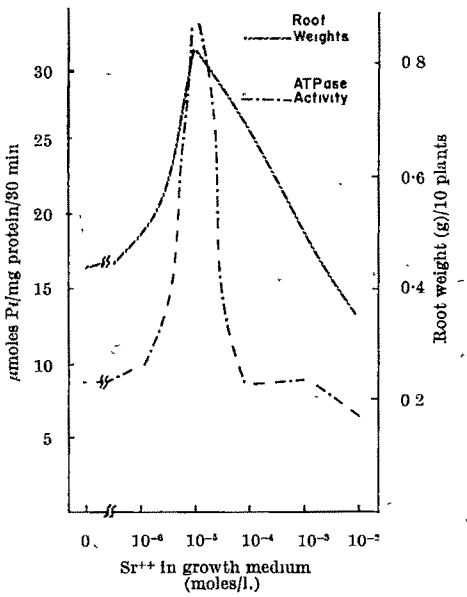

Fig. 1. Effects of altering strontium concentration of growth medium on wheat root growth and ATPase activity (particulate fraction). Strontium added as the chloride salt. ATPase assay conditions presented in the text

Considering the increased root growth associated with the higher calcium levels and limited strontium concentrations, the increase in ATPase level per plant is even more striking than that expressed on a unit protein basis. Since root growth was promoted by some strontium concentrations which did not result in increased ATPase activity, it would seem that the effect of strontium on overall protein synthesis was not identical with its effects on ATPase formation. A calcium- or strontium-activated enzyme system from guinea-pig liver which incorporates a variety of amines into proteins has been reported[6], but no attempt was made to assess the enzymatic properties of the synthesized protein.

The present results provide evidence for a rather striking and unique relationship between two possible roles of calcium and strontium in wheat roots. In one enzyme system (ATPase formation) calcium and strontium, the latter within a limited concentration range, behave in a like manner; whereas their effects on the action (ATP hydrolysis) of the very enzyme the formation of which they promote are directly opposite.

This research was supported by the U.S. Atomic Energy Commission.

PSYCHOLOGY

Biology and Schizophrenia

Huxley, Mayr, Osmond and Hoffer[1] have recently discussed transmission of what they consider the schizophrenic genotype. They have advanced the explanation of a simple, single-locus, Mendelian basis for what they regard as 'schizophrenia'. Moran[2], more recently, has combined such a hypothesis with the observations of socio-economic differences in incidence of schizophrenic diagnosis and concluded a socio-economic class-related genetic polymorphism. None of these authors, however, discussed the inconsistent observations regarding distributions of psychiatric diagnoses by different diagnosticians. The studies of Mehlman[3], as well as those of other writers[4–8], have supported doubts regarding the objectivity of recent systems of psychiatric classification and their reliability for the construction of simple, general biological concepts. Psychiatric taxonomy is essentially a symptom-oriented classification scheme, which groups patients according to symptoms rather than according to the disorders underlying the symptoms[9,10]. A simple hypothesis regarding the aetiology of 'schizophrenia', which is based on particular groups of diagnostic data, may partially reflect the concepts of the particular diagnosticians. The inconsistencies in diagnostic distributions and the biological irrelevance of the diagnostic systems may indicate that 'schizophrenia' represents a heterogeneity of disorder constellations rather than a single, universally- and reliably-diagnosed entity. A simple biological theory designed to explain the aetiology of such a category, or class differences in incidence, may be somewhat premature in this context.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, May 23

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2)—Colloquium on "A New Look at Energy Storage".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (joint meeting with the I.E.R.E. Medical and Biological Group, at Savoy Place, London, W.C.2), at 10 a.m. and 2.30 p.m.—Discussion Meeting on "Electrical Aids to the Handicapped".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Prof. Raoul H. Bott (Harvard University): "The Riemann–Roch Question in Various Guises" (Further lectures on May 24 and 26).*

ROYAL INSTITUTION, LIBRARY CIRCLE (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Mr. W. B. Proudfoot: "Copying Methods: Past and Present".

UNIVERSITY OF LONDON (at the Wright–Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2), at 5.30 p.m.—Dr. C. E. G. Smith: "The Effects of Civilization on the Viral Zoonoses" (Last of a series of four Almroth Wright Lectures).*

SOCIETY OF COSMETIC CHEMISTS OF GREAT BRITAIN (at the Washington Hotel, Curzon Street, London, W.1), at 7 p.m.—Annual General Meeting.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Mr. G. de G. Sieveking: "In the Tracks of Early Man in Thailand".

Tuesday, May 24

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Meeting on "The Chemical Engineer and Mastery of Information". Mr. R. Snel: "Information Retrieval and Decision Taking"; Dr. W. E. Batten: "Information System as an Essential Tool for the Engineer"

OPERATIONAL RESEARCH SOCIETY (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4.30 p.m.—Annual General Meeting.

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Anniversary Meeting.

INSTITUTE OF INFORMATION SCIENTISTS (joint meeting with Aslib, at 3 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. Harry K. Bourne: "The Work of the United Kingdom Scientific Mission".

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Mr. C. A. Burney: "New Evidence on Urartu from the Excavations at Kayalidere, 1965".*

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (at Guy's Hospital Medical School, St. Thomas' Street, London Bridge, S.E.1), at 6.30 p.m.—Mr. I. Roberts: "Immunology".

Wednesday, May 25

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Dr. W. H. Tonking: "Project Mohole—Exploring the Earth's Crust".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Annual General Meeting, followed by Miss Mamie Olliver: "Basic Research in the Food Industry".

Wednesday, May 25—Thursday, May 26

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 10.30 a.m. daily—Symposium on "Echinoderm Biology".

Thursday, May 26

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. L. P. Kadanoff and Prof. A. B. Pippard, F.R.S.: "Ultrasonic Attenuation in Superconductors"; Mr. S. G. Lipson: "The Righi–Leduc Effect in Copper at Low Temperatures".

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Computer Developments as a Tool for Civil Engineering Design and Control" introduced by Mr. J. R. H. Otter,

UNIVERSITY OF LONDON (at the Royal Free Hospital School of Medicine, 8 Hunter Street, Brunswick Square, London, W.C.1), at 5.30 p.m.—Dr. Frederick S. Philips (Sloan–Kettering Institute for Cancer Research, New York): "Cancer Chemotherapy: Inhibition of DNA Synthesis and Cell Death In Vivo".*

Friday, May 27

UNIVERSITY OF LONDON (at Queen Mary College, Mile End Road, London, E.1), at 5.30 p.m.—Prof. J. G. Valatin: "The Scientist's Endeavour to Understand and to Learn" (Inaugural Lecture).*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

STAFF TUTOR (preferably candidate with a good honours degree in physics) IN THE PHYSICAL SCIENCES IN THE DEPARTMENT OF EXTRA-MURAL STUDIES—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (May 25).

LECTURER or ASSISTANT LECTURER (preferably with an interest in social psychology) IN GENERAL PSYCHOLOGY IN THE DEPARTMENT OF GENERAL STUDIES—The Staff Officer, The University of Aston in Birmingham, Gosta Green, Birmingham, 4, quoting Ref. 468/2 (May 26).

TEMPORARY LECTURER IN GEOGRAPHY (physical geography and/or surveying will be of special relevance to the post)—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (May 27).

ASSISTANT EXPERIMENTAL OFFICERS or EXPERIMENTAL OFFICERS (2) (with a degree or equivalent in science or horticulture), one for work on herbicides in the Weeds Section (male only), and the other to assist in plant breeding programmes and to do cytological checks on breeding material—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (May 28).

CHAIRS (2) OF PHILOSOPHY—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (May 28).

LECTURER and an ASSISTANT LECTURER IN THE DEPARTMENT OF BIOLOGICAL CHEMISTRY—The Secretary, The University, Aberdeen (May 28).

LECTURER (preferably with an interest in transition metal or co-ordination chemistry) IN THE DEPARTMENT OF INORGANIC CHEMISTRY—The Registrar, The University, Newcastle upon Tyne, 2 (May 28).

LECTURER (with qualifications in physiology or applied physiology) IN PHYSIOLOGY—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff, quoting Ref. No. CN756 (May 28).

SENIOR LECTURER or LECTURER IN THE DEPARTMENT OF PHYSICS—The Registrar, University of Keele, Keele, Staffordshire (May 28).

ASSISTANT LECTURER (Probationary) or LECTURER (man or woman, graduate, with special interests in stratigraphy, including palaeontology and/or sedimentary geology) IN GEOLOGY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (May 30).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF PATHOLOGY,—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (May 30).

ASSISTANT LECTURER IN PURE OR APPLIED MATHEMATICS—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (May 31).

ASSISTANT LECTURER (with interests in formal logic) IN THE DEPARTMENT OF PHILOSOPHY—The Registrar, The University, Leicester (May 31).

CHEMISTS (preferably with research experience) for fundamental work on brewing materials and fermentation—The Director, Brewing Industry Research Foundation, Nutfield, Redhill, Surrey (May 31).

DEMONSTRATOR/SENIOR DEMONSTRATOR IN GENETICS—The Registrar, The University, Newcastle upon Tyne, 2 (May 31).

LECTURER and an ASSISTANT LECTURER IN THE DEPARTMENT OF COMPUTER SCIENCE—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (May 31).

PRINCIPAL OF THE NORTH WEST KENT COLLEGE OF TECHNOLOGY—The Clerk to the Governors, Divisional Education Office, Essex Road, Dartford (May 31).

ASSISTANT LECTURER IN ZOOLOGY—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 1).

ASSISTANT DEPARTMENTAL LIBRARIAN (preferably with a degree) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (June 2).

ASSISTANT LECTURER (preferably with experience in the application of Mossbauer or E.S.R. techniques to the study of solids) IN THE DEPARTMENT OF PHYSICS—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (June 4).

ASSISTANT LECTURER (with a particular interest in personality, abnormal or social psychology) IN PSYCHOLOGY—The Registrar, University College of Swansea, Singleton Park, Swansea (June 4).

LECTURER IN MATERIALS SCIENCE IN THE FACULTY OF APPLIED SCIENCE, Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee (June 4).

ASSISTANT LECTURER or LECTURER (graduate in chemistry or pharmacy) IN PHARMACOLOGICAL or PHARMACEUTICAL CHEMISTRY IN THE DEPARTMENT OF PHARMACOLOGY—The Registrar, The University, Leeds, 2 (June 6).

TUTORIAL STUDENT IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 6).

RESEARCH ASSISTANT (preferably graduate in psychology or zoology) IN THE LABORATORY OF EXPERIMENTAL PSYCHOLOGY for duties which will include carrying out behavioural experiments on various species of animals—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (June 7).

JUNIOR FELLOW (with a university degree) IN THE DEPARTMENT OF VETERINARY MEDICINE—The Registrar, University of Bristol, Senate House, Tyndall Avenue, Bristol, 8 (June 10).

JUNIOR LECTURER (graduate with medical qualifications) IN ANATOMY—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 10).

LECTURER (with special interests in the theoretical aspects of the subject) IN COMPUTATIONAL SCIENCE; and a LECTURER or ASSISTANT LECTURER (preferably with interests in numerical analysis of fluid dynamics) IN APPLIED MATHEMATICS in St. Salvator's College—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (June 10).

ASSISTANT or ASSISTANT LECTURER (with a higher degree with a minimum of three years' post-graduate experience) IN EXPERIMENTAL PHYSICS to take part in the teaching work of the department and to undertake research—The Secretary and Bursar, University College, Earlsfort Terrace, Dublin 2, Republic of Ireland (June 11).

CHAIR OF STRUCTURAL ENGINEERING WITHIN THE DEPARTMENT OF CIVIL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (June 11).

LECTURER IN BIOCHEMISTRY—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 13).

LECTURER IN THE PHILOSOPHY OF SCIENCE—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (June 13).

RESEARCH ASSISTANTS (with a good honours degree in an appropriate subject and some research experience) for studies in the biophysical fluid mechanics field under the supervision of Dr. R. L. Whitmore—The Registrar, The University, Nottingham (June 15).

LECTURER (with special interests in physical chemistry) IN THE DEPARTMENT OF CHEMISTRY, University of Tasmania—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 17).

TECHNICIAN (with L.R.I.C. or similar qualifications, experience in instrumental analysis and maintenance, especially in the field of gas chromatography, and preferably some knowledge of instruments, electronics and glass-blowing) to work in the chemical laboratory which is engaged on research into plant nutrition and soil problems, including a study of disease resistance in plants—The Director, Cawthron Institute, P.O. Box 175, Nelson, New Zealand (June 18).

SENIOR LECTURER or LECTURER (medically qualified with adequate experience) IN THE DEPARTMENT OF CHEMICAL PATHOLOGY, University of Ibadan, Nigeria—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (June 20).

LECTURER (with a superior academic record in mechanical, civil or electrical engineering) IN ENGINEERING at the University of New South Wales,

Broken Hill Division—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30).

RESEARCH ENTOMOLOGIST (with a degree in entomology or equivalent with specialization in entomology) at the Tussock Grasslands and Mountain Lands Institute, to study the effect of insects on the vegetation of eroded areas in the Southern Alps—The Registrar, Lincoln College, Canterbury, New Zealand (June 30).

SENIOR LECTURER IN BACTERIOLOGY—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (June 30).

ASSISTANT DIRECTOR (with a degree in agricultural science or in sciences basic to it, preferably experience in soil fertility work, a reading knowledge of languages and editorial experience, and the ability to write good concise English) of the Commonwealth Bureau of Soils, Rothamsted Experimental Station, Harpenden, Herts—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (July 15).

SENIOR LECTURER (with special interests in physical oceanography, including dynamic oceanography and/or marine geology) IN OCEANOGRAPHY—The Registrar, University College of Swansea, Singleton Park, Swansea (July 30).

ASSISTANT EXPERIMENTAL OFFICERS or EXPERIMENTAL OFFICERS (at least 21 with a pass degree or an appropriate Higher National Certificate) to assist in developing and producing radioisotopes in variety to meet the worldwide growth in sales of radio-chemicals—The Personnel Officer (Ref S.8934), The Radiochemical Centre, Amersham, Bucks.

CHAIR OF CHEMISTRY; and CHAIR OF ENGINEERING (Chemical and Materials) at the University of Auckland, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

LECTURERS (preferably physicists who are interested in continuing research in the fields of X-ray crystallography, infra-red spectroscopy, N.M.R., or microwave physics) IN THE DEPARTMENT OF PHYSICS—The Registrar, Portsmouth College of Technology, Hampshire Terrace, Portsmouth, Hampshire.

PROFESSOR OF CHEMICAL ENGINEERING—The Registrar, Bradford Institute of Technology, Bradford, 7.

PROFESSOR OF PHYSICS—The Staff Officer, The University of Aston in Birmingham, Gosta Green, Birmingham, 4, quoting Ref. 470/2.

SCIENCE GRADUATE (interested in publishing) to join the editorial staff of *Metallurgical Abstracts*—The Secretary, The Institute of Metals, 17 Belgrave Square, London, S.W.1.

SENIOR LECTURER (with an honours degree in biochemistry and preferably some research and/or industrial experience) IN BIOCHEMISTRY; and a LECTURER (honours graduate preferably with some research and/or industrial experience) IN MICROBIOLOGY—The Registrar, College of Technology, Park Square, Luton.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Machine Tool Technology: Decisive Factor in Industrial Development. By Prof. Janez Peklenik. (An Inaugural Lecture delivered in the University of Birmingham on 2nd December 1965.) Pp. 12. (Birmingham: The University, 1966.) 2*s*. 6*d*. [253

Pig Trypanosomiasis in Tropical Africa. By Dr. L. E. Stephen. (Review Series No. 8 of the Commonwealth Bureau of Animal Health, Weybridge.) Pp. ix+65. (Farnham Royal: Commonwealth Agricultural Bureaux, 1966.) 15*s*.: 2.25 dollars. [253

Northern Ireland: Ministry of Agriculture. Leaflet No. 89: Some Pests and Diseases of Vegetable Crops. Pp. 15. (Belfast: Ministry of Agriculture, 1966.) [253

A GOOD START

THERE are two contradictory readings of the first report of the Council on Scientific Policy, and only time will tell which is correct*. Thus it may be that the newly appointed Council has been so overwhelmed with a sense of responsibility that it has been hamstrung by respectability, and easy prey to those appeals for sober statesmanship with which H.M. Treasury is accustomed to silence the most gullible of its pensioners. Alternatively —and this is the cheerful view—the Council has calculated that the real battle to ensure the needs of science and technology in Britain will come not now but next year or the year after. In that spirit, so the argument will go, the immediate need is not a spate of polemics but the establishment of a sound philosophical base for struggles ahead. (Yet a third interpretation of the first report is that the Council has been so attracted by the intellectual delights of what is sometimes called the 'science of science' that it conceives of itself as a kind of academic institution—a rival, perhaps, to one of the university units the formation of which is described on p. 885 of this issue.)

The passive interpretation is prompted by the Council's own statement of what science policy is for, and by some ominously ambiguous pronouncements in the report. By emphasizing that the object of the science policy should be "to maintain the environment necessary for scientific discovery", the Council comfortably echoes the Haldane doctrine, but also echoes the more recent statements of Mr. Quintin Hogg when he was Minister for Science about the need that those who administer science should regard themselves as midwives and not as procreators.

Mr. Hogg, of course, was right. The Government should not set itself up as competent to decide what science is good and what science is bad. But there is no obvious reason why the Council for Scientific Policy should suffer the same restraints. On the contrary, the Council should be ready to become full-bloodedly partisan when circumstances require that it should do so. From time to time, it will find it necessary to defend the interests of the scientific community with nothing but conviction for support.

In this spirit, a lack of objective proof that a rapid expansion of postgraduate education in science would be a social and economic boon should not inhibit those concerned with the health of science (and the British economy) from proclaiming this. The Council is strangely silent on this vital point. Yet if it chooses to fight only battles which can be won by pure reason, it cannot hope to "ensure that there is balance between fields and that others are not avoidably neglected". If funds are going to be scarce, the Council will have to become skilled at inspired guesswork.

The view that the Council's first statement implies passivity is only one side of the coin, and the least attractive. The other is that the Council is seeking methodically to prepare itself for a vigorous future by creating the instruments of overwhelming authority. To be fair, this is the interpretation which the Council itself makes. And the first report is plainly an interim document—more a prospectus than a report. The consequences of the Council's forward planning are likely to be admirable. It will be splendid if the Council succeeds in developing criteria on which the making of decisions about the management of science can be predictably and soundly based. Nobody will deny the potentially great value of the proposed studies of the interactions between the different components of the British educational system and the stock of skilled manpower in the United Kingdom. Then the Council's style of working has a great deal to commend it. Evidently there will be a steady output of detailed and therefore convincing studies of particular problems—some of them commissioned from outside. Then the Council's devotion to principle has not prevented it from tackling problems such as the need to provide adequate computer facilities at British universities and, now, the paradox that Britain has a flourishing tradition of research in molecular biology, but much less university teaching in this field than circumstances require. (It will be fascinating to see how much of this trouble is traced to the fact that the Medical Research Council's Laboratory for Molecular Biology at Cambridge is not a part of the University.)

It would, of course, be easy to compile a list of similar problems that would keep the Council's members busy for a decade to come. There are a great many educational questions, including the desirability (or otherwise) of a four-year undergraduate course, and the problem of how best to marry university courses the ends of which are vocational (such as engineering, medicine and architecture) with the need for a liberal scientific education. There are problems concerned with research fellowships and studentships; rightly or wrongly, the Science Research Council's rules do not always seem sensible to those most closely affected. Post-doctoral Fellows sometimes find themselves unable to continue working in the most sensible places. Then there is the problem of what to do with the scientific literature and what attitude to take towards the proposals for the management of the literature by computers. And what about some way of making easier the transfer of people between industry and university research and teaching, or the need somehow to predict what problems and opportunities would be thrown up in Britain if the British Government should join the Common Market?

The truth is that the practical problems are so many that they will always multiply so as to outstrip the Council's resources, intellectual and material. In the circumstances, it is wise to emphasize its long-term objective of creating a framework within which decisions can be made more accurately and economically. Within such a framework, pure reason cannot be a sufficient guide. In fixing the balance between academic and more practically directed research, for example, it is improbable that everything can be determined by calculations of an economic kind. It will also be necessary to take a view about the long-term importance of science in British society.

In ways like these, the Council will have to carry the scientific community with it. The most obvious gap in its thinking so far is that it does not regard itself as the focus for public debate within the profession. But, just as a democratic government cannot move without public support, so this Council cannot hope to find criteria for making decisions without convincing working scientists

* See also pp. 877 and 885 of this issue.

that they are sound. The simplest and the best way of doing this would be to stimulate public debate among all professionally interested parties. The recent growth of interest in science policy at the universities shows that the time is ripe. Yet the Council, which is evidently anxious to reconcile the general public (including the Treasury) to the cost of science, is surprisingly cavalier in its apparent assumption that scientists will follow where it leads. Indeed, by assuming that it will usually be for research councils to make detailed decisions on the spending of money, the Council is assuming that the expert advisory committees which decide these things are fully in command of professional opinion. But is this necessarily the case, especially when the proceedings of the committees are in private and not in public? Indeed, unless the Council can set its own methodical and high-principled stamp on the legion of committees which actually spend money, there is a danger that good management at the top may be accompanied by what seems like arbitrariness lower down.

LONG MEMORIES

MR. HAAKON CHEVALIER has undermined a strong case with his book *Oppenheimer—The Story of a Friendship* (Deutsch, London, 25*s*.). The objective is an account of the relationship between Mr. Chevalier and Dr. Robert Oppenheimer when Mr. Chevalier was a professor of French at Berkeley and when Dr. Oppenheimer had not yet become the director at Los Alamos. The period was significant for both parties because it provided the raw material on which Oppenheimer later compromised Chevalier with the security authorities in the United States. Mr. Chevalier's subtitle is, of course, ironical.

By now the story of this shabby incident is a part of folk-lore. It was first brought into the open in 1954 when the Personnel Security Board of the U.S. Atomic Energy Commission examined in public the reasons why it should or should not grant a security clearance to Dr. Oppenheimer, the head of the Institute of Advanced Studies at Princeton and then a principal consultant to the Atomic Energy Commission. In the course of the evidence it emerged that Chevalier had informed Oppenheimer of a suspicious attempt to obtain secret information in the early years of the Second World War. Oppenheimer retailed this tale to the security people incorrectly. As he put it himself, he told a "cock and bull story". One consequence was to compromise Chevalier and his career. What surprised the hearings in Washington in 1954, and what rankles with Chevalier, is that Oppenheimer did not take steps to make good the damage done.

All this is now part of the public record, and a small part of the poignant history of Oppenheimer's security clearance. Chevalier's book has nothing new to say. Bitter accusations were predictable, but the result is frequently a form of words too unreflective to be communicative. Chevalier tells his tale without much feeling for the emotions concerned—even his own. When he might have thrown light on the character of his relationship with Oppenheimer, or on the tenor of their political discussions, he tends to write about the salad they had for dinner. The result is that his attempt to analyse Oppenheimer's personality reads like a briefing for a puppet show. Chevalier may feel better for having written his book, but few of his readers will be edified.

MALAISE OF CULTURE

Science and Culture

A Study of Cohesive and Disjunctive Forces. Edited by Prof. Gerald Holton. (The Daedalus Library, Vol. 4.) Pp. xxxiii+348. (Boston, Mass.: Houghton Mifflin and Company, 1965.) 6 dollars.

EVERYONE knows that the world is out of joint, but not everyone takes this to heart so much as the physicists, whose brainchild, the bomb, has brought them a profound sense of guilt. What has gone wrong? Is it nothing more than an estrangement between C. P. Snow's 'Two Cultures'? Or has science run amok and technology gone berserk? Is culture suffering from a degenerative disease called 'applied science'? Or, on the contrary, is it precisely this that we so desperately need, namely, a universal acceleration of the pace of scientific advance, which alone can triumph over the hydrogen bomb, overpopulation, and the gap between affluence and poverty? Such soul-searchings led Gerald Holton, professor of physics at Harvard, with fourteen co-authors, among them Harvey Brooks, R. Dubos, H. Marcuse, D. K. Price and E. Weil, to reflect on the mutual relationships of science and culture in the world of to-day.

Their contributions fall into three sections. The first is concerned with definitions and history. The second, more provocatively, deals with elements making for cultural coherence, and the third comes to grips with elements making for disjunction and alienation.

The second section opens with a study of the diffusion of basic concepts from one science to another, and from science to the arts and humanities. Thus the images and vocabulary of chemical equilibrium theory constantly recur in descriptions of social and economic phenomena; the idea of relativity has spread from physics to anthropology, psychology and history; and the notions of feedback and information are common to many disciplines in which 'environment' is equated with 'input' and decision with 'output'. Furthermore, there is a general acceptance that the observer interacts with the system under observation, whether the system be physical, historical or political. And there is a parallel between the abstract world picture provided by physics and the trend to abstraction in modern art and poetry, a parallel which contemporary representatives of optical and kinetic art, such as J. R. Soto, would no doubt warmly endorse. These reflexions lead Prof. Brooks to ask whether a psychologist, by studying present-day tastes in poetry, could predict the kind of theories likely to be acceptable in elementary particle physics, or vice versa.

In the same section Prof. Holton develops his challenging thesis that when one looks closely at the manner in which scientific hypotheses are initially formed, tested, and accepted or rejected, the alleged duality of culture seems to vanish. A three-dimensional propositional space, he suggests, may be used to chart the components of a scientific theory: the x-axis for empirical data, the y-axis for the analytical-heuristic dimension, and the z-axis for the thematic component—that which is rooted outside science.

Gloomy thoughts begin to emerge in the third section: modern science is an ally of a monstrous technology that threatens man's existence; and it is the growth medium of an equally monstrous ideology that engulfs the life of the mind. In the United States, we are told, the means of society are unrelated to its professed ends. American culture, because of the "permanent mobilization of the people for the eventuality of nuclear war", is swallowed by civilization. As a result, education for intellectual and emotional independence is "an all but subversive programme which involves violation of some of the strongest democratic taboos".

A number of contributors are profoundly critical of the establishment. They urge us to specify the criteria

whereby we choose between different value systems. So long as we treat science as value-free we shall continue to have a bad methodological conscience when considering questions of meaning in human life. Unaided science cannot provide a political strategy for the guidance of a blind technology. There is evidently a growing scepticism about the power of science, by itself, to improve the human lot. If there is a dualism, it lies in our two-fold image of man: on the one hand, "the lowly puppet-like figure described by science" and, on the other, "the bold, pioneering, self-possessed and self-determining fellow who invented science and appears to control the scientific establishment".

Science and Culture concludes with a report on the integrity of science prepared by a committee of the American Association for the Advancement of Science. This important document, which should be studied by statesmen and administrators as well as by scientists, puts a finger on the social hazards of experimental interference with nature, and it draws attention to the need for assembling facts relevant to value judgments. How, for example, can the benefits of nuclear testing be balanced against increased medical hazards from fall-out? The need for foresight is highlighted by glaring failures, exemplified by the adverse effects of large-scale spraying of pesticides. Above all, the report emphatically insists on free scientific debate which, for example, did not precede the *Starfish* experiment in which a 1·4 megaton bomb was detonated with melancholy repercussions now widely familiar.

Students of this book may feel it necessary to read between the lines. For it is hard to escape the impression that some contributors, skating on thin ice, would have liked to refer openly to the war in Vietnam or to the absence of China from the United Nations. If they refrained from doing so, it is because they are scholars, not politicians. Nevertheless, they see the writing on the wall and they have made it possible for others to share their vision.

J. COHEN

WOMEN IN SCIENCE

Women and the Scientific Professions

Edited by Jacquelyn A. Mattfeld and Carol G. Van Aken. (The M.I.T. Symposium on American Women in Science and Engineering.) Pp. xvii+250. (Cambridge, Mass., and London: The M.I.T. Press, 1965.) 6.95 dollars; 53*s*.

IN October 1964, the Association of Women Students of the Massachusetts Institute of Technology sponsored a symposium on the problems faced by American women in the scientific and engineering professions. *Women and the Scientific Professions* gives an account of the proceedings. The contributors included psychologists and sociologists as well as scientists. The welcome extended by the President of the Institute, where the enrolment of women is increasing, is encouraging.

The account is divided into four parts. The first, a discussion on the commitment required of a woman entering a scientific profession, was begun by Bruno Bettelheim, professor of education in the University of Chicago. The moderator was Mrs. Bunting, who as president of Radcliffe has promoted a scheme to help women with families to pursue advanced projects on a part-time basis. Prof. Bettelheim gives his reasons for accepting the invitation, adding disarmingly, "I knew it might put me out on a limb". He is deeply concerned with the adjustment of all human beings to living with modern technology. It is probably natural that I find myself in agreement with the comments of the physicist, Chien-Shiung Wu, and the anatomist, Mrs. Nachmias, on his contribution to the specific problems of a woman's commitment to her work. I am glad to see the point made that, although the majority of girls may not want to be scientists, those who do should not be made to feel odd. There is a realistic article by Mina Rees, who urged that women "must bring to the task the competence and objectivity that the task requires". Rita McCabe, of I.B.M., discussed the position of women in the computer industry, a field new to everyone and in which women have not been hampered by a long tradition that it is for men only. Dorothy Simon, vice-president of Avco Defense and Industrial Products Group, compared the position of American women in science and engineering with that of women in other countries, as deduced from the representation of, for example, the United Kingdom, India and Japan at the first International Conference of Women Engineers and Scientists held in New York in June 1964. This volume will be of interest to all those who hope to attend the second of these conferences, which is to be held in Cambridge in 1967.

The second part, on "Who wants Women in the Scientific Professions?", begins with an extremely interesting study by Alice Rossi of "Barriers to the Career Choice of Engineering, Medicine or Science among American Women". This occupies more than a quarter of the book and should be useful for reference. It is followed by a valuable article by the chairman of the Corporation of the Massachusetts Institute of Technology, who gave evidence from several sources that the proportion of women in professional occupations is dropping and that few women reach the executive and more highly paid ranks of their profession. Also, out of the 707 members of the National Academy of Sciences, only five are women. This is lower than the corresponding ratio among Fellows of the Royal Society. Both he and Prof. Jessie Bernard made it clear that it is idle for women to talk of discrimination, when there are not enough women with high qualifications. Richard Bolt gave a factual account of the present situation in industry and government.

Part 3 is a discussion on the case for and against the employment of women and includes contributions from two men experienced in recruitment in industry and the civil service. It emerges that it is only in quite recent years that the United States Civil Service has required that all appointments be made regardless of sex, with very rare exceptions.

The closing part consists of addresses by Mrs. Gilbreth, an example to us all of a woman who lives the lives of several ordinary women, and Erik H. Erikson, professor of human development at Harvard. He asked the delegates whether they had not listened too much and said too little and it would be interesting to know what was said from the floor. The whole volume is characterized by an objective approach to the problems involved, neither minimizing the difficulties nor presenting them as insuperable.

With a reasonably careful search I have not found out whether the credit for the mathematical gibberish on the dust jacket goes to a man or a woman, but the recurrence of "$m = c^2$" rather offends the eye of a physicist.

BERTHA JEFFREYS

CANCER BIOCHEMISTRY

Biochemical Approaches to Cancer

By Dr. Eric Reid. (The Commonwealth and International Library of Science, Technology, Engineering and Liberal Studies: Biochemistry Division.) Pp. xi+198+3 plates. (London and New York: Pergamon Press, Ltd., 1965.) 21*s*. net.

TWELVE years have elapsed since the publication of the second edition of the late Dr. J. P. Greenstein's classic, *Biochemistry of Cancer*. This work was authoritative, comprehensive and well documented. The advances in biochemical knowledge since 1954 make a new work on the subject most desirable. Dr. Reid's *Biochemical*

Approaches to Cancer, despite its small size, must be considered on its merits as a possible successor to the earlier work.

The first three chapters are concerned with the nature of cancer, how it is induced and the areas which are open to biochemical experimentation. Particular emphasis is laid on the necessity of comparing like with like (that is, tumours with their cell-types of origin) in biochemical investigations, even though this limits the field almost entirely to the comparison of hepatomas with normal and preneoplastic liver. The need for selecting the viable parts of a tumour is emphasized even though (p. 24) ". . . in the special case of hepatomas and perhaps of other tumours . . . necrosis may not invariably connote that the cell is dead". A short chapter follows on the effects of a tumour on its host.

The major part of the book is concerned with a comparison between the metabolism of carbohydrates, fatty acids, proteins and nucleic acids in tumours and in comparable normal tissues. The volume of fact included in this discussion is so great as to make the text too much of a catalogue to be easily readable. The lack of selectivity is symptomatic of the difficulty biochemists have in deciding changes which are and are not significant to the neoplastic process. In conclusion, those biochemical control mechanisms which are modified in cancer and the effects of cancer chemotherapeutic agents are considered.

The least satisfactory feature is the bibliography. This consists of fifty references to books and reviews followed by nearly a hundred and seventy more to 'key' papers. It is explained in the preface that a complete list of references would have been too expensive and that readers, with patience, will be able to find the references they need from the abstract literature. Since most workers are likely to want to use a book as tightly packed with facts as this as a guide to the original literature, the system adopted is unfortunate.

There is a short but adequate biochemically orientated index. It is felt that the author has attempted to write a comprehensive text on the subject in the space which would normally be allocated to a more superficial account.

D. B. CLAYSON

MEDICAL CARE

Medicine in Transition

By Dr. I. Galdston. Pp. xii + 220. (Chicago and London: The University of Chicago Press, 1965.) 5.95 dollars; 44*s*. 6*d*.

EVERYONE knows that medicine is in transition; but some doubt still clings to the questions whence it came, where it has got to, and whither it is going.

As an erudite man with a strong interest in and feeling for medical history, the author of *Medicine in Transition* is at his best in dealing with the first of these questions. In his chapter on "Patterns of Practice" (pp. 92–115), he brings out the antiquity of present-day forms of practice, finding in Greek times not only a salaried service, but also demonstrations of "free choice, fee for service, the exclusion of all parties intervening between patient and physician, and the unbreachable confidential nature of patient-physician relations"—things which have more recently been put forward as "fundamental principles, the neglect or subversion of which it is thought degrades the practice of medicine and radically reduces its effectiveness". He develops (pp. 100–105) Henry Sigerist's concept that "Social insurance is a result of the industrialization of the world". The paternalism (sketchily exercised) of feudalism was replaced by association of workers for mutual aid in sickness, and later by assumption of this responsibility by the State. We can accept the force of this analysis without necessarily following Dr. Galdston in his further implication (Chapter 9) that the growth of the affluent society will once again diminish the need for State participation in medical care. It is also something of an injustice, one hopes, to our professional forebears to write (p. 110) that "The vast majority were treated by 'doctors of the poor', most of whom were, in the extended sense of that term, also likely to be poor doctors".

In his analysis of the present state of medicine, Dr. Galdston emphasizes the increasing cost of medical care, the growing emphasis on hospital practice, the rise of specialization. These are not unfamiliar themes, but his account of them is factual and of value as a picture of present-day medicine in the United States, where the submergence of family practice by specialist practice has gone much further than in Britain. Dr. Galdston reveals himself as a strong defender of private medicine against the "threatened bureaucratization of medicine" (p. 206). Before accepting the sum of his advocacy, I would suggest three criticisms. Although not limited in time, he is parochial in space; and he generalizes what are essentially local problems, as in his long chapter on "Organized Labor and Medicine" (pp. 116–133). Although medically qualified, he does not appear to have engaged to any large extent in the actual practice of medicine. Finally, his use of the National Health Service in Britain as a foil is weakened by his dependence for information on recognized critics of the Service. As Lord Cohen says in his foreword, "the practice of medicine cannot be isolated from the social and political philosophy of a nation", and "medicine is but one limb of the body politic". It perhaps follows from this that the real determinants of the future pattern of medical practice will be social and not strictly professional.

In looking to the future, Dr. Galdston calls for a new pattern of medical education. His central theme is summarized on p. 167, where he sees the doctors of the future as "divisible into two groups, not as they are today into general practitioners and specialists, but rather into those trained and expert in dealing with serious types of episodic and emergency diseases and disorders and those trained and expert in the practice of maintenance medicine". The latter group are "as much involved in the normal as in the pathological", and on p. 174 he emphasizes the importance of nutrition and mental hygiene. This outlook he traces back to Hippocrates. Once more, I find myself a sceptic. The practicability of educating such people is not discussed; and I would even question their value. As Celsus said, "A man in health should be under no obligatory rules, and have no need, either for a medical attendant or for a rubber and annointer". Perhaps Americans have ears keenly attuned to the exhortations of the prophets of positive health; but that figure of stolid sense, the British working-man, is jealous of the fifth freedom, to do things that we are told are bad for us. For example, the evidence of association between smoking and lung cancer is enough to have made many doctors give up smoking; yet the expenditure on tobacco by the general population increases. If people could be persuaded to lead healthier lives, they would no doubt be the better for it, if not necessarily the happier; but I doubt the expediency of educating large numbers of doctors to tell them what to do. It is manifest that sanitarians have made a massive contribution to the health of us all; but they have done this by manipulating the environment, and not by exhorting individuals to lead better lives.

This speculation looks to me a piece of harmless idealism; and I would like in conclusion to return to my deprecation of Dr. Galdston's obvious dislike of a free health service. To his patent belief that the cost of a commodity increases its value, I would oppose the equally emotional and unprovable beliefs that it is bad enough to be ill without having to pay for it, and that one can accept free help from a fellow-man without respecting him less than if he charged a fee.

DOUGLAS A. K. BLACK

SCIENCE POLICY FOR BRITAIN

THE first report of the Council for Scientific Policy is concerned with the definition of objectives for the years ahead rather than with the solution of specific problems. In his introduction to the report (*Report on Science Policy*, H.M.S.O.), the chairman of the Council, Sir Harrie Massey, states that he and his colleagues have not found it easy to "ensure the development of science in an environment of relatively slow economic growth". He says that there must be a fuller understanding of the mechanism and the benefits of scientific growth, and describes his Council's first report as "our preliminary analysis".

The Council explains its concern for the principles of science policy by saying that "science needs confidence for its development", which means, in turn, "widespread public confidence in science as a necessary, desirable and well-managed investment for the future, and a main enablement for the attainment of national objectives". It goes on to say that the growth of the scale of science has made a self-conscious concern for its conduct more urgent, and announces, in a somewhat delphic manner, "the temptation may have to be resisted to throw all our limited resources into the exploitation of present knowledge, thus cutting back our capacity to advance in the future".

Strictly speaking, the Council is concerned simply to advise the Secretary of State for Education and Science, which implies responsibility for the research councils and a right to a hearing from the University Grants Committee.

At the beginning of its first report, the Council sets out to exorcize "the misconception that the advance of scientific knowledge itself can be directed from the centre. This would be to misunderstand the original and spontaneous nature of science. The advance of scientific knowledge cannot solely be achieved by the arbitrary selection of national goals and by committing resources of men and money to them".

The objective of science policy is not to direct the advance of science, but to "maintain the environment necessary for scientific discovery; to ensure the provision of a sufficient share of the total national resources; to ensure that there is a balance between fields and that others are not avoidably neglected; to provide opportunities for inter-fertilisation between fields, and between the scientific programmes of nations". It is for universities and research councils to decide what scientific objectives to aim at. The task which the Council sets itself is to look ahead nationally and internationally, to relate scientific activities to others competing for resources, and to "provide the basis for national acceptance of the scale of resources which are needed for the healthy evolution of science".

The Council refers to the recent argument about the proper level of government expenditure on research and development by the understatement that "it has been represented to us that the capacity of the national economy will not permit the growth of research council expenditure at present rates—about 13 per cent annually in real terms, or a doubling every six years—within the limits of planned national expenditures. This situation was not before our predecessors, and so far as we are aware is not yet faced by other countries in the van of scientific advance". The Council accepts that there must at some stage be a levelling off. "The question at issue is when, and at what rate, and on what criteria, the levelling-off of the growth rate should take place". With something akin to resignation, the Council goes on to say that a constructive solution should be one that maintains the morale of scientists and the vitality of science even on "relatively stable economic resources", which in turn implies greater flexibility in the management of research and development.

The Council has a powerful argument in support of planning ahead. In discussions with the research councils, it has apparently emerged that existing commitments to the recipients of grants would make necessary a substantial increase of expenditure in the financial year 1966–67. The forward commitments of the Medical Research Council are apparently such that even if there were no new grants for biological research in the universities in the current financial year, expenditure in 1966–67 would be 15 per cent greater than in the previous year. The report argues that in such a situation, comparatively small restrictions of the funds available for research can grievously hamper the starting of new projects. (This is an echo of one of the recurrent themes of the recent report of the U.S. National Academy of Sciences on the condition of physics in the United States.) In the event, the Council has settled for an increase in 1966–67 of 18·7 per cent above the £19·07 million spent by the research councils in its charge during 1965–66, although the increase in cost to public funds will amount only to 12·2 per cent in real terms, partly because of the offsetting effect of recent restrictions of capital expenditure.

For the time being, however, the Council is evidently more concerned to establish criteria for determining the strategy of science than with haggling about decimals of a per cent. Thus the Council is working with the research councils on plans to estimate in advance the consequences of any "tapering off" in research expenditure that there may eventually be.

The Council is also planning to keep a careful watch on the development of higher education in science, and it holds that "one of the important parameters for scientific growth should be the expansion of university teaching functions in science and technology, especially at the more advanced levels . . . we consider that the volume of research conducted in universities should keep pace with the growth in teaching functions".

So as to know what 'rates of growth of science are permissible in the universities and the research councils without creating serious problems for the intake of highly-qualified manpower into industry and for the long-term quality of science teaching in the schools", the Council has persuaded the Committee on Manpower Resources to establish a working party under Prof. Michael Swann.

The improvement of the "scientific environment" is given as another goal. The recommendation of the sub-committee under Prof. B. H. Flowers that expenditure on university computers should run at about £3 million a year has clearly persuaded the Council that there will be benefit in other similar exercises. Thus Sir Gordon Sutherland has been asked to lead a working party to find out whether universities could make better use of the equipment of the public research establishments, while Dr. J. C. K. Kendrew has been asked to lead a group reviewing "the problem of the development of Molecular Biology in the United Kingdom". Finally, Sir Harrie Massey will be the chairman of a group which is continually to review the conduct of international relations in science. In this connexion, the report declares there to be a distinction "between measures which facilitate the natural and essential interchange of men and ideas which is at the heart of science, and the creation of specific co-operative arrangements for the solution of particular scientific problems". The Council is in favour of arrangements of the first kind, but evidently determined to look most critically at the second.

PLASTIC FLOW AND PRESSURE MELTING IN THE DEFORMATION OF ICE I

By P. BARNES and DR. D. TABOR
Surface Physics, Cavendish Laboratory, Cambridge

THERE has been little work of a unified nature dealing with the deformation of ice over a temperature range from close to the normal melting point (0° C) to say −15° C. Investigations have been made of the creep properties mainly below the pressure melting point by Glen[1], Steinemann[2] and others. They conclude that the behaviour of ice resembles that of a metal: the deformation is plastic and the creep involves dislocation climb similar to that involved in metallic creep. The usual relation for the steady-state creep rate ($\dot{\varepsilon}$) in metals is:

$$\dot{\varepsilon} = A_1 . \sigma^m . \exp\left(\frac{-Q}{RT}\right) \qquad (1)$$

where σ is the applied stress and T is the absolute temperature. Glen investigated the creep of ice in uniaxial compression for stresses up to 10·8 bars and temperatures from −0·02° to −12·8° C. He found that after an initial stage of decreasing creep rate (the range of transient creep, $\dot{\varepsilon}_{tr}$), a steady state was reached in which the creep rate was constant and given by equation (1); the following constants were deduced:

Q = 31·8 kcal/mole

m = 3·2 or 4·2 depending on the particular analysis used

$A_1 = 8{\cdot}9 \times 10^{23}$ years^{-1} . bar^{-m}.

Weertman[3] has proposed a dislocation climb model for hexagonal crystals such as ice I. Assuming the stresses are not too high, he derives a relation similar to equation (1), where Q represents the activation energy for self-diffusion.

On the other hand, some investigations of deformation close to the melting point (0 to −1° C) undertaken by Telford and Turner[4], Kamb and LaChapelle[5] and others, show that at the pressures developed between a metal wire and a block of ice, other processes may be involved. The classical experiments of a similar nature by Faraday and others[6] suggest that, in this restricted temperature range, the main process is pressure melting. For example, using the standard Clausius–Clapeyron equation, the depression in the melting point (dT) for a hydrostatic pressure (dP), when both ice and water phases are present, is given by:

$$\frac{dT}{dP} = \frac{-\Delta V}{\Delta S} = -0{\cdot}0074 \text{ °C/atmosphere} \qquad (2)$$

where ΔV and ΔS are the ice–water changes in volume and entropy. In a direct experiment, Moser[7] found that for a pressure change of about 1 atmosphere this was very close to the observed value. In the literature there are two main alternatives to the classical Clausius–Clapeyron equation. In physical terms, both of these appear to be somewhat unrealistic. In one, due to Poynting[8], it is assumed that the melted ice is instantaneously released from the applied pressure. As a result, the lowering of the melting point is eleven times greater. In the other, Riecke[9] considers the behaviour of ice under a uniaxial compression. He assumes that the external forces do no work and the only effect is due to the release of elastic strain energy in the ice when melting occurs. The depression of the melting point is given by:

$$\frac{\Delta T}{\sigma^2} = \frac{-V_S}{2E.\Delta S} = -451 \times 10^{-9} \text{ °C . bar}^{-2} \qquad (3)$$

where E is the relevant elastic modulus, and V_S the specific volume of the ice phase. This lowering is minute: even for stresses of 1,000 bars, ΔT is less than 0·5° C, whereas for a hydrostatic pressure of the same magnitude the classical Clausius–Clapeyron relation gives a value of ΔT of about −7·4° C.

This article describes a systematic study of deformation of cold ice and ice up to its normal melting point. The deformation of ice in frictional processes has already been discussed[10]. Apart from its theoretical interest, the work may have a useful bearing on glaciological investigations.

The experiments were carried out in a large refrigerator; the temperature in specified regions could be maintained constant and monitored to an accuracy of better than 0·1° C. A study of grain sizes and orientations was also made before and shortly after deformation using polarized light. The specimens were cut with a cold saw and the cut regions (which were disturbed) removed by gentle melting until the specimens were about 1 mm thick.

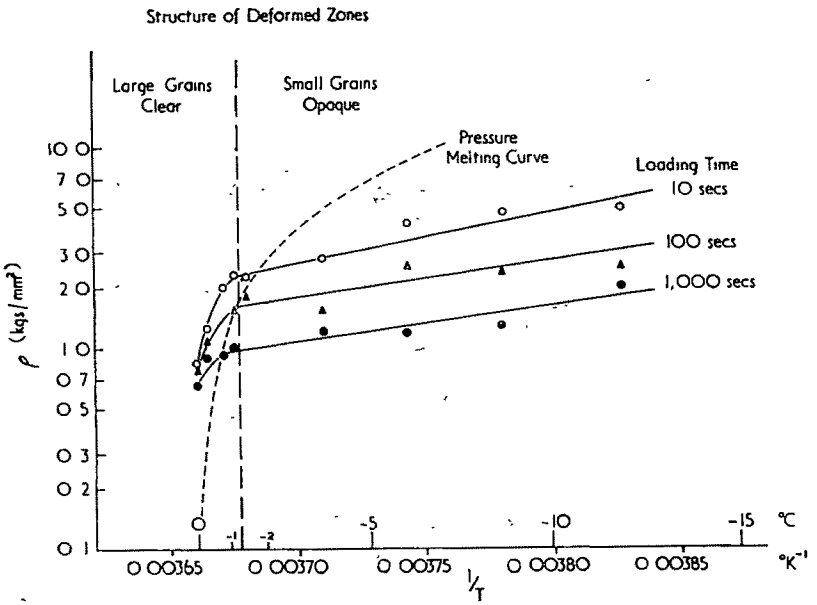

Fig. 1. Figure showing the indentation hardness (p) of ice (logarithmic scale) obtained with a spherical indenter for different loading times and temperatures (reciprocal scale). At temperatures lower than about −1·2° C (that is, to the right of the broken line), the curves are approximately straight in accordance with expected exponential variation (equation 5). At temperatures higher than −1·2° C, the hardness falls abruptly. The dotted line is a phase transition curve indicating $p - 1/T$ co-ordinates at which pressure melting is expected to occur. It is seen to cut the hardness plots at about −1·2° ± 0·3° C. The structures of the deformed zones observed in these two distinct regions are indicated

Deformation Behaviour

A few experiments were performed in which a hard indenter was dragged over the surface of the ice specimen and the width of the resulting groove determined. However, in most of the experiments, indentation hardness measurements were made under conditions of

static loading. A hard steel indenter (sphere, cone, or pyramid) was pressed with a known load for a specified time on to the surface of a smooth block of ice. After the indenter had been removed the diameter of the permanent indentation was measured and the hardness calculated as the ratio of the load to the projected area of the indentation. Sections of the ice were cut through the indentations as already described and examined through crossed 'Polaroids'.

Typical results are given in Fig. 1 for a spherical indenter of diameter 5 cm under a load of about 100 kg on ice with a crystal size of the order of 1 cm in the surface plane. Subsidiary experiments (see also ref. 11) have shown that hardness depends on crystal orientation, but in the series quoted the indenter is supported on at least four grains so that orientation effects are considerably, though not completely, "smoothed out". Indeed, very similar results are obtained on ice of very small grain size. The results show three main features:

(*a*) The hardness falls with increased loading time (t).

(*b*) The hardness increases exponentially as the temperature falls. These effects are due to creep and resemble the results obtained by Glen. They are also similar to the indentation hardness results on metals at elevated temperatures obtained by Atkins and Tabor[12]. Atkins, Silverio and Tabor[13] have derived a relation for hardness assuming the material to be in a state of transient creep. The relation between transient creep rate ($\dot{\varepsilon}_{tr}$) and steady-state creep rate ($\dot{\varepsilon}$) is assumed to be of the Mott type[14]:

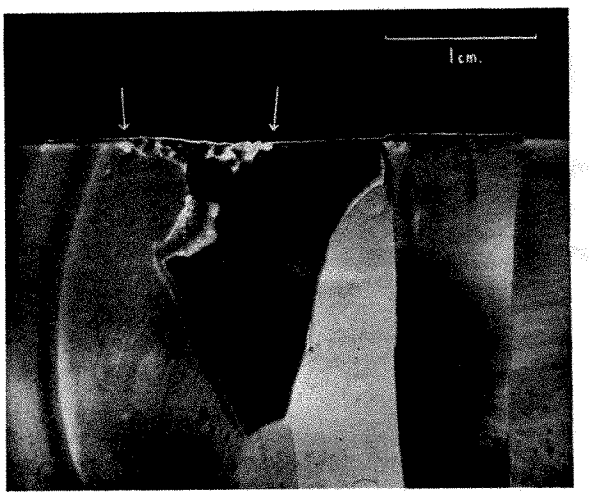
$$\dot{\varepsilon}_{tr} = A_2 \dot{\varepsilon}^{1/3} t^{-2/3} \qquad (4)$$

A_2 being a constant and $\dot{\varepsilon}$ given by equation (1). The simplified relation finally obtained for hardness (p) is:

$$p = A_3 \exp \frac{+Q}{mRT} \cdot t^{-1/m} \qquad (5)$$

where Q and m are the same constants as those used in the steady-state creep equation (1). From the results of Fig. 1, m is found to have a value of $3{\cdot}85 \pm 0{\cdot}3$ which agrees well with the limiting values 3·2 and 4·2 obtained by Glen. Q/m was found to be $7{\cdot}7 \pm 1$ kcal/mole. Using our value of m, this yields $Q = 29{\cdot}7 \pm 4{\cdot}4$ kcal/mole. This also agrees well with the activation energy value of 31·8 kcal/mole quoted by Glen. The agreement is somewhat surprising in view of the fact that the stresses involved in these hardness measurements are some 10–100 times greater than those in Glen's experiments.

(*c*) The last and most striking feature is the marked change in hardness behaviour at about $-1{\cdot}2 \pm 0{\cdot}3°$ C. Between this temperature and 0° C the hardness falls very markedly.



Changes in Crystal Structure

The change in hardness behaviour at $-1{\cdot}2°$ C is associated with a very marked change in the deformation produced by the indentation process. Distortion of the ice around the indentation is followed by recrystallization: this is shown by studying the sectioned specimens within a few hours of making the indentation. (If the ice is left for a few days, appreciable crystal growth can occur.) With cold ice (below $-1{\cdot}2°$ C) the recrystallized grain size is always very small (Figs. 2 and 3), being about 0·5 mm in diameter. The depth of this zone is small at $-10°$ C and larger at $-1{\cdot}9°$ C. This is essentially the consequence of "stress-enhanced recrystallization" within the plastic zone; the amount of recrystallization is naturally greater at the higher temperature. However, with ice warmer than $-1{\cdot}2°$ C, the recrystallized grains are consistently larger, lying between 2 mm and the original grain size (Fig. 4). This is strong evidence for pressure melting in this temperature range.

This view is supported by a visual examination of the sections. With cold ice the aggregate of small-grain ice around the deformation zone scatters light strongly and appears white in contrast to the relatively transparent surrounding ice (Fig. 5). The behaviour of the warmer ice is shown most clearly by using ice specimens deliberately prepared with inclusions of fine air bubbles. The undeformed specimen appears "cloudy". After indentation the contact zone becomes clear (Fig. 6). This provides very strong evidence indeed for the occurrence of local melting and the subsequent escape of the air bubbles. These results are not isolated examples. Numerous experiments show that there is always consistent behaviour below about $-1{\cdot}2°$ C and consistent behaviour of a different type above $-1{\cdot}2°$ C.

Magnitude of the Hardness

If the indentation process between 0° and $-1{\cdot}2°$ C is mainly due to pressure melting, we should be able to

Figs. 2–6. Examination of indentations in ice using both polarized and ordinary white light. The specimens are sectioned in the plane of the indentation (perpendicular to the ice surface) and are thinned to about 1 mm for crossed-'Polaroid' examination. The specimens shown were indented with loads of 70–120 kg and loading times of 1,000 sec, or more. The dark curved bands seen in the background of Figs. 2, 3 and 4 are caused by the circular aperture of the specimen support

Fig. 2. Indentation of ice at about $-10°$ C. Crossed-'Polaroid' examination shows the distorted zone of the grains under the indentation region (given by the arrows). The recrystallized grain size is about 0·5 mm in contrast with the large undisturbed grains. The depth of the zone is small at these temperatures

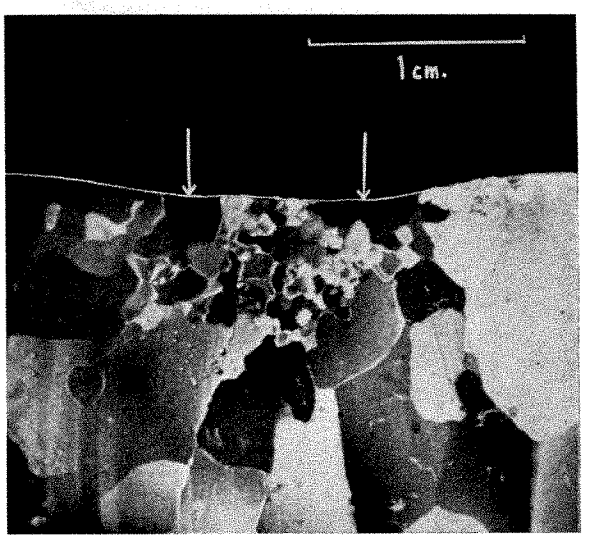


Fig. 3. Indentation of ice at $-1{\cdot}9°$ C. Crossed-'Polaroid' examination shows the distorted zone of the grains under the spherical indentation region (given by the arrows). The recrystallized grain size is about 0·5 mm. The depth of the zone is quite large

calculate from equation (2) the indentation pressure at which melting just occurs. For example, ice at $-1{\cdot}0°$ C ought to melt at a hydrostatic pressure of about 135 atmospheres if the ice and water are both subjected to the applied pressure. If we consider the stresses around a hardness indentation to be primarily hydrostatic, the hardness ought therefore to have an equilibrium value of about 135 atmospheres (or 1·4 kg/mm²) at $-1{\cdot}0°$ C. The dotted line in Fig. 1 has been calculated in this way. It is seen to cut the observed hardness curves very near the transition at about $-1{\cdot}2 \pm 0{\cdot}3°$ C.

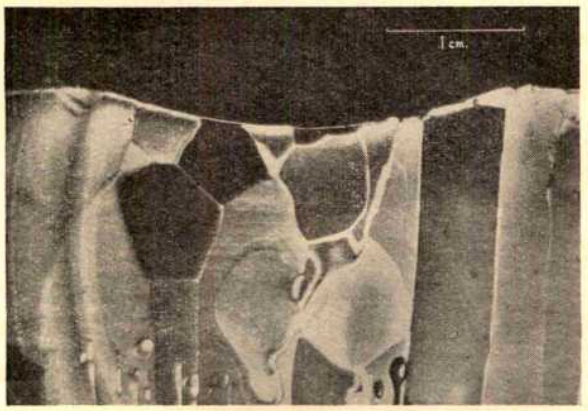

Fig. 4. Indentation of ice at 0° C. Crossed-'Polaroid' examination shows that there is no breakdown of crystal size. This is strong evidence for pressure melting. The ice is in the pressure-melting temperature range and presumably on removing the indenter the water refreezes to form large grains of size comparable with the undisturbed grains. The curved surface produced by the spherical indenter is easily seen

Although this transition agrees with the observed results it will be seen that between $-1{\cdot}2°$ and 0° C the ice is somewhat harder than one would expect on this model. The reasons for this discrepancy are two-fold. First, the pressure over the ice is not uniform in the indentation experiment, nor is it solely of a hydrostatic nature. From the theory of plasticity[15], the maximum hydrostatic stress occurs near the centre of the indentation and has a value of about 60 per cent of the overall hardness value (see, for example, ref. 16). The pressure melting curve ought therefore to be shifted a little to the left. It may be noted

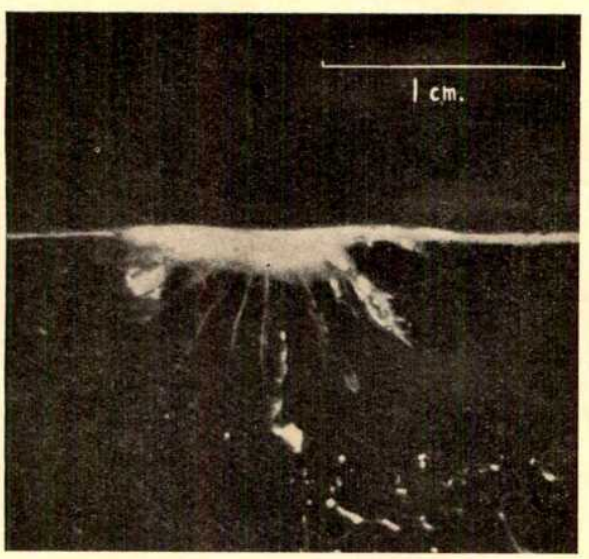

Fig. 5. Indentation of ice at $-10°$ C. Direct optical examination shows that the zone under the indented region scatters light strongly and appears white in contrast to the relatively clear undisturbed region

that indentations in this temperature range showed a well-formed hollow with sharp edges as though extruded water had frozen on escaping from the contact zone. Secondly, equilibrium can only be achieved after the liquid produced by pressure melting has been squeezed out from between the indenter and the ice. This takes a finite time so that the indentation hardness is always higher than the equilibrium value: in addition, the value is less the longer the time of application of the load. This dependence on time can, in a semi-quantitative way, be explained in terms of the viscous resistance of the liquid during extrusion.

With ice colder than $-1{\cdot}2°$ C, the pressures at which plastic deformation occurs are less than those required to produce melting. Consequently, the deformation behaviour falls into two fairly well defined zones. Presumably for shorter times it should be possible to extend the pressure melting phenomenon into a lower temperature range, and, at longer times, into a higher temperature range. This is the subject of further investigation.

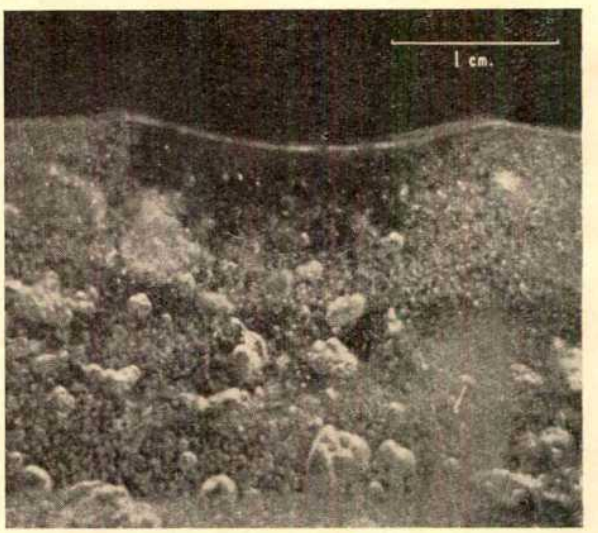

Fig. 6. Indentation of ice at $-0{\cdot}2°$ C. Optical examination of specimens specially prepared with many air bubble inclusions shows that the region under the indentation becomes relatively clear in contrast to the cloudy bubble-rich background. This again supports the view that, at these temperatures, pressure melting of ice has occurred; this makes it possible for air bubbles to escape before refreezing on removal of the indenter

It is interesting to compare these results with those of Glen obtained under conditions of uniaxial compression. Rewriting equation (1) in terms of the stress (σ),

$$\sigma = A_4 \dot{\varepsilon}^{1/m} \exp \frac{+Q}{mRT} \qquad (6)$$

It is seen that this equation is analogous to equation (5) for hardness (p) so that we can likewise draw plots of log σ against $1/T$. Varying $\dot{\varepsilon}$ will give a family of such curves just as in the hardness plots for varying loading times (t). We have recalculated Glen's data in this way and the results are plotted in Fig. 7. It is at once apparent that these results show two striking resemblances to the hardness data. First at temperatures below $-1{\cdot}2°$ C, where plastic flow and creep are occurring, the slopes are the same. Secondly at a temperature ($-0{\cdot}02°$ C) very close to the pressure melting curve, the stress for a specified creep rate is smaller than expected. Glen used Riecke's relation to show that pressure melting is impossible, but the agreement with the pressure melting curve suggests that the use of the Riecke's relation is probably unjustified. Our results suggest that crystalline creep of the ice is augmented in this temperature range by melting of ice be-

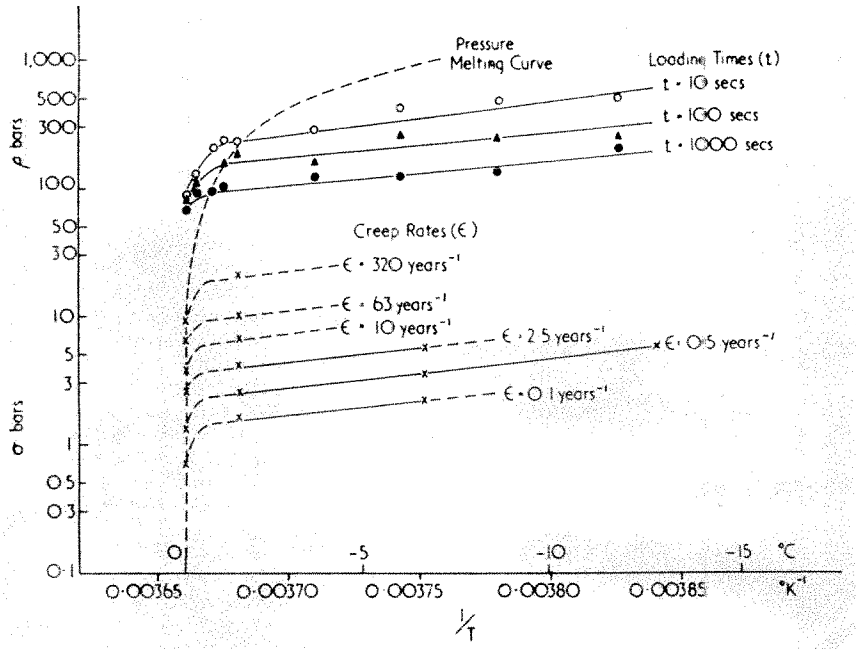

Fig. 7. Figure showing the comparison between the hardness (p) results of Fig. 1 and Glen's creep data. The latter curves (shown by crosses) represent the stress (σ) required at a temperature (T) to produce a given strain rate. The similar abrupt fall in this stress near the pressure melting curve at $-0{\cdot}02°$ C is striking. The pressure melting curve is calculated here assuming the hydrostatic pressure to be given by the compressive stress (σ)

tween the plattens and the ice specimen. In this region the magnitude of the effective hydrostatic pressure lies between the compressive stress σ and the associated hydrostatic stress (the stress invariant) equal to σ/3. This is illustrated in Fig. 8 where the pressure melting curve has been calculated for both these limiting cases. The enlarged temperature scale clearly shows that Glen's results at $-0{\cdot}02°$ C lie close to these limiting curves.

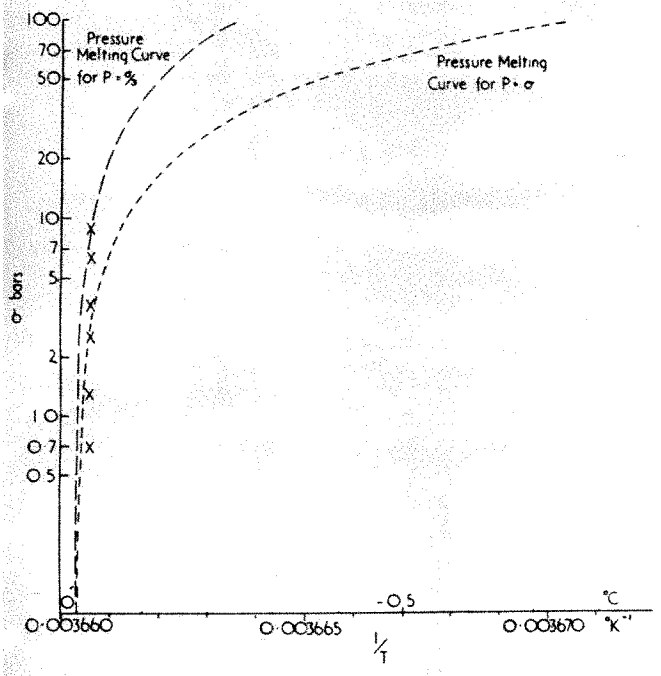

Fig. 8. Figure showing the position of Glen's data at $-0{\cdot}02°$ C on a magnified temperature scale. The pressure melting curve has been calculated in terms of the hydrostatic pressure (P) assuming that P is equal to (i) the compressive stress (σ), and (ii) the stress invariant ($\sigma/3$). It is seen that the points lie close to these limiting curves, suggesting that, in this region of Glen's experiments, pressure melting was playing an important part

Accelerated Creep and Transient Creep

Glen and Steinemann showed that after prolonged loading the creep rate accelerated because of recrystallization of the ice in an orientation favourable for easy glide along the basal plane. Our low-temperature experiments (at a much higher stress) should, according to their extrapolated data, bring us into the range of accelerated creep in about 1–1,000 sec and produce a recrystallized grain size of about 0·5 mm. This agrees with our observed grain size although with our experimental arrangement we could not detect a preferential orientation. However, even if the material near the contact zone is in a condition suitable for accelerated creep, the creep process as a whole is governed by the diffusion of the plastic zone into the virgin ice below it. This is apparently the rate-limiting part of the process and for this reason hardness results are explicable in terms of the transient creep process occurring in this region.

Conclusions

Our experiments show that in the indentation of ice for loading times greater than 10 sec and for temperatures colder than $-1{\cdot}2°$ C, the hardness behaviour may be explained in terms of transient creep. The crystal size around the deformed zone is small and provides evidence for local plastic deformation. Above this temperature there is a rapid fall in hardness and it is suggested that this is due primarily to the onset of pressure melting. This is confirmed by a study of the crystalline structure of the ice around the deformed zone; the grains are large and often continuous with the underlying ice crystals. Presumably for ice colder than $-1{\cdot}2°$ C the pressure required to produce plastic deformation, under our experimental conditions, is not sufficient to produce pressure melting.

We thank Prof. F. P. Bowden for his interest, Dr. G. de Q. Robin, Dr. J. W. Glen, and Dr. M. Imai for many helpful discussions, Dr. J. F. Nye and Dr. W. H. Ward for comments at an early stage of the work and the

Science Research Council for a research grant to one of us (P. B.) arranged by the Scott Polar Research Institute.

BECAUSE temperate glaciers consist of ice at, or within, 1° C of the pressure melting point, the results of Barnes and Tabor[1] on the flow of ice in this temperature range are likely to have critical implications in relation to the flow of glaciers.

In general, the main bulk of a glacier undergoes slow strain, and changes of strain rate and stress are likely to be relatively slow. However, processes of sliding, involving regelation against the bedrock and side walls, are likely to produce rapid changes of stress which may be of the same order as those used in the experiments described by Barnes and Tabor. The most generally accepted theory of sliding is that of Weertman[2], who has built up a theoretical model in which much of the ice is supported on a thin film of water giving low frictional resistance, while the ice is retarded by obstacles projecting through the water film into the basal ice. Stress concentration around these obstacles results in rapid rates of strain and in regelation of the ice. Kamb and LaChapelle have shown[3] that such a model is realistic, but have developed their equation of sliding on the regelation process alone.

The Sole of the Glacier

The most direct suggestion from the hardness experiments is that the sole of the glacier, a layer of relatively clear ice, sometimes containing debris and about 0·5 m thick, is the zone in which regelation–deformation processes occur, corresponding to the changed character of the hardness tests for temperatures between −1·2° C and 0° C. Kamb and LaChapelle's comments on this zone are:

(*a*) "The lowermost 0·5 m of ice above the regelation layer was relatively bubble-poor and appeared unfoliated. Above this zone, typical bubble foliation was prominent."

(*b*) "A stake anchored in the ice a distance of 10 cm above bedrock showed an average motion of 1·6 cm day^{-1} parallel to the bed. A stake 150 cm above bedrock moved 12 per cent faster. By means of a vertical profile of marker pegs spaced 10 cm apart, it was found that most of this 12 per cent differential motion occurred within the lowermost 50 cm of ice, as shear uniformly distributed except for two irregularities suggestive of 'shear zones', which, however, had only intermittent activity. In any case essentially all the motion of 1·6 cm day^{-1} took place as slip at the bedrock-ice interface."

Observations recorded by McCall[4] on the 30-cm thick sole of Skauthoe cirque glacier in Norway are broadly similar to the observations of Kamb and LaChapelle. McCall suggests that the bubble-free nature of the sole "probably originated" by meltwater percolating down the headwall of the glacier and freezing against the base of the ice. Such an explanation is unlikely to apply to the tunnel in which Kamb and LaChapelle worked.

The bubble-free nature of the ice and the relatively rapid strain rates observed in the sole of the Blue Glacier and Skauthoe both suggest strongly that regelation–deformation is occurring in the same manner as in the hardness experiments at temperatures above −1·2° C. The large crystal size in Fig. 5 of Kamb and LaChapelle's paper also suggests regelation–deformation, as the relatively rapid shear in this layer would otherwise be expected to produce smaller crystal sizes.

It must be remembered that the pressures involved in the laboratory experiments of Barnes and Tabor are of the order of 50–500 bars. Such pressures are not typical of the main ice bulk of temperate glaciers: however, Weertman's model of sliding involves stress concentrations proportional to the relative areas of obstacle and intervening glacier bed. For a mean shear stress on bedrock of 1 bar, the stress concentration factor could produce stresses up to 50 bars near the obstacles. Direct measurements of such stress concentrations have not been made. Our suggestion that the sole of the glacier is a regelation–deformation zone is based on the characteristics of the sole rather than Weertman's theory.

Catastrophic Advances of Glaciers

The proposal that temperature effects may be responsible for triggering off glacier surges in sub-polar glaciers[5] receives further support from the results of Barnes and Tabor. The slow warming of the basal ice of a glacier into the temperature range in which regelation–deformation and regelation against bedrock protuberances can occur is likely to produce an instability which could lead to rapid basal sliding and a catastrophic glacier advance. The relative roles of such processes and of the sub-glacial water film of Weertman[2] in explaining the rapid rate of flow once an instability develops need further investigation.

With regard to catastrophic advances of temperate glaciers, the results are suggestive but the answer is not clear. The time effect indicates greater apparent hardness values for shorter time intervals, which in terms of sliding would mean more resistance for higher rates of sliding, as is also indicated from the results of Glen[6]. However, in contrast to this, higher rates of sliding imply greater stress concentrations and increased flow rates due to the onset of regelation–deformation processes. It is not clear which of these two processes is the more important, but the fact that some temperate glaciers, such as the relatively flat lobes of the Vatnajökull ice cap[7], undergo catastrophic advances suggests that the onset of accelerated flow may be due to the processes shown to exist by Barnes and Tabor.

General Conclusion

The regelation–deformation process outlined by Barnes and Tabor appears likely to be of importance to short period transient processes involving relatively rapid changes of pressure, rather than to relatively slow strain rates for which much glacier flow theory has already been

developed. Its relevance to problems of sliding of ice appears to be of particular importance.

GLACIER DEPTH-SOUNDING FROM THE AIR

By DR. S. EVANS and DR. G. de Q. ROBIN
Scott Polar Research Institute, Cambridge

EARLIER[1] we announced the successful use of very-high-frequency radio echo apparatus to sound the depth of the Greenland ice sheet, providing a continuous profile of the bedrock surface by continuous recording from a moving vehicle. The detailed analysis of the records obtained in 1964 is now complete. The results mainly relate to a comparison with depths obtained by the seismic reflexion shooting technique, the relation between the radio echo strength and the ice temperature distribution, and the relation of ice surface features to bedrock topography on the small scale.

Following a generous invitation from the Defence Research Board of Canada (D.R.B.) the same radio echo apparatus was installed in a chartered *DHC-3 Otter* aircraft for flying operations based on Tanquary camp, Ellesmere Island, N.W.T. (81° 25′ N., 76° 55′ W.). The only new feature of the apparatus was the aerial arrangement designed and installed by H. Serson of the D.R.B. Telecommunications Establishment, Shirley Bay, and illustrated in Fig. 1. It was found to be more satisfactory to use one aerial for transmitting and the other for receiving, rather than to use a single aerial for transmitting and receiving, and the coupling between the two was about −45 dB. There was no discernible effect of drag on the performance of the aircraft.

A number of flights during April 10–20, 1966, covered some major glaciers and several crossings of ice caps on northern Ellesmere Island and one flight over the McGill ice cap and the Thomson glacier on Axel Heiberg Island. At 1,000 m above the surface, the echo from sea ice was about 80 dB over receiver noise (in confirmation of the overall system performance), from land about 70 dB, and from the top surface of a glacier of the order of 60 dB over receiver noise. Thus the glacier surface has a reflexion coefficient of the order of −20 dB. The echo from the bottom of the glacier was almost always weaker by 10 or 20 dB and, without giving an analysis of echo strength, ice temperature and depth, we can say that this is the order of magnitude of the attenuation due to dielectric absorption in the ice under the prevailing conditions.

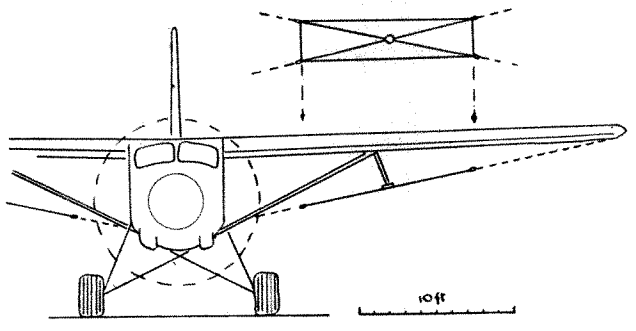

Fig. 1. Four-wire 35-Mc/s half-wave dipole aerial suspended beneath each wing of the *Otter* aircraft. Two of the conductors are driven from a coaxial cable which carries a ferrite-cored matching transformer at the centre. Conductors and supporting wires are assembled from 7/0·032 in. copperweld, 'Nico-press' sleeves, and 1-in. egg insulators (all tested to 2,000 lb.)

Thus the bottom surface of the glacier has a reflexion coefficient comparable with that of the top surface. It is possible to find exceptions to any of these statements, which are offered only as a guide.

Navigation was limited to line-of-sight paths, or sun-compass courses from identifiable landmarks on air-photo mosaics. Because the glacier surface elevations above sea-level on the maps are in error by as much as 1,000 m in some places, it was our practice to record the aircraft aneroid altimeter reading at frequent intervals. From this the true elevation of the aircraft above sea-level could be derived with an error less than ±50 m. The cruising speed was 50 m/sec (100 knots) and a height of the order of 500 m above the glacier was convenient. The top and bottom surface echoes could then be recorded on a time scale of 20 μsec total length and the error of ice depth measurement on this scale is ±8 m.

In Ellesmere Island, only the Gilman glacier depths have been surveyed previously, from gravity profiles and seismic soundings[2]. Radio echo recordings were taken along the same longitudinal profile and three distinct sections are illustrated in Fig. 2.

The first example, *a*, shows the ice cap in the vicinity of Mount Oxford. The smooth top surface is in contrast to the complex pattern of overlapping echoes from the bedrock, seen at various angles to the vertical but at right angles to the lines of sight from the aircraft. The record is typical of this ice cap, revealing mountain peaks just below the surface in addition to the visible nunataks. Example *b* shows the deepest section of the Gilman glacier, 20 km from the snout, 1,100 m above sea-level, and 660 m deep, which can be compared with a value of 700 m derived from the gravity survey at this point. Example *c* shows the snout (440 m above sea-level) which it would not have been possible to record from a surface vehicle because the finite receiver recovery time limits the minimum measurable range to about 100 m.

A comparison of the continuous echo from the smooth top surface of the Gilman glacier with that from the Otto fiord glacier in Fig. 2*d* reveals some interesting features. Between 1950 and 1959 the snout of this glacier surged forward by 3 km[3], and the chaotic ice structure is revealed by rapid fading of the top surface echo. It is probable that some of the intermediate echoes, of longer time delay than the minimum from the top surface, arise from discontinuities in structure below the surface. They cannot be differentiated from those which arise at some angle to the vertical unless there is a regular or continuous pattern beneath the surface, and we do not expect that here.

The next two examples are of thinner ice recorded on a faster time sweep. The ice rise in the Ward Hunt Ice Shelf, off Cape Discovery, is shown in *e*. We find the thickness to be 125 ±5 m and the smooth top surface (by which it is recognized visually) produces a different echo from the Ward Hunt Ice Shelf shown in example *f*. Here the thickness is 40 ± 5 m and the peaks in echo strength from the top surface occur at a rate of four or five per kilometre on the ice shelf surface, which is of the same order as the visible troughs (containing water

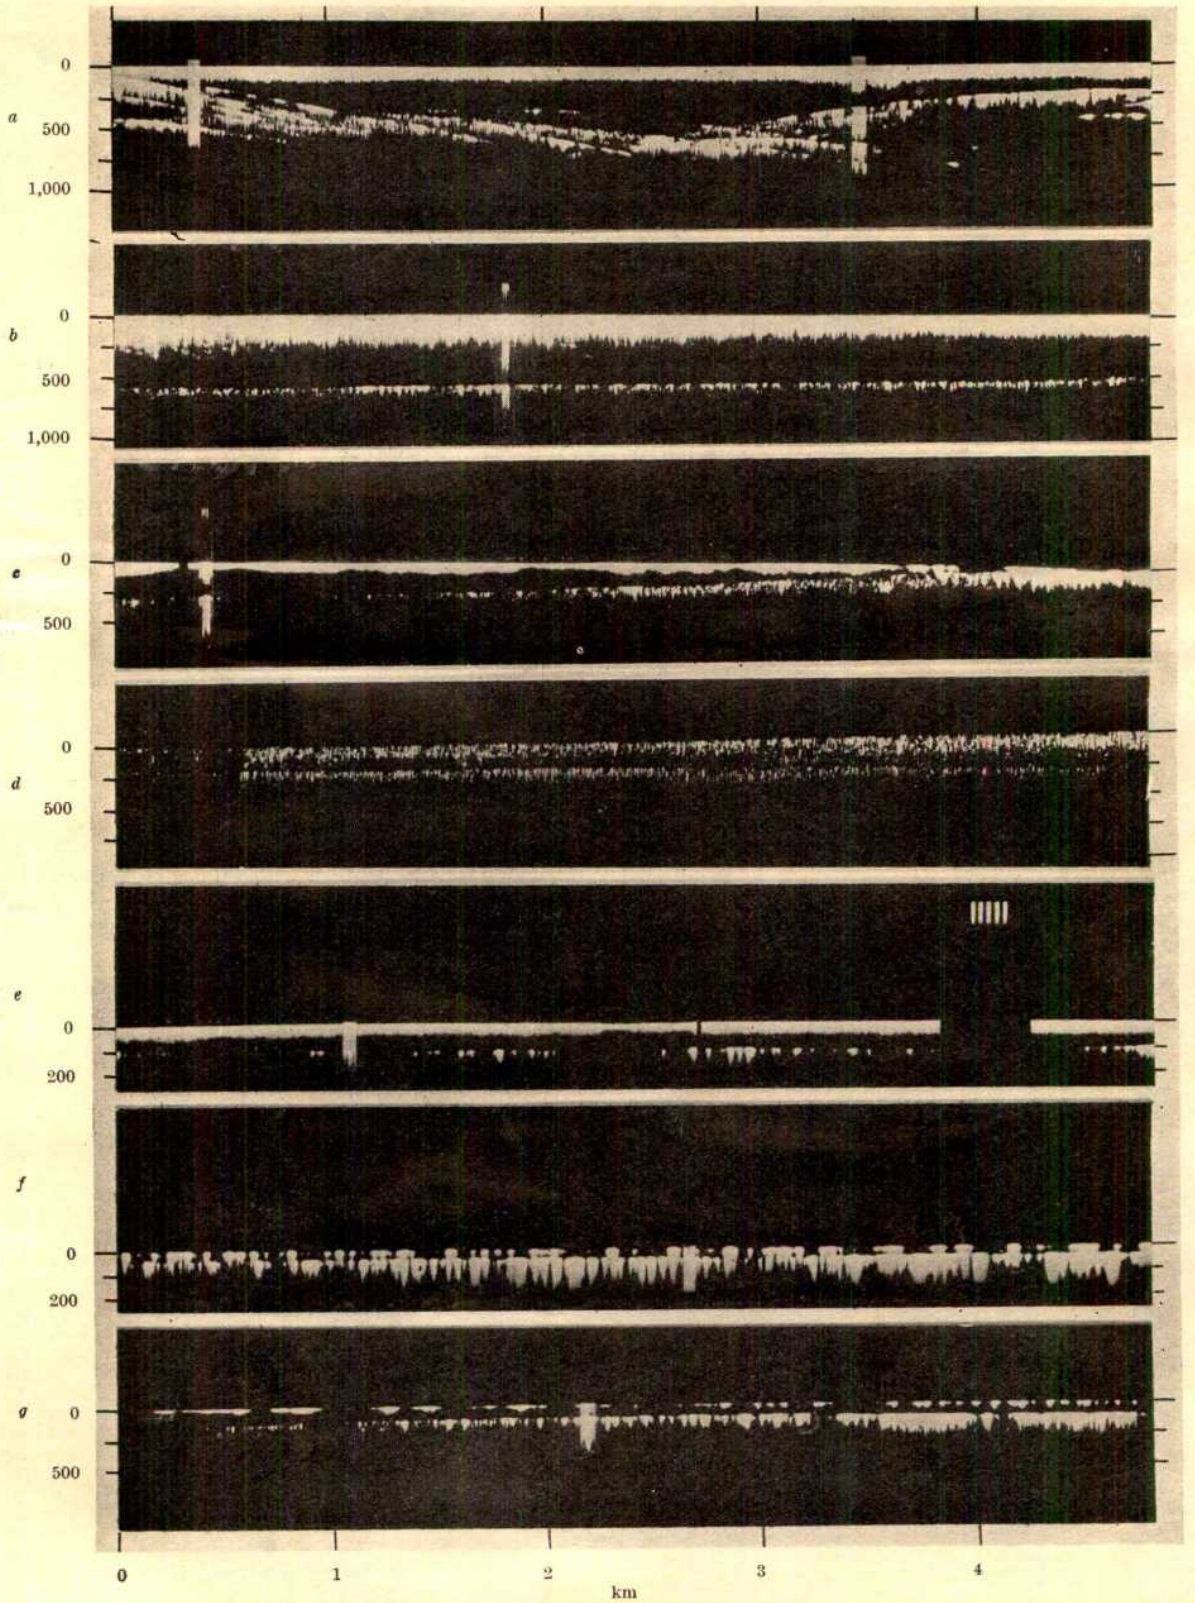

Fig. 2. *a–g*, Continuous records of radio echo soundings from the air showing various glaciological situations described in the text. In these examples, the time sweep runs vertically downwards across the film starting from the instant of the transmitter pulse, so the delay to the start of the echo from the top edge of the film represents the travel time through the air. The ragged trailing edge of the surface echo is due to the longer travel time of waves which are reflected at some distance from the perpendicular point on the top surface. Some of the power which penetrates the ice mass is reflected in the same manner from the ice/rock or ice/water interface below; the ice depth can be estimated, in metres, from the scale given at the ends of each record

in summer). Note that the bottom echo is stronger than the top echo on the floating ice shelf but much weaker on the grounded ice rise: however, both bottoms appear to be rough.

The transition from floating to grounded ice is illustrated in the final example, *g*, taken in Milne fiord. To the left, the glacier surface is smooth and the echo is stronger than the bottom echo from rock. To the right, the top surface is irregular and the echo is broken but of similar strength to the smooth section, whereas the bottom echo, from sea water, is about 15 dB stronger than that from the adjacent rock.

Echoes from intermediate layers within the ice (reported previously[1]) were not identified in this work—probably because, if they exist, they are very different in strength from the main top and bottom echoes and would easily be overlooked.

In the use of airborne techniques, it is the obvious factor of speed of coverage which will be the greatest asset for the Antarctic and Central Greenland. In mountainous country or in crevassed regions, however, the great advantage of aircraft lies in their ability to travel routes which would be dangerous or quite inaccessible on the ground: this is apparent in the present results. Our greatest debt is to the Chairman, D.R.B. (and partly the McGill Arctic Research Expedition), for the provision of the flying time, to the Department of Transport, Meteorological Branch, for hospitality at Arctic Weather Stations, and to G. Hattersley-Smith for inspired organization and direction of the field operations. Construction of the apparatus was financed by the Paul Instrument Fund, and the present development is supported by the Natural Environment Research Council.

NEWS AND VIEWS

Pattern of Science Expenditure

THE first report of the Council for Scientific Policy says that for the first time in recent history the proportion of the gross national product in Britain devoted to research and development has not increased in the period of the three years 1963–66. The total expenditure on research and development has increased at a rate of 6 per cent a year from £634 million to £756·6 million in the 3 years. Direct government spending has continued to decline and now amounts to slightly more than a quarter of all the money spent on research and development in Britain. The principal reason for this decline has been a reduction in expenditure on defence research and development. In 1955–56, expenditure under this head was £65·7 million, or 21·9 per cent of the total expenditure on research and development; in 1964–65 the amount spent on defence research had increased absolutely to £91·5 million but had declined as a proportion of the total to 12·1 per cent. In parallel with the decline of defence expenditure there has been a rapid increase in the value of research and development in universities from £14·4 million in 1955–56 to £55·9 million in 1964–65. The statistics on manpower collected in the report show a steady increase in the output of trained scientists and engineers, and a sustained recruitment of potential professionals to the universities. In 1958, 14,050 qualified people began work, 8,275 of them after taking first degrees at universities. By 1964 the total output had increased to 20,581, including 12,303 with first degrees. It is estimated that by 1968 the total output of trained people will have further increased to 26,060—most of the increase occurring between 1967 and 1968. The growth of the numbers of technically qualified people seems to have been uniform among specialists of different kinds. Mathematicians, however, are being produced in rapidly increasing numbers, and in the decade 1958–68 it is expected that the output of trained mathematicians will have multiplied four times.

On the recruitment of young people from the schools into undergraduate courses at universities and colleges of advanced technology, the Council quotes with approval the conclusion of the Dainton Sub-Committee that fears that the numbers of recruits to science and technology were declining were based on a misinterpretation of available statistics. It says that the correct interpretation is that there has been a growth of social studies, and a "striking growth in sixth form studies in subjects which do not normally lead to university education".

University Science Policy Units

A RASH of courses and research activities in the sociological antecedents of science is evident in British universities. At Sussex, Stirling, Edinburgh, Manchester and Bath (or the Bristol College of Advanced Technology) formal academic units have been or are being set up. At other universities, existing departments are tending to include studies of what has been called "the science of science" in their curricula.

Sussex is farthest ahead in this as—the university would no doubt say—in other things. Setting up a research unit for science policy at Sussex has been talked of since 1963, when Dr. Stephen Toulmin urged such a course on the university. Edinburgh became interested in a similar concept at much the same time, and it would be valuable to know how much of the planning at Stirling stems from the fact that the Vice-Chancellor, Dr. T. L. Cotterell, is an Edinburgh man. Manchester appears to have been stimulated in its plans more by its connexions with the Council on Scientific Policy and from the interest of the Departments of Economics and of Public Administration in matters closely related to science policy. There is no obvious motive but good sense for what Bath is planning.

Sussex

THE Unit for the Study of Science Policy at Sussex was established in January 1966 under Dr. Christopher Freeman. It has three full-time members already, and four more are to be appointed by the autumn. The intention is to carry out research both in the natural and social sciences relating to the economic, historical and social aspects of science policy. At present there are two main projects under way, one under Dr. Roy McLeod, a Harvard biochemist and historian, on the changing patterns of support for science. Another, on "Invention and Innovation in Capital Goods in Relation to the World Market", is directed by Dr. Freeman and is a continuation of his work at the National Institute of Economic and Social Research. The unit plans also to study the problems of science policy in developing countries; it is extending its international contacts and has already made arrangements for joint research work with the *Studiengruppe für Systemforschung* in Heidelberg, with CENSIS in Italy, and with the University of Lund in Sweden. One undergraduate seminar entitled "Science and Public Policy" is currently being offered at the University, as a contribution to the Arts–Science Scheme. More undergraduate and graduate

courses are planned, but the emphasis of the Unit will remain on research.

Bristol

THE Bristol College of Science and Technology has established a Centre for Scientific and Technological Affairs. Since the Centre is primarily a research unit, its emphasis will at first depend on the availability of funds for designated pieces of research. Some work has already begun on a comparative study of scientific policies at different times and in various countries. Other projects are planned on the internal development of the sciences and their interrelation; on the external relations of the sciences with other disciplines and the influence of basic discoveries on technological and social change; and a statistical documentation of scientific growth in the modern period. In addition, Dr. Gerald Walters, who as head of the humanities department is initially organizing the Centre, plans a monthly seminar on the social, economic, political and philosophical aspects of science.

Manchester

THE University of Manchester has decided to concentrate on teaching, and is concerned to train what the director of the unit, Prof. F. R. Jevons, describes as "journalists, teachers, administrators, and decision makers who are well grounded in science on a broad front and yet can express themselves". There will be a small entry of students in October 1966 and possibly two dozen in 1967. Central concepts in the physical sciences will be taught in conjunction with economics, sociology, history and philosophy. According to Prof. Jevons, the department will be interested in questions such as the financing of science, the study of innovation, the possibility of applying cost–benefit analysis to scientific research, science and social policy, and the methods of teaching science. He intends to offer natural or geological sciences as alternatives to the physical sciences later on, if there is sufficient interest. He hopes "that the school will form an important link, the first of its kind, between the arts and the sciences".

Stirling

THE University of Stirling will also teach undergraduates but will have no students until October 1967. In what will be called the School of Technological Economics the intention is somehow to design a course to train industrial or public administrators, analysts of industrial operations and "the industrial researcher whose work depends on a correct appraisal of sociological and economic issues". To judge from what has been said so far, the School is aimed not so much at students interested in the social and political basis of science and science policies but rather in the application of science and scientific techniques, including games theory, linear programming and statistics, to industry.

Edinburgh

AT Edinburgh the intention is to use the Science Studies Unit (under Dr. David Edge) to teach undergraduates and to conduct research "in those areas where scientific activities overlap with more general concerns of human society". There will be a short course of introductory lectures and seminars in September this year, and in the following academic year a one-year optional course for second- or third-year science undergraduates which, it is hoped, will soon become a two-year series. The teaching will be concerned with "the problems of economic growth, science policy decisions and sociological results of scientific advance".

Dr. Van Zandt Williams

THE death occurred in London on May 13 of Dr. Van Zandt Williams, director of the American Institute of Physics, at the age of fifty. He was making a short visit to discuss plans for a co-operative programme on physics abstracting and physics information services.

Dr. Williams was born in Providence, Rhode Island, gained a doctorate at Princeton University in 1941, and then entered the research laboratories of American Cyanamid Corporation, where, with Dr. R. B. Barnes, he played a leading part in the development of spectroscopic techniques for use in industry. He was among the pioneers in the application of infra-red measurements to analysis, to problems of molecular structure, and in the differentiation of some of the newer chemical products such as synthetic rubbers. He soon became the assistant director of the physics division of the Cyanamid laboratories, but it was not surprising that shortly after the Second World War he joined the recently formed Perkin Elmer instrument company. There he guided the design and rapid manufacture of commercial infra-red spectrometers and other optical instruments, some of which have become classical and have acquired universal fame. He was director of research and sales, manager of the instrument division, and later executive vice-president of the company.

A year ago he became the director of the American Institute of Physics, and would shortly have completed his term of office as president of the American Optical Society, after leading the very successful meetings in Washington two months ago to celebrate its fiftieth anniversary. He had also recently become the secretary of the committee for physics under the National Academy of Sciences, with the responsibility of maintaining relations with the International Union of Pure and Applied Chemistry.

Dr. Williams's death is a loss to American physics, to optics and spectroscopy, and to all who have international scientific co-operation at heart. Not only his colleagues in the United States, but also others the world over, and particularly in Europe, will miss his friendship, loyalty, sound counsel, wit and humanity, and share a great personal loss with his wife and two sons.

Sociology of Engineering

AN attempt to form a rounded picture of the character of the engineering profession in Britain is being made by the Council of Engineering Institutions with the financial backing of the Ministry of Technology. More than 25,000 chartered engineers are included in the sample being sent a detailed questionnaire intended to find out how engineers were trained to do their present jobs, and how they are rewarded. The survey will cover roughly 20 per cent of the membership of the thirteen engineering institutions affiliated to the Joint Council. The chairman of the Council, Sir Robert Wynne-Edwards, says in his introduction to the questionnaire that the results of the survey will be used to "help plan for the future by providing pointers towards better usage of engineering talent". Many working engineers will, no doubt, hope that the survey will also justify objectively the suspicion that engineers are paid too little.

The survey should provide sociological information of value outside engineering as such, partly because it has set out to define the levels of responsibility at which individual engineers function. To be sure, it will be a considerable test of character for a man to assign himself to category "A" by confessing that his work is "reviewed for accuracy and adequacy and for conformity with prescribed procedures", but the results could provide an important insight into the sharing of responsibility in modern industry. It is therefore all the more surprising, but entirely characteristic of the common conviction among engineers, that theirs is a job for men, that the questionnaire does not permit a woman to declare herself as such. Yet information about the employment of women engineers could have been particularly valuable in the recruitment of more.

Cyclotron for Medical Research

THE only Cyclotron Unit in Britain to be used in conjunction with medical radiobiological study and clinical applications has been operating for more than a decade at the Hammersmith Hospital. The Unit is completely owned and run by the Medical Research Council and is used by staff within the Unit, by other workers and post-graduate students at Hammersmith, and by visitors from other medical centres. In addition to the 15-MeV cyclotron, the Unit operates an 8-MeV linear accelerator and a 2-MeV Van de Graaff machine, thereby giving a wide range of radioisotopes needed for radiobiological research.

The cyclotron, built in 1955 at a cost of £250,000, has the great advantage of producing isotopes of very short half-life—ones that will last in the patient's body long enough for measurement but no longer. Since the Unit is on hospital grounds, it is practicable to use such isotopes as carbon-11, nitrogen-13 and oxygen-15, which have half-lives of 20 min, 10 min and 2 min respectively. It has also proved possible to use bone-seeking isotopes with short half-lives. In this respect, fluorine-18 has been used successfully to find bone lesions.

Radiation studies within the Unit are largely concerned with neutron beam experiments. According to the director of the Unit, Mr. D. D. Vonberg, one of the reasons for installing the cyclotron is to study the use of neutrons as an alternative to X-rays for radiotherapy, especially on cancerous tissues. Some cancers have a poor blood supply so that many of the cells are anoxic. The efficiency of X-rays on anoxic cells is reduced by as much as two-thirds, but neutron beams lose very little of their cancer-destroying efficiency. This line of research was first studied at the University of California at Berkeley but was stopped by the Second World War. Over the past ten years at Hammersmith, much research has been done on animal tumours but none on human patients. However, the hope is that the fast neutron beam can be used to treat certain types of malignancy and will be available soon for clinical use. Dr. R. L. Morgan, a radiotherapist involved in this study, stresses that while this may prove to be a useful application of the neutron beam, it is not the all-purpose cancer cure; it can only be considered a technical advance that will be useful in certain cases.

Other experiments involving the cyclotron include a tracer experiment studying the control of ventilation by carbon dioxide concentration and comparing the experimental results—the control loop being simulated by an analogue computer.

Another interesting clinical application is the use of oxygen-15 to trace heart lesions in the septum wall. In a very simple and brief test, oxygen-15 is breathed in and traced as it passes from the lungs in the form of carbon dioxide; if blood passes through a hole into the right side of the heart, a small decrease followed by a small increase, or a 'recirculation peak', would be noted as the extra blood is carried to the lungs.

In addition to the collaborative medical work with radioisotopes, the Unit provides its own engineering, radiochemical and radiation protection sections to deal with problems of accelerator design, chemical separation and purification of isotopes, and problems of radioactive contamination, leakage, and waste disposal.

Announcements

W. O. BAKER, vice-president of research at the Bell Telephone Laboratories, has been awarded the Priestley Medal by the American Chemical Society.

J. W. GARDNER, secretary of Health, Education and Welfare, has been awarded the Public Welfare Medal of the U.S. National Academy of Sciences for "eminence in the application of science to the public welfare".

MR. C. S. RICHENBERG, a senior examiner at the British Patent Office, is embarking on a study of the policy, law and practice relating to patents in a number of countries overseas. He is particularly concerned with "problems arising out of the present state of technology", and says that he would welcome the views of interested persons on "what they consider to be serious basic shortcomings of law and practice".

THE third international Congress of Radiation Research will be held in Cortina d'Ampezzo during June 26–July 2. Further information can be obtained from the Secretary-General of the Congress, Casella Postale 2359, Rome A-D.

A SYMPOSIUM on "The Molecular Biology of Viruses" will be held in the University of Alberta during June 27–30. Further information can be obtained from Dr. J. S. Colter, Department of Biochemistry, University of Alberta, Edmonton.

A MEETING of the Physical Biochemistry Group of the British Biophysical Society will be held at the Unilever Research Laboratory, Bedford, on June 29. Further information can be obtained from Dr. P. Johnson, Colloid Science Laboratory, Free School Lane, Cambridge.

THE eleventh annual meeting of the Health Physics Society will be held in Houston during June 27–30. Further information can be obtained from O. L. Pirtle, jun., Hastings Radiochemical Works, P.O. Box 60448, A.N.S., Houston, Texas.

THE second Rochester conference on "Coherence and Quantum Optics" will be held in the University of Rochester during June 22–24. Further information can be obtained from Dr. Emil Wolf, University of Rochester, Rochester, New York.

A CONFERENCE on "Precision Electromagnetic Measurements" will be held at the Boulder Laboratories of the National Bureau of Standards during June 21–23. Further information can be obtained from Mr. J. Cronland, Bureau of Continuation Education, 328 University Memorial Center, University of Colorado, Boulder.

THE second Canadian wood chemistry symposium, sponsored jointly by the Chemical Institute of Canada and the Technical Section of the Canadian Pulp and Paper Association, will be held in Sainte Marguerite, Quebec, during June 22–24. Further information can be obtained from Dr. D. B. Mutton, International Cellulose Research, Ltd., Hawkesbury, Ontario.

A SYMPOSIUM on "Discontinuous Waves" will be held by the Department of Mathematics, University of Strathclyde, in collaboration with the Institute of Mathematics and its Applications, in the University during June 30–July 1. Further information can be obtained from the Registrar, Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex.

THE third congress of the International Federation of Automatic Control, organized by the United Kingdom Automation Council with the co-operation of the Secretariat of the Federation and of its national member organizations, will be held in London during June 20–25. Further information can be obtained from the Secretariat of the Congress, c/o the Institution of Electrical Engineers, Savoy Place, London, W.C.2.

THE seventh International Congress of Gerontology, organized by the Austrian Society for Geriatrics, will be held in Vienna during June 26–July 2. The main themes of the Congress will be: the role of environment in ageing; adaptability in ageing persons; methodology, research and education in gerontology; current trends in gerontology; age, work and social change; problems of therapy in gerontology. Further information can be obtained from the Secretariat of the Congress, Wiener Medizinische Akademie, Alser Strasse 4, Vienna IX.

A HIGH-RESOLUTION STUDY OF THE RADIO SOURCE 3C273

By C. HAZARD, S. GULKIS and A. D. BRAY
Cornell-Sydney University Astronomy Center, Cornell University, Ithaca, New York*

SINCE the first detailed study of 3C273 by the "method of lunar occultations" and its subsequent identification with a stellar object[1,2] which led to the recognition of a new class of astronomical objects, it has proved to be one of the most interesting and puzzling objects in the entire sky. The early occultation observations which were made using the 210-ft. radio telescope at Parkes at frequencies of 136, 410 and 1,420 Mc/s showed that basically the source consists of two components (called *A* and *B*). A preliminary analysis of the records showed that the majority of the radiation from *B*, which is associated with a 13th magnitude star-like object, arises in a source of angular size less than or equal to 0·5″ while component *A* appeared to consist of a central core about 2″ wide embedded in a halo about 7″ wide and to be associated with a jet extending outwards from the stellar object. The jet which lies along a position angle of 43° starts at about 11″ from this object and terminates abruptly at a distance of 20″, while it was estimated that the two radio components were oriented along a line at position angle 44° and separated by 19·5″. A more detailed analysis of the 1,420 Mc/s observations[3] using the convolution procedure of Scheuer confirmed these general conclusions but indicated the presence of additional weak sources near *B* and a faint extension extending from *A* towards *B*. It also appeared that *B* was resolved with an angular size of about 0·6″, a conclusion confirmed by a similar analysis of the same data by Scheuer[4]. Later observations by Hughes[3,5] confirmed the conclusion that *A* is elongated along the direction of the jet, a conclusion also reached by Von Hoerner[6] from a series of occultation observations at Green Bank. A comparison of the observations at different frequencies showed a marked difference in spectral index between the two components, that of *A* being about −0·9 compared with a value for *B* of about 0·0.

Since the foregoing series of observations the extremely interesting observation has been made by Dent[7] that at 8,000 Mc/s the flux of 3C273 has increased over a period of 3 years by about 40 per cent. Because of the difference between the spectral indices of the source components this increase in flux must be due to component *B* and it sets an upper limit to its angular size of about 0·001″. However, the absence of any evidence of a cut-off in the spectrum of *B*, at least down to a frequency of 410 Mc/s, shows that if the emission from *B* is due to synchrotron radiation the angular size must be greater than about 0·2″, which is in better agreement with the occultation observations. This suggests either that the emission is not synchrotron radiation or that there is a genuine change in apparent angular size between 1,420 Mc/s and 8,000 Mc/s.

Because of the seriousness of the discrepancy in the estimates of angular size we have taken advantage of an occultation visible from the Arecibo Ionospheric Observatory in Puerto Rico to make a more accurate measurement of the diameter of component *B* and at the same time a more detailed comparison of the optical and radio brightness distributions. In addition we have re-analysed the earlier 1,420 Mc/s observations, as in this case the resolution limit set by the time constant and the bandwidth was about 0·5″, so close to the estimated size of *B* that there must be some doubt as to whether it had really been resolved.

Observations of the occultation which occurred on June 7, 1965, were made using the 1,000-ft. aperture telescope of the Arecibo Ionospheric Observatory which has been described in detail by Gordon[8]. The main primary feed of this instrument consists of a line feed 96-ft. long operating at 430 Mc/s and designed to correct the spherical aberration of the reflecting surface and to fill the full 1,000-ft. aperture. However, it was decided not to use this feed but to construct a special set of simpler feeds operating at 41 Mc/s, 195 Mc/s and 430 Mc/s, feeding 1,000 ft., 500 ft., and 350 ft. of the aperture respectively. There were several reasons for this decision. First, it was decided to attempt a resolution of 0·1″ and, as pointed out by Hazard[3], the finite size of the aperture sets a limit to the resolution and for an aperture of 1,000 ft. this limit is about 0·2″. Secondly, it was desired to investigate the source spectrum in more detail. Finally, the occultation occurred near the edge of the field of view of the telescope and there was some danger that part of the occultation curve would be missed using the line feed, while with the simpler feeds the field of view could be extended by mounting them offset from the main feed support. It was estimated that the apertures illuminated by the simple feeds would be adequate to achieve the desired resolution.

Because of low-level interference and the higher background noise at the lower frequencies, the 430-Mc/s record is the only record which permits a detailed study of the source structure down to a resolution of the order of 0·1″ and we will confine our attention to the observations made at this frequency. The spectral measurements have turned out to be very complex and will be discussed later.

At 430 Mc/s, a Dicke-type receiver was used with two separate channels, one channel having a bandwidth of 125 kc/s and the other 1 Mc/s. The observations were made by directing the telescope beam to the position of the source and recording the received power with the telescope in automatic motion tracking the source. The received power was recorded on magnetic tape using a time constant of 0s.1. With this time constant the limit to the resolution is set only by the receiver bandwidth and the signal-to-noise ratio. The effect of the bandwidth on the source distribution when restored using the method of Scheuer is to convolve the source distribution with a beam of half-power width about equal to 0·62 $(\Delta\lambda/D)^{1,2}$, where $\Delta\lambda$ is the width between half-power points and D is the distance of the Moon from Earth. At 430 Mc/s this corresponds to 0·09″ at 125 kc/s and to 0·26″ at 1 Mc/s. The 430-Mc/s record, smoothed with a gaussian beam 2 sec of time wide in order to show its main features, is shown in Fig. 1. The angle between the limb of the Moon and the line joining the two source components was only 15° so that the two components are not clearly separated, but their presence is shown by the beating in the fringe pattern. The extensive diffraction pattern shows the presence of fine-scale structure in the source of less than 1″.

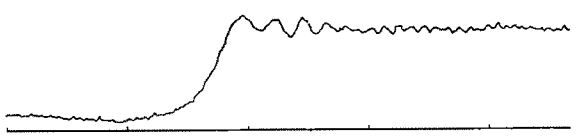

Fig. 1 Facsimile of observed occultation curve at 430 Mc/s using 1-Mc/s bandwidth and smoothed with a time constant of 1 sec. Horizontal scale: universal time, 1 div. represents 1 min

* The Arecibo Ionospheric Observatory is operated by Cornell University with the support of the Advanced Research Projects Agency under a research contract with the Air Force Office of Scientific Research.

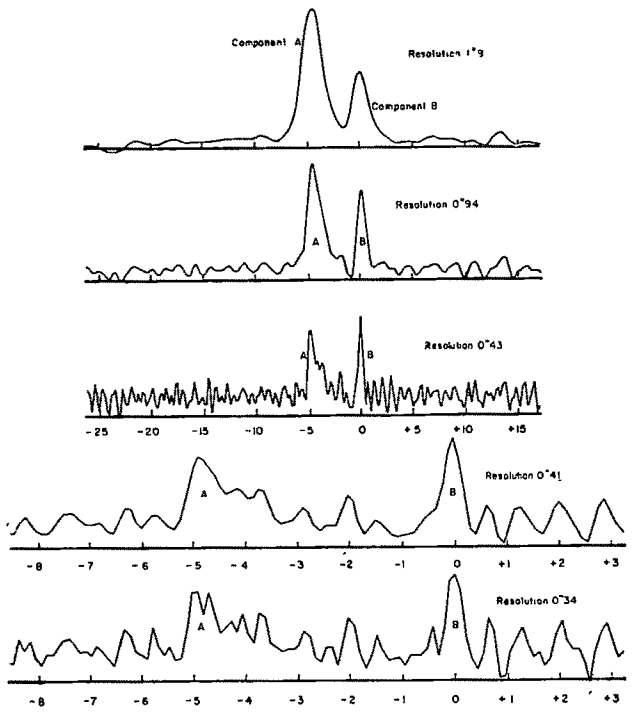

Fig. 2. Derived distributions across 3C273 using different resolutions and obtained using the 1-Mc/s bandwidth observations. The effective resolution is indicated on each curve. All records are normalized so that an unresolved source would have constant height at all resolutions. Horizontal scale: distance from component *B*, along position angle 299°, in seconds of arc

The record was analysed using a procedure based on Scheuer's convolution method for recovering the true strip brightness distribution, as seen by a beam of some assumed size, from the observed occultation curve. It differs mainly from the procedures outlined by Von Hoerner[9] and by Scheuer[4] in that account is taken of the curvature of the limb of the Moon, for, as shown elsewhere, this is an important consideration when aiming at a resolution of 0·1″ where the diffraction pattern and the restoring curve extend to a distance of 3′ from the limb of the Moon. In calculating the time scale of the diffraction pattern the source position given by Hazard, Mackey and Shimmins[1] was adopted and initially the Moon was assumed to be truly circular. However, a preliminary analysis showed that the use of the scaling factor derived in this way produced a marked asymmetry associated with a pronounced overshoot in the restored distribution of component *B*. As discussed elsewhere, this is a clear sign of an error in the restoring function (as well as evidence that the source is of small angular size) and, as the position of the source is known to the order of 1″, must be due to the relevant section of the limb of the Moon deviating from a true circle by about 2°. The scaling factor was therefore adjusted experimentally until all signs of the overshoot had disappeared and the narrowest distribution for *B* obtained, a procedure analogous to focusing. This procedure is justified as there is no mechanism which could produce a narrower distribution than the true distribution.

Having obtained the true scaling function, the observed occultation curves were restored with a series of restoring functions each using a different assumed beam width. The restored curves for a 1-Mc/s bandwidth are shown in Fig. 2. These curves represent the true brightness distribution convolved (*a*) with the assumed beam and (*b*) with a gaussian of half-power width 0·26″ due to the bandwidth. The effective beam width in each case is indicated on each curve; at the maximum resolution used it is set almost entirely by the receiver bandwidth. The curves are normalized so that an unresolved source would have a constant height at all resolutions.

Some interesting features are immediately obvious from these curves. As the height of component *B* is constant for all resolutions within the limits of experimental error and as there is no significant broadening at the highest resolution it must have an angular size $\leqslant 0{\cdot}3''$. On the other hand, the curves for component *A* show an appreciable diminution in height going from a resolution of 3·6″–1·8″, showing that it contains structure wider than 2″ of arc. As the resolution is decreased below 1″ the nature of this structure becomes clear. There is a weak extended source just visible in the noise and at least 5 sec of arc in extent on which sits a narrower source in which the majority of the emission originates; the extension from *A* to *B* noted earlier is probably part of this extended source. A comparison of the areas under the curves at different resolutions indicates that the extended region contains 40 per cent of the total flux from *A* while the central region contains the remaining 60 per cent. At the highest resolution, structure begins to appear in the central region itself which may be considered to consist of two separate components. One component has a half-width of 1·5″ and overall extent of about 2″ with a remarkably flat top and contains 40 per cent of the total flux of *A*; the second component contains 20 per cent of the total flux, is asymmetrically placed with respect to the extended central component and has a half-width less than or equal to 0·3″. The exact configuration of these two sources is somewhat uncertain as the shape of the restored curve depends on the scaling factor adopted for the restoring function and this is not necessarily the same for *A* as for *B*. However, there is no doubt that the asymmetry of *A* is real and that the small angular size component is situated on the side of the extended source more remote from *B*. Apart from a suggestion of a weak discrete source between *A* and *B* there is no evidence of any other source in the region.

In order to increase the resolution we now consider the observations made with a bandwidth of 125 kc/s which sets a limit to the resolution of about 0·1″. These restored curves are shown in Fig. 3. At a resolution of 0·35″ the restored curve is similar to that obtained for the same resolution using a bandwidth of 1 Mc/s, but with a poorer signal/noise ratio. As the resolution is increased still further component *A* disappears into the noise while *B* is still clearly visible. Because of the low signal/noise ratio of the narrow component of *A* and the possibility that the scaling factor is not the same as for *B* there is no evidence that it has been resolved. Its angular size is therefore $\leqslant 0{\cdot}3''$. The signal/noise ratio also limits the resolution for *B*. The half-width of this source at a resolution of 0·22″ appears to be slightly increased to 0·29″, but on the other hand there is no significant change to its height. The broadening is therefore not significant and we conclude that its half-width is $\leqslant 0{\cdot}15''$. A comparison of the total fluxes observed at different resolutions

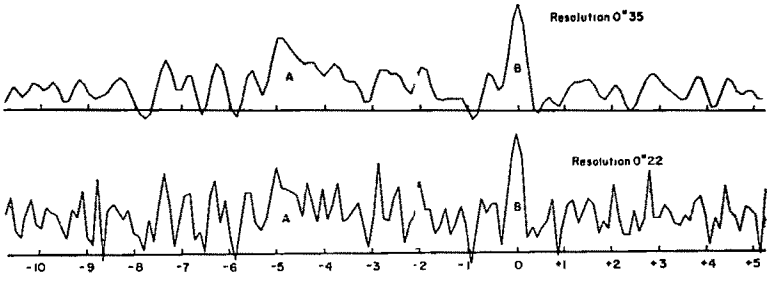

Fig. 3. Derived distributions across 3C273 using the 125 kc/s bandwidth observations and effective resolutions of 0·35″ (upper curve) and 0·22″

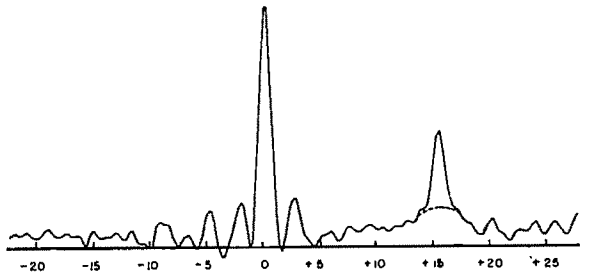

Fig. 4. 1,420 Mc/s distribution across 3C273 at position angle 103° using a resolution of 0·6″. The broken line represents the possible separation of *A* into a narrow central source situated on a more extended region of emission

shows that within the limits of experimental error all the flux from *B* arises in this small angular size component.

In order to compare the results of the present investigation with those made earlier at 1,420 Mc/s using a comparable resolution, we show in Fig. 4 the restored 1,420-Mc/s distribution using an effective beam of 0·63″. This is close to the maximum possible resolution which is limited to 0·52″ by the bandwidth and time constant. The basic structure of component *A* is the same at the two frequencies. Thus there is a narrow component superimposed on a weaker, more extended source, and running towards *B* and more clearly visible at coarser resolutions a faint flat extension. Unlike the 430-Mc/s curves the narrow source is not asymmetrically placed with regard to the extended source which appears to extend away from *B* on the far side of *A*. The width of the narrow component is difficult to estimate because of the uncertainty in the base level. If we consider the extended source and central component as a single source then its half-width is 0·9″, indicating a source size of about 0·6″, while if we draw the zero as indicated by the broken line the central region is not significantly resolved and has a width $\leqslant 0{\cdot}4''$. The structure seen around component *B* on the 1,420 Mc/s curve is not visible at 430 Mc/s and must be considered spurious and probably due to irregularities in the limb of the Moon, although the possibility remains that it is genuine but that the sources have a steeper spectral index than *B*. It is the presence of these sources which apparently led to the conclusion that *B* has a core-halo type of structure—a conclusion which is certainly not true at 430 Mc/s. However, the 1,420 Mc/s results still indicate that *B* is resolved, for the observed half-width is 0·92″, corresponding to an angular size of 0·7″. As the presence of the irregularities near *B* indicates that for this occultation the irregularities in the limb of the Moon may be a significant source of error it is possible that they are responsible for its apparent resolution although the narrow width observed for the central region of *A* is a strong suggestion that the resolution may be real. In this case, the structure at 1,420 Mc/s must be different from that at 430 Mc/s. This is, the source may be elongated or it may indeed have a core-halo structure but with the halo having a steeper spectral index than the core. Alternatively there may be two sources present with different spectral indices, only one being visible at 430 Mc/s and both visible at 1,420 Mc/s. A further possibility is that the two sources are oriented so that they passed simultaneously behind the Moon on June 7 but with an apparent separation of about 0·5″ on October 26, 1962. Whatever the explanation, it is now clear that component *B* has structure less than about 0·15″ of arc and there is no discrepancy between the occultation observations and alternative methods of estimating the source size.

It is now of interest to compare the optical and radio distributions. It seems reasonable to assume that component *B* is in fact coincident with the stellar object and that this object can be used as a reference point in making the comparison. Hughes and Van Hoerner have shown that the radio emission is essentially confined to a line joining *A* and *B*, a conclusion which was suggested by the early occultation observations. If we make this assumption then the position and extent of the various components of *A* can easily be deduced from the angles between the limb of the Moon and the axis of the source at the times of occultation.

The results of this analysis are summarized in Fig. 5. The narrow component at both frequencies lies very close to the end of the jet, 19·3″ and 20·1″ at 430 and 1,420 Mc/s compared with the optical value of 20·0″. The flat extended component at 430 Mc/s merges into the noise at a distance of about 8″ from *B* while the long flat extension at 1,420 Mc/s becomes visible at a distance of 10″, which is close to the start of the optical jet at 11″ from *B*. The sharp fall in the flux from the extended source visible at 430 Mc/s with a resolution of 0·4″ is 14″ from *B* which corresponds closely at 1,420 Mc/s to the edge of the extended source lying beneath the narrow component.

It seems clear that this extended source at 1,420 Mc/s is associated with the flat central component observed at 430 Mc/s, the main difference being that while at 1,420 Mc/s it reaches at least 6″ beyond the edge of the jet there is no evidence for any extension of the central component at 430 Mc/s. However, the 0·9″ resolution curve in Fig. 2 suggests that the extended region of *A* does reach beyond the edge of the jet which indicates that at least part of the extension at 1,420 Mc/s may be associated with the long flat extension rather than the central extended component. There is therefore a remarkable correlation between the optical and radio features; of particular interest is the constancy of the flux at 430 Mc/s over a large region of the visible jet and the strong suggestions that the narrow component arises in a shock-front at the leading edge of the jet. It may be noted that the change in the structure of the source with frequency will lead to an apparent change in position with frequency unless the resolution is adequate to reveal the detailed structure.

A comparison has been made of the ratio of the fluxes of *A* and *B* from the 430 Mc/s records of August 20, 1962, and those of June 7, 1965. The comparison is somewhat complicated by the different angles of cut across the source in both cases and by the presence of some weak structure which may not lie along the line joining *A* and *B*. However, adopting all possible interpretations, it is clear that the ratio of *A* to *B* has not changed by more than 7 per cent and more likely by less than 2 per cent over the 3-year period. This suggests that unless both components are varying in the same way the flux of *B* has changed by less than 7 per cent which may be compared with the value of 51 per cent estimated by Dent at 8,000 Mc/s over approximately the same period.

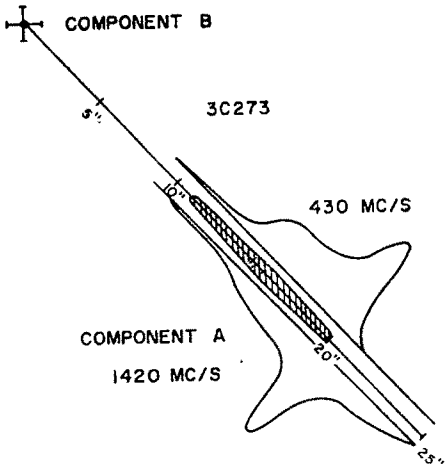

Fig. 5 Schematic representation of the optical, 430-Mc/s and 1,420-Mc/s distributions along the axis of 3C273. It has been assumed that component *B* is coincident at both frequencies with the stellar object. The shaded area represents the faint optical jet

We thank Prof. W. E. Gordon for his interest and encouragement throughout the course of the work.

BRIGHTNESS TEMPERATURE OF SOLAR ACTIVE REGIONS DETERMINED FROM DRIFT CURVES OF THE SUN ACROSS A BROAD ANTENNA MAIN LOBE

By DR H. W. URBARZ
Weissenau Radio Astronomy Station, Astronomical Institute of the University at Tubingen, Germany

TWO methods are being used in investigating solar active regions of small diameter at radio frequencies; these are: scanning the Sun by high-resolution radio telescopes with fan beams or pencil beams and discussing solar eclipse curves providing high resolution in one dimension. Another method and its results are briefly discussed here, which can be described as the superposition of wide-beam transit curves.

From October 1960 to March 1964 continuous measurements of the total solar radio flux density were made with some interruptions at Tubingen at 3,750 mc/s. The main lobe of the 10 ft. horn fed reflector was about 110 min of arc wide. A number of solar transits were recorded from time to time in order to check the antenna characteristics. The integrated brightness temperature and flux density were derived from the antenna temperature of the continuous records, which is the maximum transit value[1,2]. The measurements were made to find the daily mean values of the quiet and slowly varying components and to record burst events. The slowly varying component is due to coronal condensations, which appear as small areas of enhanced temperature on the solar disk and disappear over periods of weeks or months. The apparent brightness temperature of the small active areas may be derived by superposing drift curves, provided the location and diameter of the enhanced areas on the solar disk are known. These data were available from optical maps and high-resolution radio observations. The results show that small active areas may be determined by the superposition method with small radio telescopes as used for daily measurements of mean values. The method may in particular be interesting at other frequencies than 9·1 cm and 21 cm at which solar radio maps are produced by high-resolution instruments. The 21-cm maps were edited from 1959 to October 1962 by Fleurs Observatory and the 9·1 cm radio maps are being edited by Stanford Observatory[3,4]. The essential idea of the superposition method is to regard the solar brightness distribution as a disk of uniform temperature superposed by Gauss-type sources of defined location and maximum temperature and width. A measured drift curve may be considered a result of the superposition of individual drifts of the main lobe across the quiet Sun described by a cylindric source model and a number of small areas of much higher temperature described by Gauss-type sources. The drift curve of an antenna main lobe described by a Gauss distribution $F_n = \exp(-\zeta^2/\alpha'^2 - \gamma^2/\beta'^2)$ across a cylindric source characterized by radius $R_\odot$ and uniform temperature T_c is given[1] by the relation:

$$T_{Ac} = T_c\left(1-\beta_s\right)\frac{R_\odot^2}{\alpha'\beta'}\exp\left(-\frac{\zeta^2}{\alpha'^2}-\frac{\gamma^2}{\beta'^2}\right)\left\{1-\frac{R_\odot^2}{2\alpha'^2}\left(\frac{1}{2}-\frac{\zeta^2}{\alpha'^2}\right)-\frac{R_\odot^2}{2\beta'^2}\left(\frac{1}{2}-\frac{\gamma^2}{\beta'^2}\right)\right\} \quad (1)$$

T_{Ac} is the main lobe contribution to antenna temperature caused by the source, and α', β' are the Gauss parameter of the main lobe, β_s is the stray factor of the antenna and ζ, γ are the distances of the source centre relative to the main lobe-centre in a rectangular co-ordinate system.

The term in parentheses is a correction if the source radius $R_\odot$ is not very small relative to α', β'.

The drift curve of a Gauss-type source across the main-lobe described by maximum temperature T_g and width parameters α, β is given by:

$$T_{Ag} = \left(1-\beta_s\right)T_g\frac{\alpha\beta}{\alpha'\beta'}\exp\left(-\frac{\zeta^2}{\alpha'^2}-\frac{\gamma^2}{\beta'^2}\right) \quad (2)$$

In equation (2) it is assumed that $\alpha, \beta \ll \alpha', \beta'$, that is the widening of the transit curve due to finite source extension is neglected, since the half power width (HPW) would be $\mathrm{HPW} = \sqrt{\ln 2}\ \alpha\ \{1+1/2\ (\alpha/\alpha')^2\}$

The response of antenna temperature to a drift in ζ-direction through the centre of the solar disk and a number of small sources imposed located at (a_n, b_n) may now be written:

$$T_{A,tot} = T_{Ac}\left(\zeta, 0\right) + \sum_{n=1}^{n} T_{Ag}\left(\zeta - a_n, \gamma - b_n\right) \quad (3)$$

The summation of the stationary mean values of noise powers is correct if the contributions of the individual areas are incoherent. This is no doubt the case for any surface element of the solar disk emitting noise. Fig. 1 shows the location of the sources relative to the main lobe centre and the corresponding drift curves, where ζ and γ may be identified as hour angle and declination respectively. The resulting drift curve across the quiet Sun and one or more small hot areas is essentially the sum of exponential functions with different amplitudes K_n and different deviations a,b of the maximum with respect to the centre $\zeta = 0$ of the quiet Sun drift curve.

The maximum excentric deviation is $\zeta_{max} = R_\odot$, representing a source on the solar limb located at $\gamma = 0$. The resulting maximum of the superposed transit curve will be located between $\zeta = 0$ and $\zeta = R_\odot$. Since $\alpha', \beta' \sim 4\,R_\odot$ the amplitude at ζ_{max} will be practically the same as at $\zeta = 0$; at $\zeta = 1/2\ R_\odot$ we have $\exp(-1/69) = 0{\cdot}985$. So one may conclude that in any case the resulting maximum of $T_{A,tot}$ (ζ) will be situated close to $\zeta = 0$. The approximation $\zeta_{max} = 0$ simplifies the analysis considerably, the error being the smaller, the smaller the ratios $(R_\odot/\alpha'; R_\odot/\beta')$. If, for example, two or more hot areas are located on one half of the solar disk, the effect of unsymmetry will accumulate. But in general the sources will be distributed over the east and west half, so that the unsymmetry of $T_{A,tot}$ (ζ) will be partially cancelled. The best way, it is felt, of studying a special case of source distribution is to write equation (3) with all numerical values. The numerical values of the parameter of our telescope not related to the superposed sources are[1]:

$T_\odot = 27 \times 10^3$ °K, $\beta_s = 0{\cdot}415$, $R_\odot = 32'$, $\alpha' = 4{\cdot}14\ R_\odot$, $\beta' = 3{\cdot}85\ R_\odot$

Inserting these values in equation (3) and setting $\zeta = 0$ we get the relation:

$$T_{A,tot,\max} = 958 + \sum_{n=1}^{n} T_{g\,n} \frac{\alpha_n \beta_n}{30{\cdot}34\ R_\odot^2} \exp\left\{ - \frac{a^2 n}{17{\cdot}13\ R_\odot^2} - \frac{b^2 n}{14{\cdot}83\ R_\odot^2} \right\} \quad (4)$$

This relation may be applied to any distribution of enhanced areas on the solar disk, if the maximum antenna temperature of the transit curve $T_{A,tot,\max}$ has been recorded with our telescope.

Now this relation is to be used in connexion with the solar radio[3] may of October 31, 1960, reproduced in Fig. 2. The optical solar map of the Fraunhoferinstitute[7] shows two large sunspots near the radio spots in the north-east and south-east quadrant of the disk, coinciding with Ca-plage regions. Table 1 gives the co-ordinates a,b and the Gauss parameters of the sources gathered from the 21-cm radio map. It may be assumed that the temperature maxima of the 21-cm spots coincide with the maximum at 8 cm. With the data of Table 1 and equation (4) we get a simple relation for the T_g and α,β values at 8 cm:

$$1{,}529 = 958 + 0{\cdot}034\ T_{g1} \frac{\alpha_1 \beta_1}{R_\odot^2} + 0{\cdot}036\ T_{g2} \frac{\alpha_2 \beta_2}{R_\odot^2} \quad (5)$$

This is an equation with four unknowns, and, to get more relations, two assumptions on the spectrum are made which may include considerable error: that the ratio of maxima temperatures and that of the source parameters is the same at 8 cm as it is at 21 cm. From Table 1 we have:

$$T_{g1}/T_{g2} = 1/2{\cdot}58 \quad (6)$$

$$\frac{\alpha_{8\ cm}}{\alpha_{21\ cm}} = \frac{\beta_{8\ cm}}{\beta_{21\ cm}} \quad (7)$$

$$\alpha_1\beta_1/\alpha_2\beta_2 = 2 \quad (8)$$

The brightness temperatures of the quiet Sun were found conventionally by extrapolating the daily mean values of the flux density to the sunspot number 0 plotted in a scatter diagram. Data of the period from October 15,

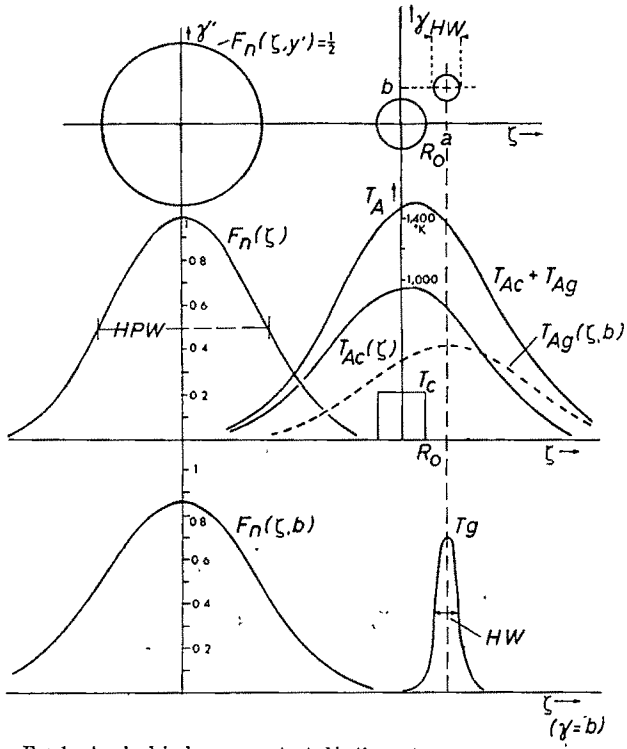

Fig 1. A cylindrical source is situated in the centre A Gauss-type source is at (a, b) of the ζ γ system A Gauss-type antenna main lobe is swept across the two sources in ζ direction. The resulting response of antenna temperature is the sum of the individual drift curves $T_{Ac}(\zeta)$ and $T_{Ag}(\zeta,b)$. The following parameters are used in the true scale graph: $a' = 4\ 14R_\odot, \beta' = 3{\cdot}85R_\odot, a = 2R_\odot, b = 1{\cdot}5R_\odot, \alpha,\beta = 0\ 6R_\odot, HW = R_\odot$

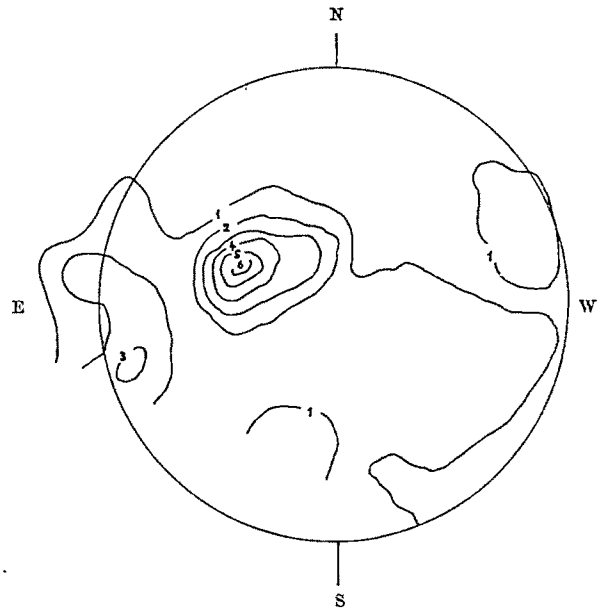

Fig. 2. October 31, 1960 ζ=21-cm spot scan, Fleurs, Sydney; $T_\odot = 10^6$ °K: isophote level

1960, to February 28, 1961, were included[2,3,5]. Labrum[6] has found that the quiet Sun component of the total solar flux density and consequently the apparent disk temperature show variations in the ratio 1 : 2 from sunspot minimum to maximum. The adopted values ($T_{\odot,21\ cm} = 1{\cdot}1 \times 10^6$ °K and $T_{\odot,8\ cm} = 2{\cdot}7 \times 10^4$ °K) represent the quiet sun level during the period in question. The daily mean values of the Heinrich-Hertz-Institut at 21 cm were plotted in the scatter diagram with the proposed correction factor of 0·7 (ref. 8).

Little is known about the morphology and the spectrum of radio condensations, but from known observations one may state qualitatively that the area of a condensation as well as the apparent brightness temperature increases with wave-lengths. In our case this means the 8 cm area is not larger than the 21-cm area and the same holds for the maxima temperatures. To find some 8-cm parameters, the following procedure was used. First, the β values of Table 1 were inserted in equation (5) and the values T_{g1}, T_{g2} were determined using equation (6). The temperatures of Table 1 were then inserted in equation (5) and the source parameters α,β were found from equations (7) and (8) and Table 1. Table 2 gives the results. The parameters of the model describing the 8-cm condensation found by this procedure are the minimum values. The true 8-cm values of T_g and α,β will be closer to the 21-cm data. Interpolating simply between the two models found by the superposition method, $T_{g21\ cm}$ $\alpha_{8\ cm}$ $\beta_{8\ cm}$ and $T_{g,8\ cm}$, $\alpha_{21\ cm}$ $\beta_{21\ cm}$, might lead to a better approximation of the true distribution (Table 3).

Examining 21-cm and 9·1-cm radio maps one finds a variety of enhanced areas regarding diameters and maximum temperature. Unfortunately these recordings only overlap a few months. Furthermore, we now know that mapping the Sun with 0·5 min of arc pencil beams is required instead of a 3 min of arc beam width. More statistical material of very high resolution at three or more frequencies is desirable in order to find the spectral features and to determine the emission process of condensations. It can be supposed that two basic types exist: purely thermal emission and thermal emission with gyromagnetic emission. These may be ascribed to weak condensations of coronal or lower temperatures or to intense condensations exceeding it, both giving different spectral features. The gyro mechanism of radiation from condensations was proposed in ref. 12. The collected observations in ref. 8 tend to indicate that higher tempera-

tures than coronal exist, and this should be confirmed by observations at very high resolutions.

Some spectral features regarding size seem to be definite. Plotting the diameter of fourteen different condensations against frequency given in refs. 8–11 shows no variation of diameter from 3 cm to about 15 cm, while from 15 to 30 cm wave-length the simple relation $A=1\cdot6\lambda+b$ can be adopted, where A is the area in sq. min of arc (product of HPW of profiles), λ is the wave-length in cm, and b is a constant varying from one condensation to another. According to Table 1, source 1 has an area of 55 sq. min at 21 cm, and $b=21$ gives 44 sq. min at 8 cm. The interpolated values of Table 3 give 38 sq. min which is in fairly good agreement.

It is not, however, possible to find a similar relation for peak temperatures from the present observations. Eclipse measurements give the extent of sources in one dimension correctly, but to deduce temperature from brightness requires both diameters in perpendicular directions. An estimate of the lacking diameter leads to an estimate of peak temperature only[9–11]. On the other hand, as the present pencil beam observations yield flattened values of peak temperatures, the estimates of Table 3 cannot be improved, and interpolating in this way may be adopted as a feasible procedure.

TRIGGERING OF THE ALASKAN EARTHQUAKE OF MARCH 28, 1964, AND MAJOR AFTERSHOCKS BY LOW OCEAN TIDE LOADS

By EDUARD BERG

Geophysical Institute, University of Alaska, College, Alaska

DURING the investigation of the tsunami in South-central Alaska, many of the interviewed inhabitants of the damaged harbours, villages and isolated homesteads stated that it was very fortunate that the 'quake had occurred during the low tide levels. The tsunami thus did not cause nearly as much damage as if it had occurred at high tide level which is generally some 4–5 m higher. The low tide has therefore been considered as a possible trigger for the main earthquake and larger aftershocks. Stresses and strains induced in the crust either from atmospheric disturbances or from the solid earth tides have been considered possible influences on the occurrence of earthquakes. Knopoff[1], however, has shown that the solid earth tides do not have a statistically meaningful influence in California. The peak-to-peak strains induced are about $1/2\times10^{-7}$.

Those induced in the area of the Gulf of Alaska are considerably higher. The results of other investigations seem to indicate the incidence of earthquakes in regions where some anomalous crustal loading occurs. D. S. Carder[2] reports earthquakes associated with the reservoir loading of the Boulder Dam area and his calculations indi-

cate the correct relation between earthquake energy and deformation under the water load. Dr. and Mrs. Gough also reported a higher incidence of shocks as a result of waterloading in a dam area from Rhodesia[3]. McGinnis[4] investigated the earthquake incidence due to water load changes in the Mississippi Valley Region, where the earthquake frequency increases with an increase in the rate of change of river stage, and the rate of energy release increases with an increase in water mass, the addition of a water load only aiding the movement of a subsiding crust.

Very pronounced occurrence of earthquake swarms under low ocean tidal loads have been described in the Bay of Sagami area by Matuzawa[5] (after research by the Imamura group). In this case, however, the tide variations at the coast are only about 1 m (peak to peak), whereas those in the shelf area of the Gulf of Alaska are about 4–5 m (peak to peak). In Japan, as in Alaska, the earthquakes occur during the low water half of the tide cycle.

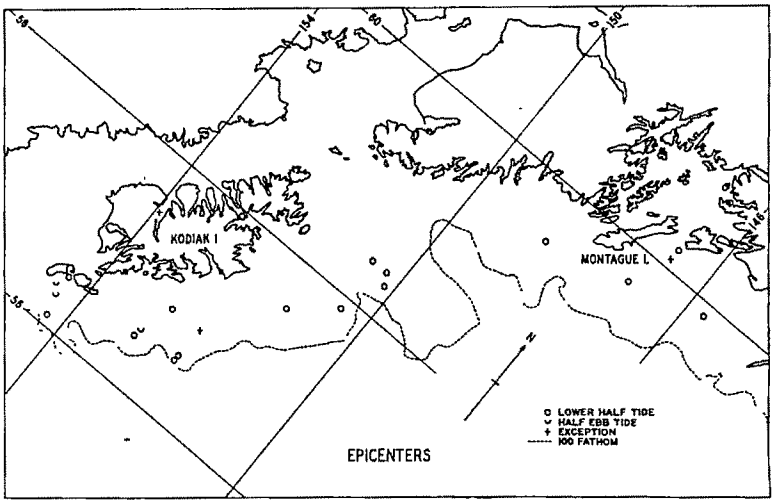

Fig. 2. Epicentre locations of shocks with $m_B \geq 5{\cdot}5$, O, lower half tide; U, half ebb tide, +, exception; - - -, 100 fathoms

The tidal diurnal ranges in the Gulf of Alaska are very high compared with elsewhere. In the preparation of Fig. 1, only those locations very close to open water have been chosen, to give an idea of the loading in the shelf area itself. This shelf area is here (more or less arbitrarily) considered to be limited by the 100-fathom line, since from there on the depth increases very rapidly towards the Aleutian Trench (or its extension) to about 2,000 fathoms within 70 km in the middle section of the aftershock area, and twice as fast south of Kodiak Island[14]. The tide ranges are highest in the north-eastern part and diminish progressively further out along the Aleutian Chain. Since Middleton Island, situated almost on the edge of the shelf, has a diurnal range of 10·3 ft., I feel that 3 m is a representative level for most of the Gulf area, compared with diurnal variations some 20 per cent higher (12·3 ft.) at Cordova in the Prince William Sound area. Also, the absolute water levels have drastically changed throughout Alaska (by about 6 ft. at Cordova, 20 ft. in most of Montague Island and 5 ft. in Kodiak) although the tidal variations stood basically the same. Therefore, the predicted tides still could be used for the present investigation.

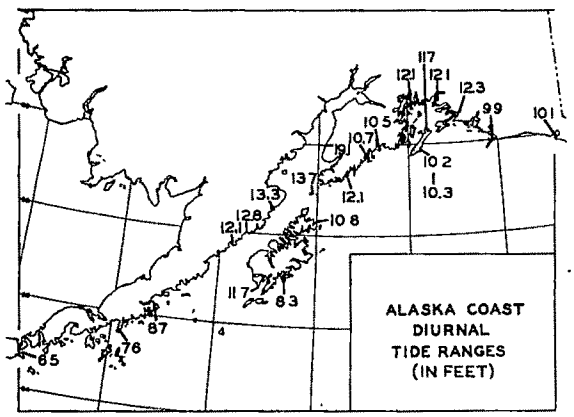

Fig. 1. Tide ranges along the Alaskan coast (in ft.)

Fig. 2 shows the location of the epicentres of all the shocks of magnitude $m_B \geq 5{\cdot}5$ to August 30, 1964, listed in the first part of Table 1, except for the main shock. The table includes all the aftershocks of $m_B \geq 5{\cdot}5$ listed by the U.S. Coast and Geodetic Survey starting 24 h after the main shock. The aftershocks for the first 24 h are not included, since their occurrence is predominantly determined by the aftershock release mechanism.

Fig. 3 shows the tide levels for Cordova and partly for Kodiak (dashed lines) and the time (A.S.T.) of occurrence of the earthquakes with respect to the tides up to April 19. It is found that most of the quakes occur in the lower

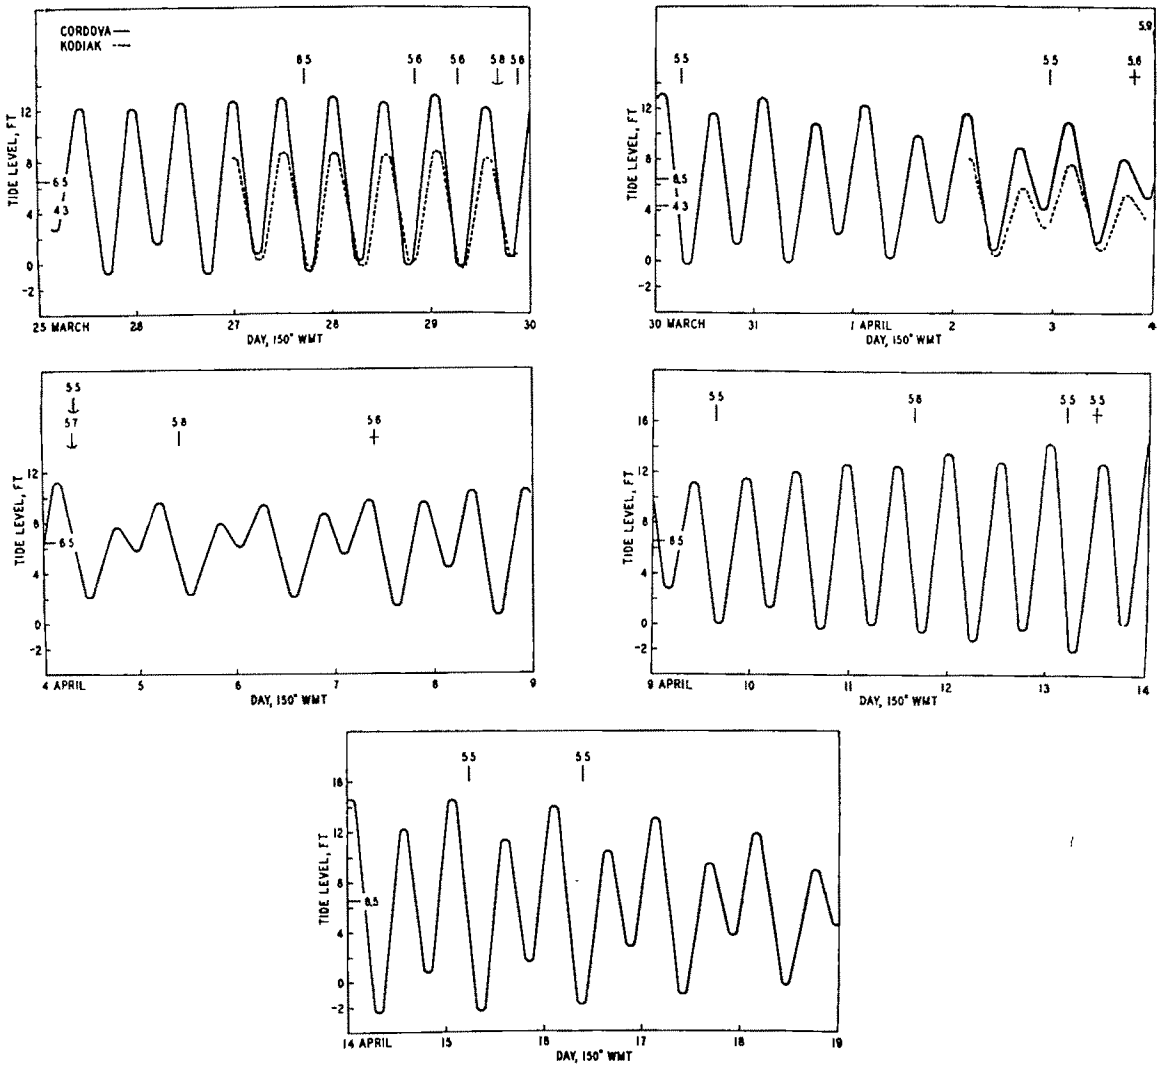

Fig 3 Earthquake occurrence and tide levels[6]

half of the tide cycle or very close to the half ebb tide. The exceptions which may be explained are: two 'quakes at a depth of 39 and 40 km, the 'quakes inland or on Kodiak Island, and one off the shelf area. Since the stresses induced by the tide load diminish with depth and with the distance from the coastline and the tide levels also diminish with the depth of water, these exceptions may be expected.

The exceptions are marked on Figs. 2 and 3 by a cross. The 'quakes marked with an open half circle are those very close to the half ebb tide.

The remaining two 'quakes which are exceptions are those of May 29 at the north-eastern end of the aftershock zone and the one of August 2 at the very south-western end (off the map). No attempt has so far been made to consider shocks of magnitude $m_B < 5{\cdot}5$.

No attempt is made to solve the problem of the fracture mechanism of rocks *in situ*, that is, at the earthquake failure zone. But if it is admitted that the 'quakes examined here have been effectively triggered by the unloading of the crust, some more data limiting the figures for rock strength in an important earthquake belt are obtained.

During a half-tide cycle of about 6 h duration the pressure varies approximately by 0·3 kg/cm² on the ocean floor of the shelf area. This pressure variation seems to act as a trigger for the main 'quake and the subsequent aftershocks (excluding the first 24 h) of $m_B \geqslant 5{\cdot}5$. Since brittle fracture seems to be excluded at some depth, and on the other hand strain and tilt observations prior to large earthquakes point towards rapidly increasing values as the failure approaches, it is assumed that a 'creep' fracture is involved. The rocks *in situ* are already stressed far beyond the yield point into the strain-hardening portion of the stress-strain curve, possibly into the strain-softening area, so that the additional shear force generated by the unloading of the crust (see Fig. 4) in the shelf area and applied during a few hours is sufficient to bring the material to the fracture point. It may be that the very shallow 'quake (5 km) of May 29, which did not occur during the unloading, is an indication that the creep or flow fracture is confined to greater depth and does not apply to very shallow depth earthquakes.

In laboratory experiments the shear strength of rocks is of the order of 100–400 kg/cm²,[7] but several workers pointed out that strengths of rocks *in situ* are reduced by

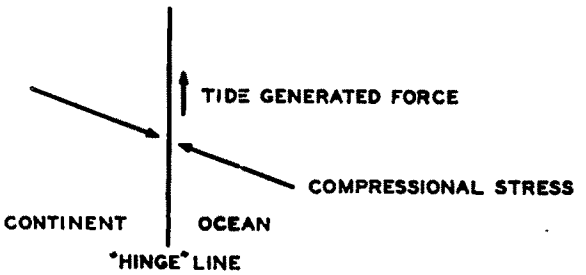

Fig 4 Stress system along the hinge line

up to 2 orders of magnitude[8]. It seems reasonable, therefore, to assume that the crustal unloading is able to initiate fracture when the pressure variation is of the order of 1 per cent or less of the total fracture stress. Also, laboratory stress experiments with other materials indicate that failure occurs much more rapidly if a very small cyclic stress is superimposed on a continuous one, where the amplitude of the cyclic stress is even less than 1 per cent of the continuous one. In a particular kind of steel under an 'equilibrium' stress of 120,000 lb./in.^{2} and strain of 4×10^{-2} large flow rates of 5×10^{-3}/sec in strain are initiated by only a 1·5 per cent overstress[9].

Assuming similar behaviour for rocks *in situ*, an upper limit for the failure stresses encountered can be obtained. Using 0·3 kg/cm^2 × 100, a value roughly of the order of 30 kg/cm^2 is found which will, however, diminish with increasing depth.

Balakina[10] has shown that for all the major earthquakes (with one exception) in the Aleutian Chain and the Alaska belt, the principal stress axis is compressional and more or less perpendicular to the tectonic trend. In addition it is directed slightly upward on the Pacific Ocean side for focal depths less than 100 km. I found[11] that this holds also for the main shock and major aftershocks (partly unpublished data) in the Alaska 1964 event.

The periodical unloading of the crust generates an additional upward directed component of force, introducing a periodic shear enhancing the existing stress system and the tectonic movement along the 'hinge' line. The 'hinge' line separates zones of land rise on its ocean side from land subsidence on its continental side[12,13] (Fig. 4).

The unloading of the crust by large ocean tides may be considered as a triggering mechanism for the Alaska earthquake of March 1964 and major aftershocks. The stress system is compatible with that deduced from fault plane solutions and land-uplift and subsidence which occurred during the main shock.

Since brittle fracture seems to be excluded at some depth, the time interval of a few hours and the pressure variation involved as a result of the ocean tide cycle seem to be significant in carrying the last part of the stress-strain curve in the 'strain-softening' region towards failure.

I thank Dr. Maurice Ewing, Dr. Jack Oliver and Mr. William Best for valuable discussions and strong encouragement to publish these data.

This research was supported by the U.S. Air Force Office of Scientific Research as part of the Advanced Research Projects Agency's Vela Uniform programme.

DEPENDENCE OF CONTACT ANGLES ON TEMPERATURE: POLAR LIQUIDS ON POLYETHYLENE

By HAROLD SCHONHORN
Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

INVESTIGATIONS of the dependence on temperature of the advancing contact angle of liquids on 'low energy' solids, notably the thermoplastic polymers, have been reported by Phillips and Riddiford[1] and Johnson and Dettre[2]. Before these investigations, relatively few data existed for the effect of temperature on the contact angle[3]. This communication presents the results of some experiments and calculations on the effect of temperature on advancing contact angles between polar liquids and polyethylene. The experimental data on contact angles for the glycerol–polyethylene system are analysed in the light of current theoretical approaches to interfacial phenomena[4,5]. The impetus for this investigation has been the extensive wettability investigations of Zisman[6] and the theoretical work of Fowkes[4] and Good *et al.*[5]. Moreover, the implications in the area of adhesion are considerable[7].

The glycerol, which was used without further purification, was a 'Baker Analysed' reagent from the J. T. Baker Chemical Company. The surface tension at 20° C was 63·4 dynes/cm as measured with a Du Noüy tensiometer.

The polyethylene was a 'Marlex 5003' obtained from the Phillips Chemical Company, Bartlesville, Oklahoma. The polymer had a melt index of 0·3 and a density at 20° C of 0·95. A 0·010-in.-thick film was formed by moulding at about 1,000 lb./in.^{2} and 160° C.

For the measurements of contact angle, the polyethylene film was mounted on a standard microscope slide, using double-backed adhesive tape, then placed on a hot stage. A surface thermometer with an accuracy of ±1° C, manufactured by the Pacific Transducer Corporation, Los Angeles, California, was placed on the polyethylene surface external to the area used for contact angle measurement to provide a record of the interfacial temperature.

The advancing contact angles were measured directly using a telescopic device equipped with an ocular protractor which was built by the Gaertner Scientific Corporation, Chicago, Illinois. Three separate drops were placed on the polymer surface with opposite edges of the drops being measured. The drops were equilibrated for 10 min at each temperature before reading the contact angle. The reproducibility of the readings was about ±2°. The comparatively high vapour pressure of both water and formamide precluded their study under the conditions of the present experiment.

The results of the temperature dependence of the contact angle of glycerol on polyethylene are presented in the last column of Table 1. The contact angles were between 78° and 80° in the temperature range from 20° C to about 120° C, just below the melting point of the polyethylene. The readings were taken at 10° C intervals, although only the 20° C and the 90° C are reported in Table 1. We shall attempt to interpret these results in view of the recent approaches by myself[8], Fowkes[4] and Good[5].

Schonhorn[8] has proposed on the basis of the surface-tension experiments of Schonhorn and Sharpe[9,10] that at 25° C:

$$\gamma_{LV} = \gamma_c \qquad (1)$$

where γ_{LV} is the surface tension of the supercooled liquid polymer and γ_c is the critical surface tension of wetting[6]. Further, we propose that equation (1) is valid at all temperatures. Then we may state that:

$$d\gamma_{LV}/dT = d\gamma_c/dT \quad (2)$$

When γ_{LV} is known as a function of temperature, we automatically know the temperature dependence of γ_c.

The Young equation:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV}\cos\theta \quad (3)$$

in conjunction with Fowkes's expression[4]:

$$\gamma_{SL} = \gamma_{SV} + \gamma_{LV} - 2(\gamma^d_S\gamma^d_{LV})^{1/2} \quad (4)$$

and equation (1) yields:

$$\cos\theta = \frac{2[(\gamma_{LV})_p\gamma^d_{LV}]^{1/2}}{\gamma_{LV}} - 1 \quad (5)$$

where p refers to the polymer.

To estimate cos θ as a function of temperature the temperature dependence of $(\gamma_{LV})_p$, γ^d_{LV} and γ_{LV} must be known. Schonhorn and Sharpe[9] have measured the surface tension of polyethylene over an extended temperature interval. The values for surface tension listed in Table 1 were obtained by extrapolating the data of Schonhorn and Sharpe[9] to low temperatures. The γ_{LV} values for water[11], glycerol[11] and formamide[11] are also recorded in Table 1. To estimate γ^d_{LV}, we propose that the ratio $\gamma^d_{LV}/\gamma_{LV}$ is invariant with temperature. Fowkes[12] has estimated the γ^d_{LV} values at 20° C for water, glycerol and formamide to be 21·8, 37·0 and 40·7 dynes/cm, respectively. Now equation (5) becomes:

$$\cos\theta = \frac{2k^{1/2}(\gamma_{LV})_p^{1/2}}{\gamma_{LV}^{1/2}} - 1 \quad (6)$$

where $k = \gamma^d_{LV}/\gamma_{LV}$. The results of these computations for the systems under investigation are summarized in Table 1. The validity of the foregoing proposal is readily apparent from the agreement between the experimental and calculated values of cos θ or θ for the glycerol–polyethylene system.

The water contact angle remains remarkably constant, but does show signs of decreasing at elevated temperatures. The predicted value of θ = 103° is in agreement with the work of Fowkes[12] but does not agree with the experimental value of Zisman[6]. Fowkes demonstrated that a plot of cos θ vs. $\sqrt{\gamma^d_{LV}/\gamma_{LV}}$ yields a γ_c of about 35 dynes/cm for polyethylene. This agrees quite well with the γ_{LV} value of 36·2 dynes/cm obtained by Schonhorn and Sharpe[9]. If the experimental value of θ = 94° is employed, poor agreement is obtained in a Fowkes-type plot. This implies that the measured value of θ = 94° is somewhat low.

The calculated contact angles for the formamide–polyethylene system are remarkably constant over an extended temperature range. There is better agreement between the calculated and the experimental values of θ at 20° C for the glycerol–polyethylene and formamide–polyethylene systems than the water–polyethylene system.

Since the accuracy of any measurement of contact angle is about ±2°, no change in the wettability should be observed in any of the foregoing systems. Although both $(\gamma_{LV})_p$ and γ_{LV} decrease with increasing temperature, the ratio of their square roots remains essentially constant for the polyethylene–polar liquid systems. It would be fortuitous indeed if the ratio $(\gamma_{LV})_p^{1/2}/(\gamma_{LV})^{1/2}$ always remained constant. In reality, we might expect:

$$d(\gamma_{LV})/dT > d(\gamma_{LV})_p/dT$$

and, therefore, that there may be a point where $(\gamma_{LV})_p = \gamma_{LV}$. If this occurs, then cos θ = 1 and θ = 0.

COBALT-60 GAMMA-RADIOLYSIS OF DEUTERIUM–OXYGEN MIXTURES

By DR. DON A. KUBOSE

U.S. Naval Radiological Defense Laboratory, San Francisco, California

THIS laboratory has been examining the radiological health hazard involved from an accidental release of tritium gas in a confined area. Pinson and Langham[1] have shown that the internal radiation hazard from tritiated water vapour is several orders of magnitude greater than that from molecular tritium at equivalent concentrations. Hence, much of our work on this problem has been directed toward measurement of the rates of the self-initiated reactions of tritium and water vapour (exchange) to form tritiated water vapour, and of tritium and oxygen to form tritium oxide.

Yang and Gevantman[2] investigated the isotopic exchange of tritium with water vapour. Using initial tritium activities of 0·05–0·7 mc./c.c., they found the rate of exchange to be second-order with respect to initial tritium concentration. The reported rate constant with respect to tritium was $1·67 \times 10^{-3}$ c.c./mc./h. The rate was also found to be constant over a four-fold variation in the density of water vapour.

The self-oxidation of tritium in oxygen to form tritium oxide has been investigated by Casaletto, Gevantman and Nash[3]. The rate of reaction was found to be second-order with respect to initial tritium concentration over the concentration range 0·02–1 mc./c.c. The rate constant reported was $1·19 \times 10^{-3}$ c.c./mc./h. Dorfman and Hemmer[4] have also investigated this reaction but at

much higher initial concentrations of tritium. The rate of reaction was directly proportional to the initial tritium concentration. A rate constant of $7{\cdot}14 \times 10^{-3}$/h was reported. The range of initial tritium concentration was between 94 and 324 mc./c.c.

In both investigations of the self-oxidation of tritium, the methods used to follow the rate of reaction precluded the detection of products other than the assumed tritium oxide. Casaletto *et al.* determined the amount of product formed by condensing the product, pumping off the unreacted reactants, and counting the condensate with a liquid scintillation spectrometer. Dorfman and Hemmer followed the reaction by direct measurement of the pressure change of the reaction system.

The present investigation of the cobalt-60 γ-radiolysis of mixtures of oxygen and deuterium (used as a tritium substitute) was undertaken to determine whether any other product, such as deuterium peroxide, would be formed, and to gain further insight into the mechanism of the oxidation reaction.

Deuterium (Bio-Rad Laboratory, Richmond, California) of a stated purity of 99·5 per cent was used without further purification other than passing it through a U-tube immersed in liquid nitrogen. Extra-dry-grade oxygen (Matheson Co.) of 99·6 per cent minimum purity was used without further purification. Research grade argon (Matheson Co.) was used for blank runs. Nitrous oxide (Edwards Dental Supply, San Francisco), before it was used for absorbed dose measurements, was purified by trap-to-trap distillation, using liquid nitrogen-isopentane and liquid nitrogen-toluene slushes. Analysis of the purified nitrous oxide showed less than 10^{-3} mole per cent nitrogen.

All gas handling was performed on a high vacuum system of conventional design. The base pressure of the system (as measured by a 'Veeco' ionization gauge) was 1×10^{-7} torr. A calibrated Toepler pump was built and incorporated into the vacuum system to permit pressure-volume measurements of product gases.

The irradiation cell, of 'Pyrex', consisted of two volumes connected by a break-seal; the larger volume had another break-seal which was used to empty the cell after a run. The larger volume, nominally 125 c.c., was cylindrical and had an internal diameter of 1·6 cm and length of 15 cm. The smaller spherical volume, nominally 25 c.c., was joined to one end of the cylindrical volume by the connecting break-seal. Each volume had a 2-mm capillary tubulation for filling and subsequent sealing. This cell design enabled the deuterium and oxygen to be introduced (deuterium in the spherical volume and oxygen in the cylindrical volume) and sealed off separately to avoid any thermal reaction between deuterium and oxygen due to the heat of the sealing operation. After both volumes had been filled and sealed off, the connecting break-seal was broken with a 'Pyrex' slug (previously put into the cylindrical volume during the fabrication of the cell) and the deuterium and oxygen allowed to mix.

The general procedure used for filling a cell was as follows. After attachment of the cell to the vacuum system, it was flamed *in vacuo* with a gas–air torch and evacuated to 10^{-7} torr. On cooling to room temperature, the gas was introduced into the cell up to the desired pressure, as measured by a mercury manometer. The deuterium was passed through a U-tube, immersed in liquid nitrogen, before entering the cell. The oxygen was kept condensed at liquid nitrogen temperature in a trap outside the cell during the filling operation, and it was allowed to warm up to the desired pressure by lowering of the liquid nitrogen dewar from the trap. The filling of cells with nitrous oxide for dosimetric measurements was performed in a manner similar to that for oxygen. Argon was expanded directly into the evacuated cell. In all instances a trap cooled by either liquid nitrogen, a liquid nitrogen-toluene slush, or a dry-ice-acetone bath was used to prevent mercury vapour from entering the cell during the filling operation. All cells were filled to a total gas pressure of 600 torr.

All irradiations were carried out at ambient temperature in a 2,000-c. cobalt-60 radiation source at a dose rate of $5{\cdot}61 \times 10^{16}$ eV/c.c./h, as determined by nitrous oxide dosimetry[5].

After irradiation, the cell was sealed to the inlet of the calibrated Toepler pump and the product deuterium oxide condensed in liquid nitrogen. The break-seal was then broken, and the unreacted deuterium and oxygen pumped out. After the cell had been evacuated to 1×10^{-7} torr, the cell was warmed to room temperature and the amount of deuterium oxide determined by pressure-volume measurements.

The search for reaction products other than deuterium oxide, presumably deuterium peroxide and ozone, was carried out using both ferrous sulphate[6] and titanium sulphate[7] reagents. The technique used was the following. After irradiation, a bulb containing the reagent was attached to the cell via a ball-and-socket joint and the break-seal was broken. The ferrous sulphate or titanium sulphate reagent was introduced into the cell, the cell was shaken for approximately 10 min, and the solution was then centrifuged to clear it of small glass particles. A Cary 'Model 11' recording spectrophotometer was then used to analyse the solution for either ferric ion or the $[TiO_2(SO_4)]^=$ complex[7] at 3020 Å and 4100 Å, respectively. Blank runs of irradiated mixtures of deuterium and argon and of oxygen alone were treated in an identical manner.

The data obtained from measurement of the amount of deuterium oxide formed as a function of absorbed dose for each initial concentration of deuterium were treated with conventional kinetic expressions. The data for the low initial deuterium concentration ($3{\cdot}7 \times 10^{-4}$ mole/l.) were found to fit first-order kinetics, giving a rate constant, k_1, of $5{\cdot}3 \times 10^{-3}$/h with respect to deuterium concentration. The high initial deuterium concentration ($3{\cdot}7 \times 10^{-3}$ mole/l.) data fitted zero-order kinetics, giving a rate-constant, k_0, of $4{\cdot}5 \times 10^{-6}$ mole/l./h with respect to deuterium concentration. The two plots are shown in Figs. 1 and 2. Data obtained for two intermediate initial deuterium concentrations fitted a zero-order kinetic plot most closely. The reaction was carried out to at least 30 per cent completion in all cases. The amounts of deuterium oxide formed in irradiated mixtures of deuterium and argon were negligible.

Nitrous oxide was used as the dosimeter: the nitrogen produced was measured and the G value, $G(N_2)$, of 11·4 (11·4 molecules of nitrogen formed per 100 eV energy absorbed) was used. The dose rate as measured in nitrous oxide was $5{\cdot}61 \times 10^{16}$ eV/c.c./h.

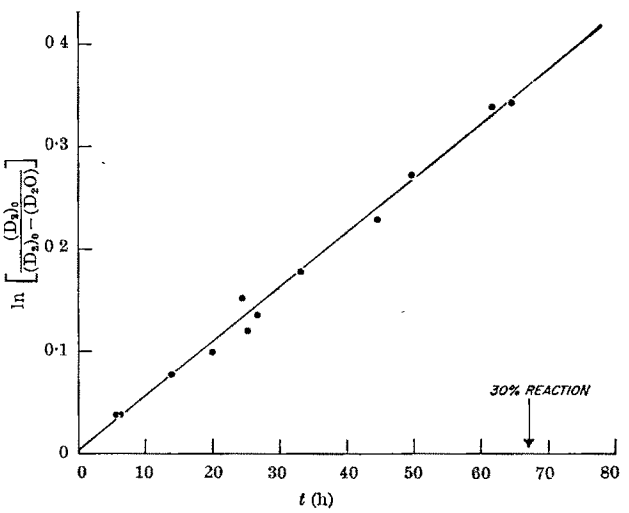

Fig. 1. First-order plot for $(D_2)_0 = 3{\cdot}7 \times 10^{-4}$ mole/l.

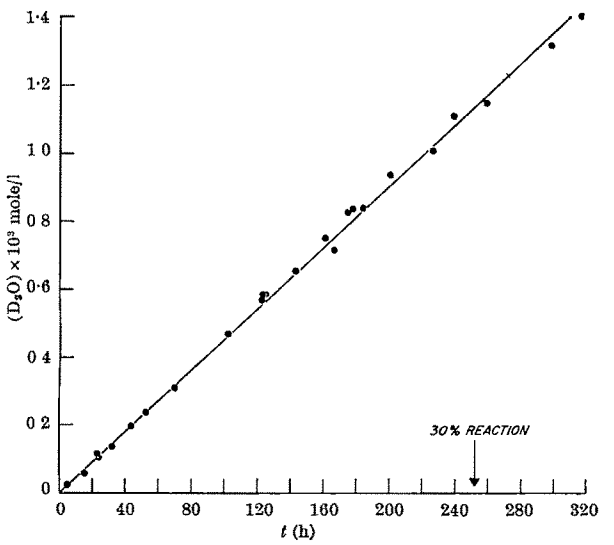

Fig 2. Zero-order plot for $(D_2)_0 = 3\,7 \times 10^{-3}$ mole/l.

The initial G values for deuterium oxide formation were calculated in the following manner. A general expression for dose absorbed, D, in eV/c.c. can be written:

$$D = \left(\frac{N \text{ molecules}}{\text{mole}}\right)\left(\frac{[P] \text{ mole}}{\text{litre}}\right)\left(\frac{100 \text{ eV}}{G(P) \text{ molecules}}\right)\left(\frac{\text{litre}}{1{,}000 \text{ c.c.}}\right) = \frac{N[P]}{G(P)10} \quad (1)$$

where N is Avogadro's number, $[P]$ the concentration of a product in mole/l., and $G(P)$ the G value for the formation of P. The expressions for the dose absorbed by nitrous oxide, D_{N_2O}, and by the deuterium–oxygen mixture D_M, are:

$$D_{N_2O} = \frac{N[N_2]}{G(N_2)10} \quad (2a)$$

$$D_M = \frac{N[D_2O]}{G(D_2O)10} \quad (2b)$$

D_{N_2O} and D_M are related by:

$$\frac{D_{N_2O}}{D_M} = \frac{Z_{N_2O}}{Z_M} \quad (3)$$

where the Z's represent electron densities of the respective systems. Combining equations (2) and (3) and solving for $G(D_2O)$:

$$G(D_2O) = \frac{Z_{N_2O}}{Z_M} \cdot \frac{[D_2O]\,G(N_2)}{[N_2]} \quad (4)$$

Substituting the equivalent kinetic expression for the concentrations of deuterium oxide and nitrogen into equation (4) gives, for the low initial concentration of deuterium:

$$G(D_2O) = \frac{Z_{N_2O}}{Z_M} \cdot \frac{G(N_2)[D_2]_0(1 - e^{-k_1 t})}{k_0' t} \quad (5)$$

where $[D_2]_0$ is the initial concentration of deuterium, k_1 the first-order rate constant for deuterium oxide formation, k_0' the zero-order rate constant for the formation of nitrogen from nitrous oxide, and t the time in hours. The limit of equation (5) as t approaches zero is:

$$G_0(D_2O) = \frac{Z_{N_2O}}{Z_M} \cdot \frac{G(N_2)[D_2]_0 k_1}{k_0'} \quad (6)$$

The analogous expression for $G_0(D_2O)$ at the high initial deuterium concentration is:

$$G_0(D_2O) = \frac{Z_{N_2O}}{Z_M} \cdot \frac{G(N_2)k_0}{k_0'} \quad (7)$$

where k_0 is the zero-order rate constant for deuterium oxide formation at the high initial deuterium concentration.

Analogous expressions (each applying to the appropriate concentration region) for the calculation $G_0(T_2O)$ derived from the data of Casaletto *et al.*, and Dorfman and Hemmer are:

$$G_0(T_2O) = \frac{k_2 NB[T_2]_0}{C\,100}; \; [T_2]_0 \text{ in mc./c.c.} \quad (8)$$

where k_2 is Casaletto's second-order rate constant, in c.c./mc./h, for the formation of tritium oxide, B is $1{\cdot}71 \times 10^{-8}$ mole/mc. and C is $7{\cdot}58 \times 10^{12}$ eV/mc./h; and:

$$G_0(T_2O) = \frac{k_1' NB}{C\,100} \quad (9)$$

where k_1' is Dorfman and Hemmer's first-order rate constant.

A comparison of pertinent quantities between the tritium–oxygen and deuterium–oxygen systems is shown in Table 1. The observed value of $1{\cdot}04 \times 10^{-5}$ mole/l./h for k_0' was used in the calculations.

The results using the ferrous sulphate reagent, which is known to react with all suspected oxidizing products, are summarized in Figs. 3 and 4. For the low initial deuterium concentration the difference in absorptivity of ferric ion between the irradiated mixture and oxygen blank is still about 0·2 at about 30 per cent reaction, while for the high initial deuterium concentration it is zero at about 15 per cent reaction. If this difference can be attributed to deuterium peroxide, its maximum concentration is of the order of 1×10^{-5} mole/l. Blank runs of irradiated argon–deuterium mixtures and argon alone gave negligible ferric ion absorbances.

Table 1. Comparison of Pertinent Quantities for the Deuterium–Oxygen and Tritium–Oxygen System

Radiation	Initial concentration of T_2 and D_2	Reaction order	Rate constant	$G_0(T_2O)$, $G_0(D_2O)$
			T_2–O_2 system	
Internal T_2 β	0 02–1 mc./c.c. ($3{\cdot}4 \times 10^{-7}$–$1\,7 \times 10^{-5}$ mole/l.)	2nd	$1{\cdot}19 \times 10^{-3}$ c.c./mc./h ($6{\cdot}96 \times 10\,1$/mole/h)	1 62 $(T_2)_0$ [$(T_2)_0$ in mc./c.c.] $9\,47 \times 10^4$ $(T_2)_0$ [$(T_2)_0$ in mole/l.]
	95–328 mc./c.c. ($1\,6 \times 10^{-3}$–$5\,6 \times 10^{-3}$ mole/l.)	1st	$7{\cdot}14 \times 10^{-3}$/h	9·7
			D_2–O_2 system	
External ^{60}Co γ	$3{\cdot}7 \times 10^{-4}$ mole/l.	1st	$5\,3 \times 10^{-3}$/h	$7{\cdot}7 \times 10^3 (D_2)_0$
	$3{\cdot}7 \times 10^{-3}$ mole/l.	0	$4{\cdot}5 \times 10^{-6}$ mole/l./h	7 3

Titanium sulphate, a reagent known to be specific for hydrogen peroxide in the presence of ozone[7], was used in an attempt to establish the presence of deuterium per-

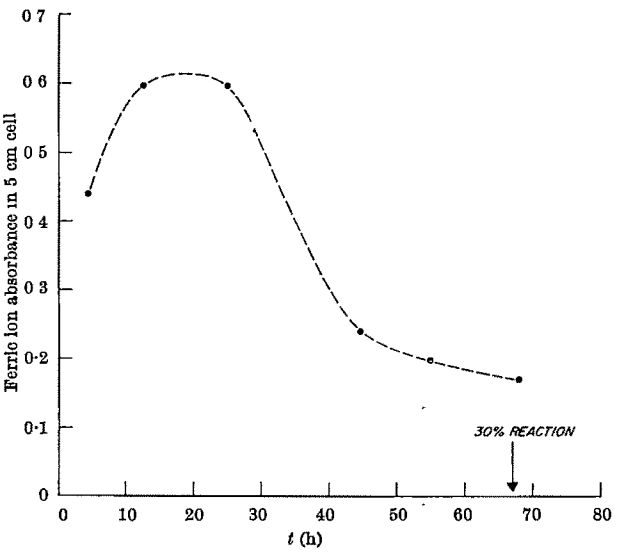

Fig 3. Difference in ferric ion absorbance between mixture and oxygen blank versus irradiation time. Initial concentration of deuterium in mixture = $3\,7 \times 10^{-4}$ mole/l.

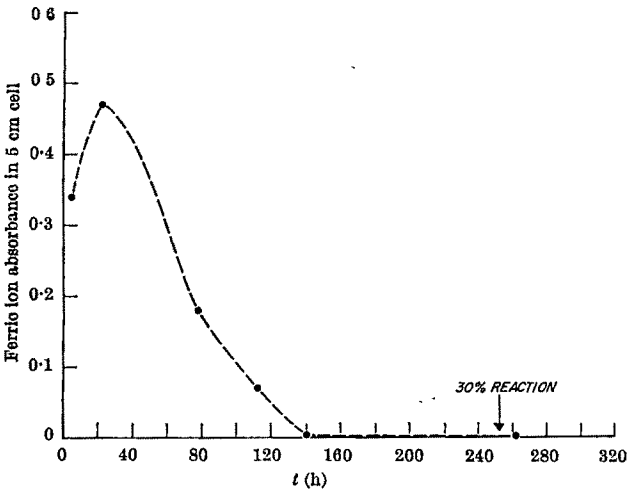

Fig. 4. Difference in ferric ion absorbance between mixture and oxygen blank versus irradiation time. Initial concentration of deuterium in mixture = $8{\cdot}7 \times 10^{-5}$ mole/l.

oxide. Calibration of this reagent with known amounts of hydrogen peroxide established that a concentration of 5×10^{-6}/l. of hydrogen peroxide will give an absorbance of 0·025 at 4100 Å in a 10-cm absorption cell. The absorbance increased linearly with added peroxide. Therefore, the amount of deuterium peroxide attributed to the difference in ferric ion absorbance between the mixture and oxygen blank, 1×10^{-5} mole/l., should have been easily measurable. However, when a mixture of deuterium and oxygen and an oxygen blank were irradiated for a time corresponding to the maximum shown in Fig. 3, no change in absorbance was observed at 4100 Å using a 10-cm absorption cell when the titanium sulphate reagent was used. Several runs were made and each gave a negative result, indicating that some species other than deuterium peroxide is oxidizing the ferrous sulphate in the irradiated deuterium–oxygen mixtures.

Several runs were made using the ferrous sulphate with cells the surface-area-to-volume ratio of which was increased eight-fold by placing lengths of small diameter 'Pyrex' tubing in the irradiation cell. The difference in ferric ion absorbance between the irradiated mixtures of deuterium and oxygen and oxygen blanks obtained for the cells with larger surface-area-to-volume ratio was essentially the same as that obtained for the cells with normal surface-area-to-volume ratio. The amounts of deuterium oxide formed were also about the same for both types of cell.

It is of interest to make a speculative comment on the orders of reaction observed for the tritium–oxygen and deuterium–oxygen systems. For the rate expression suggested by Casaletto *et al.*:

$$\frac{d(T_2O)}{dt} = k_2[T_2]_0[T_2] \qquad (10)$$

(the subscript '0' denotes initial conditions), it was suggested by them that one of the tritium terms remained as the initial concentration (since it represented the radiation intensity) and thus was not consumed in the normal sense during the reaction. If this is true and if their second-order kinetics hold at the lowest initial deuterium concentration used here, the use of deuterium and external radiation would lead to the observed first-order kinetics for the deuterium–oxygen system. Extending this line of thought to Dorfman and Hemmer's study, the observed zero-order kinetics for the deuterium–oxygen system would be expected.

In contrast to the results reported here (that is, no deuterium oxide formation in blank runs using argon in place of oxygen), Casaletto *et al.* found no decrease in the rate of tritium oxide formation using reagent grade helium in place of oxygen. It must be noted that as little as 0·005 per cent of oxygen in the inert gas would be sufficient to give their observed results. They explained the apparent result that the formation of tritium oxide was independent of oxygen concentration by suggesting an ion cluster mechanism in which O_2^-, formed by attachment of free electrons to oxygen, neutralized positive ion clusters, the resulting active species ultimately leading to the formation of stable products. Since the reaction is with O_2^-, it would be zero-order with respect to oxygen. Since the results using deuterium showed a dependence on oxygen concentration, the mechanism involved here must overshadow the one suggested by Casaletto *et al.*

The initiating step of the mechanism involved here would be the absorption of energy by the oxygen to form ozone and oxygen atoms by way of a mechanism such as that suggested by Magee and Burton[8]. An additional route subsequent to ionization of oxygen is the formation of the perhydroxy radical by an ion-molecule reaction[9], followed by neutralization:

$$O_2^+ + D_2 \rightarrow DO_2^+ + D \qquad (11a)$$

$$DO_2^+ + e \rightarrow DO_2 \qquad (11b)$$

The possible fates of the deuterium and oxygen atoms include reactions such as:

$$D + O_2 \rightarrow DO_2 \qquad (12)$$

$$O + D_2 \rightarrow OD + D \qquad (13a)$$

$$OD + O_3 \rightarrow DO_2 + O_2 \qquad (13b)$$

Although little or no deuterium peroxide is found as a product, probably it is formed as a transient species as a consequence of reactions such as:

$$2DO_2 \rightarrow D_2O_2 + O_2 \qquad (14)$$

The deuterium oxide may then be formed from the direct decomposition of deuterium peroxide and from reactions of the type:

$$O + D_2O_2 \rightarrow D_2O + O_2 \qquad (15)$$

The ion-molecule reaction:

$$O_2^+ + D_2 \rightarrow D_2O^+ + O_2 \qquad (16a)$$

$$D_2O + e \rightarrow D_2O \qquad (16b)$$

may also contribute[10].

The results using the titanium sulphate reagent show that very little, if any, deuterium peroxide is formed as a measurable reaction product. It is noteworthy to mention here that Volman[11] has observed almost complete removal of hydrogen peroxide when ozone and hydrogen peroxide are brought together in the gas phase. However, it is felt that the difference in the absorbance of ferric ion produced between the irradiated mixtures and irradiated oxygen blanks is real. It seems unreasonable to expect that the small amount of deuterium ($[D_2]\,[O_2]^{-1} = 0{\cdot}012$) present and D_2O formed would increase the production of ozone in the mixture relative to that produced in the oxygen blank to the extent represented in Figs. 3 and 4.

The product measured by ferric ion absorbance must then be due to some other species capable of oxidizing ferrous ion but not reacting with titanium sulphate. Since D_2O, D_2O_2 and O_3 are the only products that can exist in the gas phase, this species must be on the wall of the cell since it is stable for at least several minutes after removal from the radiation field. The results using cells with increased surface-to-volume ratio indicate that the species is formed in the gas phase and diffuses to the wall where it is stabilized. No attempts were made to establish the identity of this species.

Comparison of Figs. 3 and 4 shows that the difference in absorbance between the mixture and the oxygen blank approaches zero much sooner in terms of percentage reaction for the mixture with the high initial deuterium concentration. This observation suggests that at the low initial deuterium concentrations the wall 'competes' favourably with other reaction paths for the unknown

species, while at the high initial deuterium concentration almost all of it is available for reactions leading to formation of deuterium oxide. This may account, in part, for the change in reaction order and increased yield of deuterium oxide at the high initial deuterium concentration.

FOAM FRACTIONATION OF PHENOL

By Prof. R. B. GRIEVES and R. C. ARONICA
Illinois Institute of Technology, Chicago

FOAM separation processes have been used for the removal from aqueous solution of proteins and enzymes including catalase, pepsin and albumin, of fatty acids and detergents, of dyes including bromothymol blue, congo red and methyl orange, of cations such as calcium, magnesium and strontium, and of anions including picrate, gallate and 1- and 2-naphthoic acid[1]. For non- or weakly-surface-active materials, foaming agents have been added. For inorganic and organic cations and anions, various mechanisms have been postulated by which the ions, together with the surface-active additive, are carried into the foam phase. These include the formation of a surfactant–ion complex which is then adsorbed at the air–aqueous solution interfaces of the foam-producing bubbles; and the electrostatic attraction between the anionic or cationic surfactant adsorbed at the interfaces of the bubbles and the non-surface-active ion of opposite charge.

Phenol is of particular interest to sanitary chemists and biologists due to its influence on the quality of water supplies. Phenol and phenolic compounds impart strong tastes and odours to water, particularly in the presence of chlorine, and they can have deleterious effects on aquatic life. The U.S. Public Health Service drinking water standard for phenol is 0·001 p.p.m. Phenol is weakly surface-active, producing a maximum depression of the surface tension of water from 72 to 41 dynes/cm. The aeration of an aqueous solution of phenol produces a very wet, unstable foam.

Eldib[2] has studied the foam separation of phenolate from spent caustic solutions produced from the sweetening of petroleum fractions. Using 0·04 per cent patent blue dye as a foaming additive, a limited separation was obtained. Other surfactants were not investigated, but the use of cationic surfactants of opposite charge to the phenolate anion appears to be a logical choice. Phenol has been chemisorbed successfully on to strongly basic anion exchange resins in the quaternary ammonium salt form[3,4]. There is some evidence of the formation of a compound of the form $—[R_4N]^+ C_6H_5O\text{-}Cl^-$ by the adsorption of phenolate ($C_6H_5O^-$) at the amine group[4].

The objective of this research was the investigation of the foam fractionation of phenol (phenolate) from aqueous solution using a cationic surface-active agent, a quaternary ammonium salt. The effects of *p*H, phenol concentration and surfactant concentration were elucidated, and the separation is discussed in terms of the residual phenol concentration, the enrichment ratio, and the relative removal of phenol and surfactant.

The foam fractionation apparatus was similar to that used in previous investigations[5,6]. All experiments were carried out in a cylindrical glass column, 9·5 cm in diameter and 52 cm in height. Nitrogen gas was saturated with water, metered with a calibrated 'Rotameter', and passed through a sintered glass diffuser, 3 cm in diameter and of 50μ porosity. The average nitrogen flow rate was 350 ml./min (at 25° C and a pressure of 1 atm.). For each experiment 2 L. of feed solution in distilled water were prepared containing from 13·5 to 672 mg/l. ($1·44 \times 10^{-4}$ to $7·15 \times 10^{-3}$ M) phenol (Analytical Reagent Grade) and from 200 to 600 mg/l. ($5·28 \times 10^{-4}$ to $1·59 \times 10^{-3}$ M) ethylhexadecyldimethylammonium bromide (EHDA-Br), a cationic surfactant. The *p*H was adjusted with 0·2 M sodium hydroxide. The feed solution was placed in the column and the nitrogen flow was begun. Foam was continuously collected at a port located 44·5 cm above the base of the column, 16·3 cm above the feed solution level, and each experiment was terminated after all foaming had ceased, which required approximately 2·5 h operation. Temperature was maintained within the range 24–26° C. At the end of each experiment the volume of the residual solution was measured, the residual concentration of phenol was determined using the modified aminoantipyrine method[7], and the residual concentration of EHDA-Br was measured by a two-phase titration technique[8]. The phenol analysis was accurate to within 2 per cent and the EHDA-Br analysis to within ± 2 mg/l. Several control experiments were conducted to establish if any phenol was removed from aqueous solution (no EHDA-Br) by volatilization into the gas stream. In all cases, negligible reductions were obtained.

Effect of *p*H. For each experiment, the following material balances can be written:

$$V = V_r + V_f \quad (1)$$

$$z_i V_i = z_r V_r + z_f V_f \quad (2)$$

$$x_i V_i = x_r V_r + x_f V_f \quad (3)$$

V_i, V_r and V_f are the volumes in litres of the feed solution, residual solution and collapsed foam, respectively; z is the concentration of phenol and x is the concentration of EHDA-Br in the appropriate solution; the subscripts i, r and f refer to the feed, residual and collapsed foam, respectively. For feed solutions containing 200 mg/l. of EHDA-Br and 23·2 and 92·6 mg/l. phenol, the effect of *p*H on the ratio of the residual phenol concentration to the feed phenol concentration is presented in Fig. 1. In each case, little reduction is obtained until the *p*H is elevated to approximately 9·0, and minima in both curves are produced at *p*H ≈ 11·5. The greater reduction for the feed solutions with z_i = 23·2 mg/l. is clearly brought about by the higher EHDA-Br to phenol ratio in the feed (2·14 g ion EHDA/g ion phenolate as compared with 0·54 g ion/g ion for z_i = 92·6 mg/l.).

As the *p*H is increased from 6·0, the ratio of phenolate ion ($C_6H_5O^-$) to phenol continually increases. At *p*H 10, the ratio is 1·0, at *p*H 11 the ratio is 10, and at *p*H 12 the ratio is 100. Since the foam fractionation process either relies on the production of a complex between the phenolate anion and EHDA cation or on the electrostatic

attraction between the ions at the air–solution interfaces associated with the bubbles, lower residuals would be expected as the *p*H is elevated and phenolate becomes the predominant form[5]. The increase in the values of z_r/z_t above *p*H 11·5 is more difficult to explain. Since quaternary ammonium bases are considered to be strong electrolytes and no dissociation constants are reported, it is unlikely that the EHDA ions react with the hydroxide ions to form ethylhexadecyldimethylammonium hydroxide. Decomposition of the EHDA ions to an amine and an alcohol should occur to a very slight degree at the atmospheric temperatures used. The most logical explanation is that above *p*H 11·5 the hydroxide ions are in sufficiently high concentration to interfere with the phenolate ions from a consideration of complex formation with or attraction to the EHDA cations. From this behaviour, it is most likely that the mechanism of the foam fractionation process involves ion attraction at the bubble interfaces. The predominance of phenolate over bromide as far as the attraction is concerned is undoubtedly brought about by the hydrophobicity and surface activity of phenol.

In these experiments, the volumes of collapsed foam produced and residual concentrations of surfactant were very insensitive to *p*H and to the feed concentration of phenol. For the twenty-four experiments shown in Fig. 1, the collapsed foam volume ranged from 0·07 to 0·21 l. in a random manner. The concentration of phenol in the foam was thus maximized at *p*H $\approx$ 11·5. For the same runs, the residual concentration of EHDA-Br ranged from 6·0 to 12·0 mg/l., also in a random manner.

Effect of feed phenol concentration and surfactant concentration. A second series of experiments was conducted to establish the influence of the concentrations of phenol and EHDA-Br in the feed solutions on the foam fractionation process. The *p*H was maintained at approximately 12·9; this value was selected to avoid inconsistencies in results which would have been realized if 11·5 had been chosen. In the *p*H range 11–12 better reductions in phenol would have resulted, but in this region the data would have been very sensitive to small *p*H variations. A total of twenty-seven experiments was made with the feed solutions containing from 13·5 to 672 mg/l. of phenol and 200, 400 and 600 mg/l. of EHDA-Br. Feed ratios thus ranged from 6·15 to 0·074 g ion EHDA to g ion phenolate. The residual concentrations of phenol (actually phenolate but referred to as phenol herein) are plotted along the abscissa in Fig. 2 versus the feed concentrations of phenol along the ordinate. The three curves are for x_t = 200, 400 and 600 mg/l. and the straight line (dotted) for x_t = 0 (no phenol separation). At x_t = 200 mg/l., z_r/z_t ranged from 0·27 to 0·93, at x_t = 400 mg/l. from 0·15 to 0·82, and at x_t = 600 mg/l. from 0·12 to 0·79. At constant x_t, z_r/z_t always increased with z_t, and clearly at constant z_t, z_r/z_t always decreased as x_t was increased. For the same data, enrichment ratios, defined as the concentration of phenol in the collapsed foam divided by that in the residual solution, ranged from 1·4 to 71·2. A value of 1·0 corresponds to no separation.

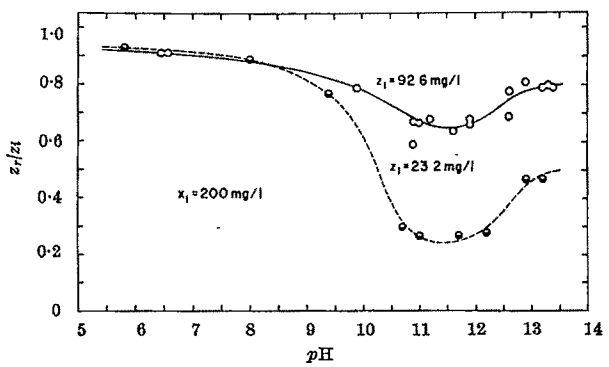

Fig. 1. Effect of *p*H on ratio of residual phenol concentration to feed phenol concentration

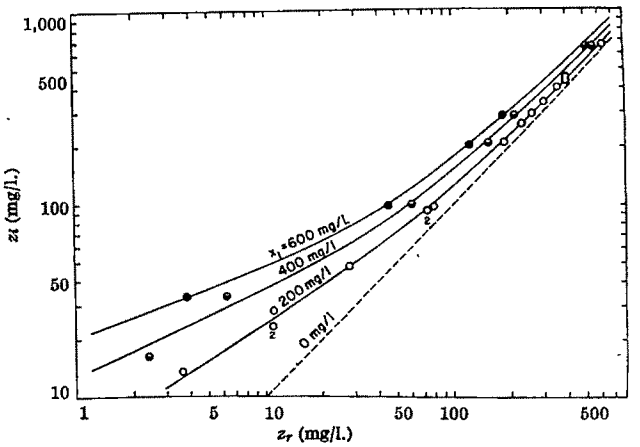

Fig. 2. Relationships between residual phenol concentration and feed phenol concentration for three feed surfactant concentrations

In these experiments, the volume of collapsed foam was independent of the feed concentration of phenol and was related only to the feed concentration of EHDA-Br. On the average for x_t = 200 mg/l. V_f = 0·21 l., for x_t = 600 mg/l. V_f = 0·42 l., and for x_t = 600 mg/l. V_f = 0·61 l. The residual concentration of EHDA-Br was independent of both z_t and x_t, ranging from 4·0 to 14·0 mg/l., in a random manner. It is interesting to observe that the presence of phenol had no effect on the collapsed foam volume or residual surfactant concentration, compared to the foam fractionation of pure EHDA-Br solutions.

A useful parameter which provides some insight into the nature of the foam fractionation process is $z_f/x_f]_{\text{Fractionation}}$[5]. In any foam separation process the surface-active agent and other solutes of interest are carried into the foam phase in two manners: one in the surface layers at the air–solution interfaces of the bubbles, the other as entrained bulk solution carried into the foam mechanically. Of course, a large percentage of the entrained bulk solution drains from the foam if a column of sufficient height is provided. In order to compute the relative concentrations of phenol and EHDA-Br in the surface layers, the quantities of both in the entrained bulk solution must be subtracted from the quantities of both in the total foam stream. For this investigation this was done in an approximate manner first by assuming that the fraction of the foam consisting of entrained bulk solution was very large compared with the fraction corresponding to the air–solution surface layers; and secondly by using the arithmetic average of the feed and residual concentrations of phenol and EHDA-Br to compute the composition of the entrained bulk solution, which decreased continuously from z_t to z_r during a run. The former assumption has been validated in an examination of the foam fractionation of pure surfactant solutions[9]. The latter assumption was validated partially by several rate experiments which indicated a linear decrease in the residual phenol concentration with time. With these assumptions:

$$z_f/x_f]_{\text{Fractionation}} = \frac{z_f - \left\{\frac{z_t + z_r}{2}\right\}}{x_f - \left\{\frac{x_t + x_r}{2}\right\}}$$

From the experimental data the following relationship between $z_f/x_f]_{\text{Fractionation}}$ and z_t and x_t was obtained:

$$z_f/x_f]_{\text{Fractionation}} = 0{\cdot}06\ (\exp)^{-0{\cdot}00443 x_t}\ z_t^{(0\ 0134 x_t^{\ 0{\cdot}608})} \qquad (4)$$

At constant x_t, $z_f/x_f]_{\text{Fractionation}}$ increases as z_t is increased; at constant z_t, the parameter decreases as x_t is increased for

small z_i but increases as x_i is increased for large z_i. For the twenty-seven experiments considered, $z_f/x_f]_{\text{Fractionation}}$ ranged from 0·035 to 0·306. If one phenolate anion is removed in the bubble surface layers with each EHDA cation, $z_f/x_f]_{\text{Fractionation}}$ will be 0·249, the ratio of the molecular weights of phenol and EHDA-Br. All but two of the experimental values were less than 0·249, indicating that more surfactant is required than the theoretical amount, and that there is some competition between bromide and hydroxide with phenolate for the EHDA cations[5].

Phenol has been foam fractionated using a cationic surface-active agent, ethylhexadecyldimethylammonium bromide. The mechanism of the process involves either the formation of a surface-active complex between EHDA cations and phenolate anions or the electrostatic attraction between the ions at the air–aqueous solution interfaces associated with the bubbles. From these investigations it appears that the latter is the true mechanism. Little separation is obtained until the *p*H is elevated to 9, and a minimum in the residual phenol concentration is obtained at *p*H $\approx$ 11 5. Considering a broad range of feed phenol and EHDA-Br concentrations, the residual concentration of phenol may be reduced to 0·05 of the feed concentration, but this requires about 50 g EHDA-Br/g phenol. A new parameter is introduced relating the quantities of phenol and EHDA-Br in the surface-layers of the foam bubbles. Values are compared with the theoretical value.

STRUCTURAL SPECIFICITY OF α-CHYMOTRYPSIN: POLYPEPTIDE SUBSTRATES

By GARY L. NEIL and [the Late] PROF. C. NIEMANN
Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena
AND
PROF. GEORGE E. HEIN
Department of Chemistry, Boston University, Boston

THE specificity of proteolytic enzymes towards model substrates has been extensively investigated during the past two decades. The relation of these investigations to the biological specificity of proteolytic enzymes for proteins is still an open question. It is the purpose of this discussion to relate the available information on the specificity of chymotrypsin towards polypeptides[1] with the considerable information on its specificity towards acylated amino-acid esters. A similar analysis of data for pepsin has recently been published[2].

The suggestion that the specificity of proteolytic enzymes is determined by the number, constitution, configuration and sequence of amino-acid residues in a peptide chain was first advanced more than 50 years ago by Emil Fischer[3]. The importance of specific residues was questioned during the early decades of this century by several groups of workers, but the data available were not sufficient for a clear picture to emerge. (Pertinent references and a brief history are given by Bergmann, M., *Adv. Enzymol.*, 2, 49; 1942).

The researches of Bergmann and his collaborators in the 'thirties gave a concrete foundation for the first time to general concepts of enzyme specificity. Bergmann synthesized a large number of small peptides of known structure and stereochemistry, containing most of the amino-acids commonly found in proteins, and he subjected these to semi-quantitative enzyme catalysed hydrolysis. He concluded[4] that the specificity observed for proteolytic enzymes, and especially for pepsin, trypsin and chymotrypsin, depended primarily on the nature of the side chain of a single, specific amino-acid and secondarily on the nature of amino-acid residues farther removed from the susceptible bond.

During the following two decades, from approximately 1940–60, considerable attention was focused on the aforementioned primary factor, the nature of the side chain of the carboxyl residue of susceptible bonds.

In particular, the specificity of α-chymotrypsin has been investigated thoroughly. This work gained impetus from the discovery of the esterase activity of chymotrypsin[5] and from the development of rapid kinetic techniques based on the use of *p*H-stats[6]. Extensive investigations by Niemann and his collaborators have resulted in a specificity theory which correlates the kinetic data obtained for the enzyme catalysed hydrolysis of more than 150 substrates of chymotrypsin[7,8].

In the past few years, the question of the specificity of chymotrypsin for larger peptides has received renewed attention from the use of this enzyme, among others, in the elucidation of amino-acid sequences of polypeptides and proteins. A number of 'abnormal' splittings have been observed[9] and the concept of secondary specificity, determined by amino-acid residues adjacent to the susceptible amino-acid on the carboxyl side of the bond which is to be split, has been reintroduced[1,10,11].

Classification of Enzyme Specificity

It is probably advantageous to discuss levels of enzyme specificity for proteolytic enzymes, in terms similar to those used for protein structure. Thus, one may speak of the primary, the secondary and the tertiary specificity of proteolytic enzymes. Primary specificity refers to the minimum structure required for enzyme specificity to be manifest. For proteolytic enzymes this is usually an amino-acid residue containing a side chain, an amido group and a carbonyl function. For chymotrypsin, trypsin and pepsin, the primary specificity is observed in the carboxyl end of the susceptible peptide bond. Specifically, the primary specificity of trypsin is towards arginyl and lysyl bonds; of chymotrypsin for aromatic, leucyl and perhaps methionyl bonds. The secondary specificity of proteolytic enzymes refers to the influence of adjacent amino-acid residues in a polypeptide chain on the observed hydrolytic reaction. A common example is the negative influence of prolyl residues, when attached to a carboxyl group, on hydrolytic rate for both chymotrypsin and trypsin catalysed hydrolyses. The tertiary specificity refers to the action of proteolytic enzymes on

native, active protein molecules in solution. Typical examples are the activation of chymotrypsinogen by trypsin—in which only a few of the many bonds which should be split by trypsin on the basis of primary specificity of this enzyme are susceptible[12]—or the unique splitting of a single peptide bond in ribonuclease by subtilisin[13].

The similarity of the proposed nomenclature to that introduced by Linderstrøm-Lang[14] and commonly used for proteins is no accident. He derived his classification scheme from a consideration of the effect of proteolytic enzymes on native and denatured proteins. The common first reference to the Linderstrøm-Lang terminology is to a lecture entitled, "The Initial Stages in the Breakdown of Proteins by Enzymes"[14]. However, the present usage differs from the conventional subdivision of protein structure into primary, secondary and tertiary. For convenience, we have defined the primary and secondary specificity of proteolytic enzymes so that both refer to aspects of the primary structure of a protein substrate. Tertiary specificity of proteolytic enzymes refers to all other aspects of the structure of protein substrates. There is too little information available at this time concerning the effects of secondary and tertiary protein structure on susceptibility towards enzymatic hydrolyses to try to subdivide there. This task remains to be undertaken in the future.

A partial understanding of the primary specificity of α-chymotrypsin was achieved only after investigation of the kinetics of a very large number of model compounds. A similar level of knowledge of secondary specificity would require a corresponding experimental effort. Some qualitative work along this line was performed by Bergmann and his collaborators. Fortunately, information concerning the secondary specificity of chymotrypsin can be obtained from results in the literature on its action towards polypeptides and denatured proteins. It is the purpose of this article to examine some of the available literature and to propose, so far as possible, a secondary specificity pattern for α-chymotrypsin catalysed reactions. A preliminary attempt along these lines has recently been reported[1].

The question of the tertiary specificity of any proteolytic enzyme cannot yet be discussed intelligently. On the one hand, too little is known about the tertiary structure of proteins in solution. On the other hand, relatively little information is available on the effect of proteolytic enzymes on native proteins. Especially in the case of proteins for which the primary structure, the amino-acid sequence, is known, quantitative studies on enzyme kinetics may prove to be of increasing value[15–18].

Specificity of Chymotrypsin

We have chosen to examine the specificity pattern shown by α-chymotrypsin for a limited number of peptides and proteins. Only compounds the complete amino-acid sequence of which has been determined have been included in the survey. Those analysed are human haemoglobin γ chain[19], human haemoglobin α chain[20], ribonuclease[21], α-corticotropin[22], glucagon[23], insulin[24], horse heart cytochrome *c*[25], baker's yeast cytochrome *c*[26], and tobacco mosaic virus[27,28].

The analysis of data in the literature which was not compiled for this purpose raises several difficulties. The chains discussed contain a total of 910 amino-acid residues. The size of the sample, as well as the diverse origin of the proteins, indicates that a representative sample is available. The distribution of amino-acids, ranging from eleven tryptophan residues to seventy-eight alanine residues, is not unusual for amino-acid compositions[29,30]. The number of different kinds of peptide linkages is also compatible with the tabulation of Sörm *et al.*[31].

A more difficult question concerns the problem of minor splittings observed in enzyme-catalysed peptide hydrolyses. These could be due to bonds which are split more slowly than others, to an impurity in the enzyme preparation, or they could even be present before enzyme is added. Such free groups could account for trace end-group analyses which are sometimes reported. We have chosen to include essentially all bonds reported broken by chymotrypsin. Other enzyme impurities in modern chymotrypsin preparations are exceedingly small. Also, in cases of minor splittings observed, there was usually no pattern which would implicate another enzyme. For example, chymotrypsin causes the splitting of a lysyl-lysine bond in both α- and β-corticotropin. Although in the latter case this split has been attributed to a trypsin impurity in the chymotrypsin preparation[32], this was the only one of several trypsin-sensitive bonds cleaved[33]. There is no doubt that the problem of minor cleavages raises some questions. In the absence of control experiments, that is, when the same specificity pattern is observed in the presence of an inhibitor for the suspected contaminating enzyme[33], either inclusion or rejection of this class of observations will introduce some error. We have chosen the former course.

If the concepts of primary, secondary and tertiary specificity have any significance, as defined, the latter two should manifest themselves as perturbations of the primary specificity. The ideal, and ultimate, criterion for any questions concerning relative specificity is kinetic information about the rate of cleavage of the bonds involved, Such information should be obtained under precisely determined conditions of concentration, temperature, *p*H, etc. Needless to say, this level of data is not at present available. One must, therefore, rely on a statistical analysis of relative frequency of occurrence of any particular peptide bond hydrolysis for a number of experiments performed under different conditions. Fortunately, the conditions used for protein analysis fall within a narrow range. The substrate-to-enzyme ratio is usually between 300 : 1 and 50 : 1; the reactions are carried out near room temperature for long times: 6–24 h; the *p*H is usually near the optimum for α-chymotrypsin between 7 and 9, but efforts have not been made to control ionic strength. Recent experiments have demonstrated that variations in *p*H[34] and ionic strength[35] can affect the relative specificity of α-chymotrypsin.

The variations in experimental conditions make any analysis of the recorded results tentative. However, the enzyme-catalysed hydrolysis of peptides was usually carried out until the rate had slowed down considerably. Therefore, it is probable that further hydrolysis would not have significantly altered the results. At best, the number of minor splittings observed might have been increased slightly. As the experiments were performed until all the more susceptible bonds were split, only those variations in reaction conditions which would vary the relative specificity of the enzyme might affect the conclusions.

Primary specificity. Table 1 lists the number of bonds split involving any of the twenty naturally occurring amino-acids as the acyl component, as well as the fraction of all bonds involving that particular acid which were reported hydrolysed by chymotrypsin. The amino-acids range from the 'classic' substrates of chymotrypsin to only four amino-acids for which no bonds were split. Table 1 also lists kinetic constants obtained for acylated amino-acid methyl esters as substrates of α-chymotrypsin.

Of the twenty amino-acid species listed, sixteen are involved in hydrolysis at least once. Although some small fraction of these hydrolytic cleavages may be due to an impurity in the enzyme preparation, it is clear that chymotrypsin has a very wide primary specificity. As indicated, the amino-acids can be divided into three groups. Group I includes those which seem to be hydrolysed a large percentage of the times they appear: the classic aromatic substrates—tryptophan, phenylalanine and tyrosine—and leucine. Somewhat arbitrarily, methionine has also been included. Of a total of 171 residues containing these amino-acids, 123 (72 per cent), are

hydrolysed by the action of chymotrypsin. The second group involves eleven amino-acids which undergo hydrolysis at least once. Arbitrarily, for purposes of further comparisons, methionine has also been included in this group. Only forty-six out of 558 residues (8 per cent) are hydrolysed among this group. Finally, Group III amino-acids are not hydrolysed although they account for 195 residues.

The classification of substrates into groups permits a 'statistical' comparison to be made. For Group I amino-acids, the primary specificity is probably dominant: hydrolysis is the rule with only a few exceptions. By examining the amino-acid sequence near those group I residues which are not hydrolysed, factors which hinder hydrolysis may become apparent. Conversely, for Group II amino-acids, the secondary specificity may be dominant. By examining the amino-acid sequences surrounding those Group II residues which are hydrolysed, factors which favour hydrolysis may become apparent.

A comparison of the peptide hydrolysis data with the kinetic data on *N*-acylated-L-amino-acid esters indicates that the primary specificity pattern for polypeptides is a direct reflexion of the specificity observed for the model compounds. To the extent of the kinetic data available, k_0/K_0, the catalytic rate constant divided by the observed Michaelis constant[36], for models and the susceptibility of bonds in denatured proteins to hydrolysis can be correlated. This comparison is an important step forward in the evaluation of the relevance of investigations of model compounds to the *in vivo* action of chymotrypsin.

Secondary specificity. In order to examine the secondary specificity pattern, it is necessary to tabulate the residues found adjacent to the bond hydrolysed Each peptide was classified by use of a tabulation which listed the amino-acid residues on either side of the site of cleavage. These were labelled CO^1, the carboxyl component of the peptide bond hydrolysed, NH^1, the amino component of the bond hydrolysed, CO^2, the *N*-acyl amino-acid on CO^1, etc. An example of this system of nomenclature, which is identical with that used by Tang[2], is shown in the following:

CO^3	CO^2	CO^1	NH^1	NH^2	NH^3
Ser	Val	$CySO_3H$	Ser	Leu	Tyr
Ser	Leu	Tyr	Glu	Leu	Glu
Glu	Asp	Tyr	$CySO_3H$	Asp	

↖ Peptide linkages hydrolysed

From the number of bonds hydrolysed, 163, and the total number of sequences available, it became clear that only for the CO^2 and NH^1 positions were enough data available to arrive at even tentative conclusions.

The effect of adjacent residues on the susceptibility of any particular bond to hydrolysis must be modified to account for 'vacant' positions due to other splittings or terminal groups. Thus, an NH^1 residue with a free carboxyl group may have a different secondary effect than the same NH^1 residue attached to an NH^2 residue. If it is assumed that each splitting observed is the last to occur, it is possible to tabulate the maximum possible number of 'vacant' positions for each of the groups of specific residues for which hydrolysis is observed. Table 2 lists the total number of bonds split for each group as well as the number and percentage of CO^2 and NH^2 positions which are vacant. Group −I refers to sequences where the CO^1 position is occupied by a Group I residue, tryptophan, tyrosine, phenylalanine, leucine or methionine, but no hydrolysis is observed.

Table 2. EFFECT OF "VACANT" POSITIONS ON THE SECONDARY SPECIFICITY OF CHYMOTRYPSIN

Residues at CO^1	Total bonds	"Vacant" CO^2	Percentage of total	NH^2	Percentage of total
Group I	123	14	11	17	13
Group −I*	47	7	15	12	25
Group II	46	4	8	2	4

* No hydrolysis with a Group I residue at the CO^1 position.

The significant data in Table 2 concern the Group II and Group −I residues. The Group II residues include those which are only sometimes split. It might be expected that secondary specificity would play an important part among this set. For Group −I, the lack of observed hydrolysis must be interpreted in terms of unfavourable secondary specificity requirements. It can be seen from Table 2 that vacant CO^2 and NH^2 positions are found for Group II residues in only 8 per cent and 4 per cent, respectively, of the observed hydrolyses, although they account for 15 per cent and 25 per cent, respectively, of the unsuccessful Group −I positions. In other words, of the total of forty-six splittings observed in which the carboxyl end contained a Group II residue, only six of these, or 13 per cent, have a vacancy at either the CO^2 of the NH^2 position. In contrast to this, of the forty-seven 'non-splittings' observed for Group I residues nineteen, or 40 per cent, occur when either the CO^2 or the NH^2 position is vacant.

These observations lend support to the classification of chymotrypsin as an endopeptidase. Location at the

N-terminal end or penultimate to the C-terminal end of a peptide chain appears to be a major reason for lack of hydrolysis of a normally susceptible, Group I, residue.

In the discussion of the effect of residues at the NH^1 and CO^2 positions on hydrolysis, presented below, residues with vacancies at CO^2 or NH^2 were not included where this might influence the results.

The effect of structure at the NH^1 position on hydrolytic susceptibility is presented in Table 3. Again, the significant information can be gleaned from the listings under Group II, the less suceptible but sometimes hydrolysable residues, and Group −I, the non-hydrolysis of high susceptible residues. For each type of residue we have listed the number of times its appeared as the amine component of a peptide bond which involves one of the highly susceptible amino-acids at the carboxyl end (Group I); a peptide bond which involves one of the less susceptible amino-acids at the carboxyl end (Group II); and finally the number of times it appeared as the amine component of a peptide bond which involves one of the highly susceptible amino-acids at the carboxyl end but with no hydrolysis observed (Group −I). These values ("Found") are compared with values which might be observed ("Expected") simply on the basis that any particular residue will appear in any position as often as its fractional contribution to the total number of residues. For example, of the 910 total residues, seventy-eight or 8·6 per cent are alanines. Thus, we would expect 8·6 per cent of the 123 amino components at NH^1 associated with Group I residues, or ten residues, to be alanines.

A few types of residues appear to have a favourable effect on hydrolysis when in the NH^1 position. These residues are found more than the "expected" number of times in association with Group II hydrolyses and less than the expected number of times for Group −I "non-hydrolyses". The three favourable residues appear to be alanine, glycine and lysine.

Conversely, a few residues seem to prevent hydrolyses. These residues are found less than the expected number of times in association with Group II hydrolyses and more than the expected number of times for Group −I "non-hydrolyses". Aspartic acid, proline and possibly histidine are such residues.

That proline in the NH^1 position is unfavourable for hydrolysis has been known for some time. The effect of aspartic acid can be ascribed to the free carboxylate group, although the same effect does not appear to be observed for glutamic acid. Confirmation of the secondary specificity of chymotrypsin for glycyl and alanyl residues in the NH^1 position must await quantitative experiments on suitable model compounds.

In Table 4 the possible secondary specificity towards CO^2 residues is examined. The data are presented in the same manner as in Table 3, except that the total number of residues has been reduced by the number found at

Table 3. SECONDARY SPECIFICITY OF CHYMOTRYPSIN: AMINO COMPONENT

Residue	Total No. in proteins	Group I NH^1 Found	Group I NH^1 Expected†	Group II NH^1 Found	Group II NH^1 Expected†	Group −I* NH^1 Found	Group −I* NH^1 Expected†

* No hydrolysis with Group I residue at CO^1 position.
† Number of residues expected at this position in the absence of any specificity. Obtained by multiplying the total number of residues of any particular amino-acid by the total number of residues found at that position/total effective number of residues.
‡ Figures in parentheses refer to cystelc acid.
§ Figures in parentheses refer to methionine sulphone.

CO^1 to arrive at an effective total number of residues equal to 747.

Again, comparison of the figures for Group II and Group −I occurrence suggests that some residues are particularly favourable for promoting hydrolysis while others hinder it. Lysine, valine and perhaps isoleucine when present in the CO^2 position favour hydrolysis, while aspartic acid, asparagine, histidine and serine may all hinder hydrolysis when in the CO^2 position.

Perusal of Tables 3 and 4 reveals that all conclusions concerning secondary specificity must be tentative at this time. The results are suggestive and this approach may be fruitful, but it is clear that a much larger sample is required before more definitive conclusions can be on the basis of statistical analyses. With the present accelerating rate of sequence determinations, the necessary data may soon be available for defining the secondary specificity of chymotrypsin and other proteolytic enzymes.

We thank Prof. W. P. Bryan for his helpful comments. This work was supported in part by a grant from the National Institutes of Health, U.S. Public Health Service.

STRUCTURE OF ACETYLCHOLINE AND OTHER SUBSTRATES OF CHOLINERGIC SYSTEMS

By Dr. F. G. CANEPA
Department of Physics, Northern Polytechnic, London, N.7

Dr. PETER PAULING

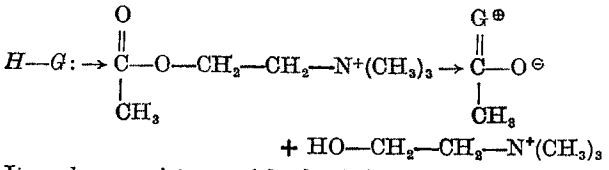
AND



and Dr. H. SÖRUM
Fysisk Institutt, Norges Tekniske Høgskole, Trondheim, Norway

FOR many years a great deal of effort has gone into the investigation of the properties of many substances agonistic and antagonistic to cholinergic transmission systems in order to characterize such systems and determine their mechanisms. Our understanding is still far from complete. For various reasons[1], we have undertaken a re-investigation of the crystal structure of acetylcholine bromide and have recently completed the X-ray diffraction single-crystal structure analysis. The structure is necessarily in the solid state but has certain features which can be compared with known crystal structures of other relevant molecules and with the pharmacological evidence available on the action of various molecules in cholinergic systems.

The three-dimensional single-crystal X-ray diffraction data of Sörum[2,3] have been corrected for the presence of twinned crystals and the structure solved by a careful examination by one of us (F. G. C.) of the observed Fourier synthesis phased on refined co-ordinates of the bromine atom determined by Sörum. The structure was solved in spacegroup $P2_1$, but we observed that the two independent molecules determined in this space-group are racemates related by a glide plane. The proper spacegroup is thus $P2_1/a$ or $P2_1/c$, confirming the suggestion of Dunitz[4] from certain unusual systematic absences in the diffraction data that the crystals are twinned $P2_1/a$ and not $P2_1$. The structure has been refined by least squares methods and the residual $R = 0{\cdot}10$ for the 770 observed diffraction maxima.

A drawing of the molecule in the solid state giving interatomic distances and angles is shown in Fig. 1. The interatomic distance from one substituted ammonium methyl carbon atom C_1 to the ester oxygen atom O_1 is 3·02 Å and the interatomic angles are such that this methyl group seems to form a bent hydrogen bond through one of its hydrogen atoms to the ester oxygen atom, though the hydrogen atom positions have not been determined in this analysis. This distance can be compared with the sum of the van der Waals radii of a methyl group and an oxygen atom of 2·0 + 1·4 = 3·4 Å. The nitrogen atom N to ester oxygen atom O_1 distance is also fairly short at 3·29 Å. The ester oxygen atom O_1 to carboxyl carbon

atom C_6 distance is 1·32 Å, just significantly less than the single-bond distance 1·44 Å. This implies that the ester oxygen to carboxyl carbon bond O_1—C_6 has partial double-bond character, consistent with the co-planar arrangement of the group C_5 O_1 C_6 O_2 C_7. This partial double-bond character is relevant to the first step of the mechanism of the hydrolysis of acetylcholine by acetylcholinesterase (H–G:) proposed by Wilson[5,6]:

It is also consistent with the infra-red evidence on the nature of the C=O bond of acetylcholine in various solvents investigated by Canepa and Mooney[7].

There are three planes of atoms in the molecular structure of acetylcholine: (1) the plane of the ester oxygen carboxyl group just mentioned, C_5 O_1 C_6 O_2 C_7; (2) the plane of one methyl carbon atom, the nitrogen atom and the two CH_2 group carbon atoms, C_3 N C_4 C_5; (3) the plane of the ester oxygen–CH_2 bond and of one methyl carbon–nitrogen bond, O_1 C_5 C_1 N, though the last four atoms are not quite co-planar.

Some of these features of the crystal structure of acetylcholine bromide are very similar to those of the two related solid-state structures which are known, choline chloride[8] and muscarine iodide[9]. The structure of choline chloride with interatomic distances and angles is shown in Fig. 2 and that of muscarine iodide in Fig. 3. In each of these structures there exists a close methyl carbon atom to (ester) oxygen atom distance, C_1–O_1 = 3·07 Å in choline chloride and 2·87 Å in muscarine iodide, and a fairly close nitrogen atom to (ester) oxygen atom distance, N–O_1 = 3·26 Å and 3·07 Å in the compounds, respectively. In choline chloride, one methyl group carbon atom, the nitrogen atom and the two CH_2 group carbon atoms lie in one plane, C_3 N C_4 C_5, and the oxygen–carbon bond and one methyl carbon–nitrogen bond almost lie in another plane, O_1 C_5 C_1 N, identical within the experimental error to the molecular arrangement in acetylcholine bromide. In muscarine iodide, one methyl group carbon atom, the nitrogen atom, the two CH_2 group carbon atoms and one ring carbon atom lie in one plane, C_3 N C_4 C_5 C_8, and four atoms of the ring, C_5 O_1 C_6 C_8, lie in another plane in which one methyl group carbon nitrogen bond C_1–N very nearly lies. Though the pharmacological effects of these three compounds active on cholinergic receptors are very different, they have these similar structural features in the common molecular portion. The differences in the structures of the common portions of the three molecules as analysed are not statistically significant, being less than three times the estimated standard deviations. Some similarities between the choline, acetylcholine and betaine chains involved in plant physiology have been pointed out by Canepa[11] on the basis of crystallographic and radiation decomposition evidence.

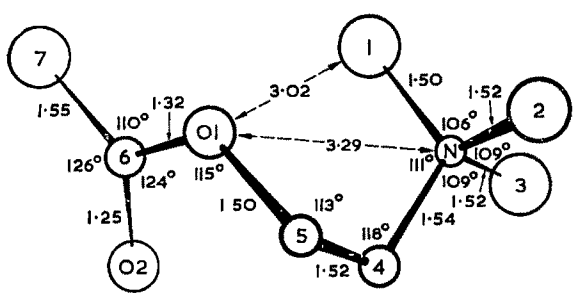


Fig. 1. The structure of the acetylcholine molecule in crystals of acetylcholine bromide, with interatomic distances and angles. Estimated standard deviation of the distances is less than 0·06 Å. In crystals both the molecule shown and its mirror image exist

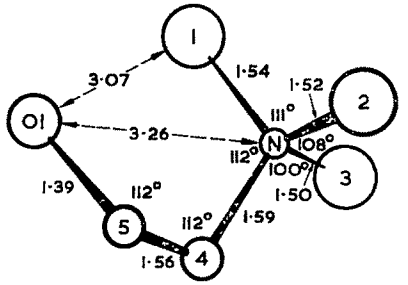

Fig. 2. The structure of the choline molecule in crystals of choline chloride[8], with interatomic distances and angles. Estimated standard deviation of distances is 0·03 Å

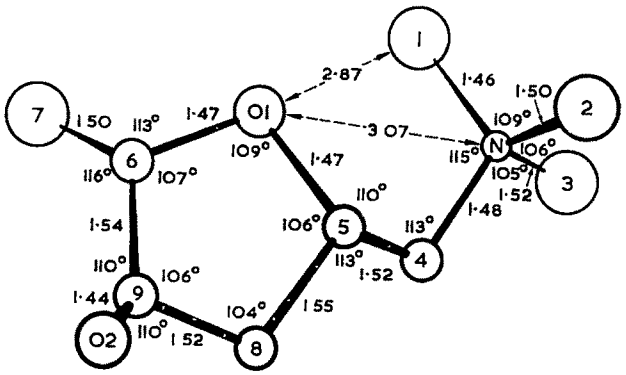

Fig. 3. The structure of the muscarine molecule in crystals of muscarine iodide[9], with interatomic distances and angles. Estimated standard deviation of distances is 0·08 Å. The configuration shown is the absolute one for that of the active L(+) form[10]

A number of investigators have endeavoured to map the active sites of cellular acetylcholine receptors and of acetylcholinesterase by determining binding strengths or rates of hydrolysis of various substances and building models of the relevant molecules. The structure of acetylcholine can be compared with these results.

Foldes, van Hees, Davis and Shannor[12] and Wilson and Quan[13] endeavoured to determine the distance between anionic and esteratic sites of acetylcholinesterase and presumably the distance between the nitrogen atom and the carboxyl group of acetylcholine by an investigation of the binding strength of various inhibitors of acetylcholinesterase as a function of $(CH_2)_n$ chain length. They concluded that the nitrogen atom to carboxyl group distance in acetylcholine should be of the order of 4·84 Å. In the solid-state the nitrogen atom to carboxyl carbon atom distance N–C_6 is 4·10 Å and the nitrogen atom to carboxyl oxygen atom distance N–O_2 is 4·42 Å.

The absolute configuration and relative pharmacological activities of the stereoisomers of acetyl-β-methylcholine have been determined and compared with that of L(+)-muscarine by Ellenbroek and van Rossum[14] and by Beckett *et al.*[15,16]. It is easy to see why the L(+) isomer is very active on muscarinic receptors and the D(−) form is not. The extra methyl carbon atom occupies the position of C_8 of muscarine in Fig. 3, just adding to the chain C_3 N C_4 C_5 of acetylcholine in Fig. 1 as it is added to by C_8 in muscarine. The extra methyl group of D(−) acetyl-β-methylcholine, however, interferes in two ways. First, it fits into the important and crowded region between the ester oxygen atom and the trimethyl ammonium group, and secondly, steric interference between this extra methyl group and the methyl group C_2 forces the molecule to change its conformation to some extent. It is interesting that the structure of muscarinic substrates determined by these solid-state investigations agrees well with the structure suggested by Beckett *et al.*[15,16] solely from pharmacological data.

Belleau and Lacasse[17] found that of a series of 1,3-dioxolane inhibitors of acetylcholinesterase, optimum affinity is shown by L(+)-*cis*-2-methyl-4-trimethyl-

ammoniummethyl-1,3-dioxolane iodide and deduced therefrom the stereospecificity of the active site. This molecule presumably has exactly the conformation shown in Fig. 3 (L(+)-muscarine) with O_2 removed and C_5 changed to an oxygen atom. Similar stereospecific effects of 1,3-dioxolanes on muscarinic receptors were shown by Belleau and Puranen[18].

Although there is no direct evidence that these solid-state investigations are relevant to the environment *in vivo*, that these three known structures have similar conformations in the common portion of the molecules encourages us to believe the analyses relevant to the biological mechanism of cholinergic synaptic transmission.

We thank Mrs. Ann Graeme-Barber for assistance, Dr. G. B. Robertson for some calculations, and Mr. John Cresswell for the drawings.

SUCROSE PERMEASE OF *Proteus mirabilis*

By Dr. J. A. SMIT
Atomic Energy Board, Pretoria
AND
Prof. J. N. COETZEE
Department of Microbiology, University of Pretoria

EXTRACTS of most *Proteus mirabilis* strains possess fructofuranosidase activity, but intact organisms usually do not ferment sucrose since they lack a permeability factor which controls the penetration of the disaccharide into the cell[1]. To study this permeability factor, strain 24 and a sucrose fermenting variant (24 *suc*$^+$) were used. This strain belongs to the group 1*a* previously described[1]. 'Difco' nutrient agar and a minimal medium[2] with 0·006 per cent nicotinic acid and 0·01 per cent tetrazolium chloride (medium GNM) were used. Medium GNM with 0·2 per cent sucrose substituted for glucose is called SNM. Other media used have been described[1]. Spontaneous *suc* mutants in large populations of strain 24 *suc*$^+$ were selected by a penicillin enrichment technique[2] in fluid SNM and replication was from GNM to SNM. Intrastrain transductions were done with the use of phage 34/13 with the general techniques previously described[3]. After 30 min at 37° C the adsorption mixture was centrifuged, the deposit suspended in 1 ml. saline and 0·1 ml. plated on SNM. Sucrose positive transductants appear as large red colonies after 47 h incubation. Bacterial suspensions were prepared as before[1] and the concentration estimated by determination of the deoxyribonucleic acid content[4]. Cell extracts for enzyme and sugar assays were prepared as follows: Bacterial suspensions (20 ml.) were centrifuged and the pellets resuspended in the same volume of ice-cold water. Suspensions were then sonicated in a Raytheon 50-W 9 kc/s oscillator for 30 min at 4° C. Unbroken organisms and cell debris were removed by centrifugation and the supernatant used for assays. Penetration of sucrose, lactose and fructose into cells was measured as follows: To ice-cold bacterial suspensions (5 ml.) a cold solution (0·5 ml.) of sucrose, lactose or fructose in broth was added to a final concentration of 1 per cent sugar. The experimental samples were then immersed in a water-bath at 36° C and identical controls kept at 0° C. After 5 min the mixtures were diluted with 30 ml. ice-cold broth and centrifuged (15,000*g*) for 15 min at 0° C. The pellets were washed five times to remove exogenous sugar, and cell-free extracts were used for sugar determinations[5–7]. β-Fructofuranosidase in cell-free extracts was determined as previously described[1]. The glycolytic enzymes fructokinase[8], hexokinase[9], phosphofructokinase[10] and aldolase[11] in the cell-free extracts were also determined. Protein was estimated by the biuret method[12] and paper chromatography of sugars was done according to Partridge[13].

Nineteen spontaneous *suc* mutants of strain 24 *suc*$^+$ were obtained from thirty-five different isolation experiments. Colonial growth of these mutants was identical to strain 24 on GNM, nutrient agar or 1 per cent sucrose nutrient agar, and growth curves of the mutants in a casein hydrolysate medium in the presence or absence of sucrose were identical. The reversion rates of the *suc* mutants varied from 4×10^{-7} to 1×10^{-9}/bacterium/generation. Many revertants were examined phenotypically and enzymatically. They all resembled the parent *suc*$^+$ strain and may be back mutations. Strain 24 *suc*$^+$ and mutants *suc*-3, -5, -6, -9, -10 took up sucrose under test conditions. Sucrose in the organisms was demonstrated chemically and chromatographically. The remaining strains did not take up sucrose or took up less than 1 per cent that of positive strains. Results were not affected by prior growth on 1 per cent nutrient agar. Transport is stereospecific in that strains which took up sucrose did not accumulate lactose under identical conditions. Penetration of sucrose is temperature (Fig. 1) and energy dependent. Inhibition of ATP generation by 1 mM sodium azide or 2,4-dinitrophenol results in reduced permeation of sucrose by 29 and 69 per cent respectively. A time course of uptake of sucrose by strains *suc*-5 and *suc*-10 is presented in Fig. 2. These results are taken to support the enzymatic nature of sucrose transport across the permeability barrier of the cell and the enzyme will be called a permease[14]. Strains which were positive with respect to sucrose permease had little or no β-fructofuranosidase activity apart from the *suc*$^+$ parent which was active in both respects. Prior growth on GNM or 1 per cent sucrose nutrient agar did not affect results. Permease negative strains possessed β-fructofuranosidase although specific activities varied over a wide range (Table 1). This latter phenomenon was investigated by adding extracts of *suc*-7 (low β-fructofuranosidase) to extracts of strain 24 *suc*$^+$ and estimating the invertase activity of the mixture. In other experiments, extracts of *suc*-15 (high β-fructofuranosidase) were substituted for *suc*-7. In all cases the activity of mixtures corresponded to the sum of individual activities. This is an argument

against the presence of soluble inhibitors or stimulators of fructofuranosidase activity in extracts of the two *suc* mutants. All strains were capable of fructose uptake and were also positive for hexokinase, fructokinase, phosphofructokinase and aldolase.

Results of transduction experiments divide the wild organism and *suc* mutants into two distinct linkage groups *P* and *F* (Table 1). Intra-group transductions yield significantly less transductants than combinations where organisms from one group are treated with phage lysates of the other group or with phage derived from the *suc*$^+$ strain. The correspondence in numbers of transductants obtained from the two latter procedures indicates that the two groups are not linked. This experiment was done five times. There was always the same absolute distinction between the two groups but results of intra-group transductions were too variable for use in ordering the sites within loci. There is good correlation between

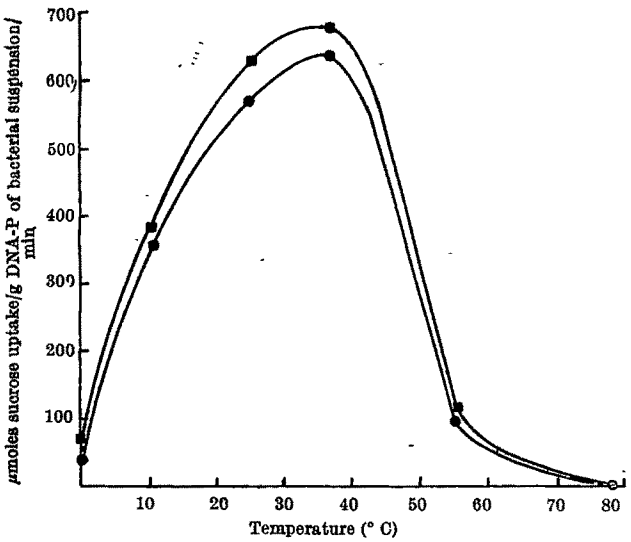

Fig 1. Effect of temperature on the uptake of sucrose by *Proteus mirabilis* mutants. ●, 24 *suc*$^+$; ■, *suc*-10. Sucrose permease activity is expressed as μmoles of sucrose uptake/g DNA-P of bacterial suspension/min.

β-fructofuranosidase activity is expressed as μmoles sucrose hydrolysed/g of protein/min.

Results are the average of three separate experiments.

the genetic and biochemical divisions of *suc* mutants. Thus, members of genetic group *F* all possess strong permease activity and no (or only traces of) β-fructofuranosidase. Members of the genetic group *P* lack permease activity but possess varying degrees of fructofuranosidase activity.

In *Escherichia coli* the lactose permease gene is closely linked to the β-galactosidase structural gene, but the L-arabinose permease locus is unlinked to genes which synthesize enzymes necessary for arabinose utilization[15]. Biochemical definition of *suc* mutants has supplemented genetic data in demonstrating the complexity of the sucrose permease (*P*) gene. Like the gene governing L-ribulokinase activity in *E. coli*, mutations in the *P* linkage group have dual effects[16]. These *P* mutants lack sucrose permease but have increased or decreased constitutive levels of β-fructofuranosidase as compared with the *suc*$^+$ parent (Table 1). The β-fructofuranosidase is constitutive[1] and differences in fructofuranosidase activity due to variability of induction appear to be excluded. The fact that the *P* and *F* loci are not linked makes an explanation on grounds of these genes acting as a "genetic unit of co-ordinate expression"[17] difficult to apply and a regulator mechanism for the *F* locus controlled by the *P* structural gene may have to be postulated. Such a dual function is not unknown and in the classical lactose system of *E. coli* there is evidence that the operator locus may be part of the β-galactosidase structural gene[18].

PHAGE-DIRECTED SYNTHESIS OF DIPHTHERIAL TOXIN IN NON-TOXINOGENIC *Corynebacterium diphtheriae*

By DR. MORIHIRO MATSUDA and PROF. LANE BARKSDALE
Department of Microbiology, New York University School of Medicine, 550 First Avenue, New York

THE synthesis of diphtherial toxin is controlled by a bacteriophage gene, tox^+ (ref. 1). Although it has been shown that this gene is expressed in lysogenic, toxinogenic *Corynebacterium diphtheriae* (2, 2*a*) and in non-toxinogenic strains being lysed by phage[3], until now no investigations have been made of the kinetics of toxin production and phage production in the latter system, and this has mainly been due to the lack of a stable, virulent phage. Such a mutant phage, $\beta hv64^{tox+}$, has been isolated from a stock of the clear-plaque corynebacteriophage *B* (ref. 2). This phage is obligately lytic and has been used to introduce the tox^+ gene into cells of a population of a non-toxinogenic strain of *C. diphtheriae*, designated $C7_s(-)^{tox-}$ (refs. 3 and 4). By carrying out the adsorption of bacteriophages to bacteria in the presence of chloramphenicol and afterwards ridding the infected bacteria of chloramphenicol, unadsorbed virus and residual toxin present in the phage preparation[3], it has been possible to examine the expression of tox^+ in a single cycle ('one-step growth curve') of corynebacteriophage multiplication in non-toxinogenic diphtheria bacilli.

This article reports data derived from experiments using this system and designed to ascertain: (*a*) the kinetics of the production of toxin and of phage; (*b*) the effect of iron on the synthesis of these two entities; (*c*) the time of appearance of intra- and extra-cellular toxin; (*d*) the immunochemical relationship of the toxin synthesized to 'standard' diphtherial toxin produced by the $PW8_r(Pdi)^{tox+}$ strain[3]. The conditions for these experiments are given in the legends for Figs. 1, 2 and 3.

The production of toxin by various lysogenic strains of *C. diphtheriae* is inhibited by iron[5]. Because little was known about the effect of iron on toxin production during the lytic cycle, all lots of basal media were deferrated[6] and various amounts of iron were added to them depending on the purpose of the experiment.

In the experiments reported here the infected cells were synchronized with respect to the initiation of viral synthesis in the following manner. Bacteriophage and bacteria were combined in the presence of 125 μg/ml. chloramphenicol (a gift of Dr. H. E. Machamer, Parke, Davis and Co.) and adsorption was allowed to proceed for 20 min. This concentration of chloramphenicol was shown to have no apparent effect on phage adsorption but to block completely viral multiplication and toxin production so long as cells were exposed to it. Once chloramphenicol was removed viral multiplication and toxin production began and lysis occurred after the usual latent period. At the end of the adsorption period, the infected cells were centrifuged and washed once to remove chloramphenicol and unadsorbed virus. After resuspension in fresh medium, they were incubated with gentle shaking, and the growth of virus and the production of toxin followed. The samples for assay of phage as plaque-forming units and extracellular toxin as skin-test doses were sterile filtrates. Intracellular toxin production was followed by assaying filtrates derived from samples in which cells had been disrupted in a Ribi cell fractionator. The number of minimum reacting doses per sample was determined by assaying decrements of each sample by injection into the shaven skin of the backs of rabbits.

The results reported would seem to establish three facts regarding the synthesis of diphtherial toxin by non-toxinogenic *C. diphtheriae* infected with corynebacteriophage $\beta hv64^{tox+}$: (1) toxin production and the synthesis of new phage particles appear to be parallel events; (2) intracellular and extracellular toxin begin to increase early in the latent period of viral growth; (3) added iron causes about 90 per cent inhibition of synthesis of toxin without similarly affecting the synthesis of plaque-forming phage particles.

From Fig. 1 it is evident that with one cycle of viral multiplication there is a better than 10,000-fold increase in diphtherial toxin. The first toxin detectable in disrupted cells appears right after the removal of chloramphenicol. The first free phage is liberated at about the 65th

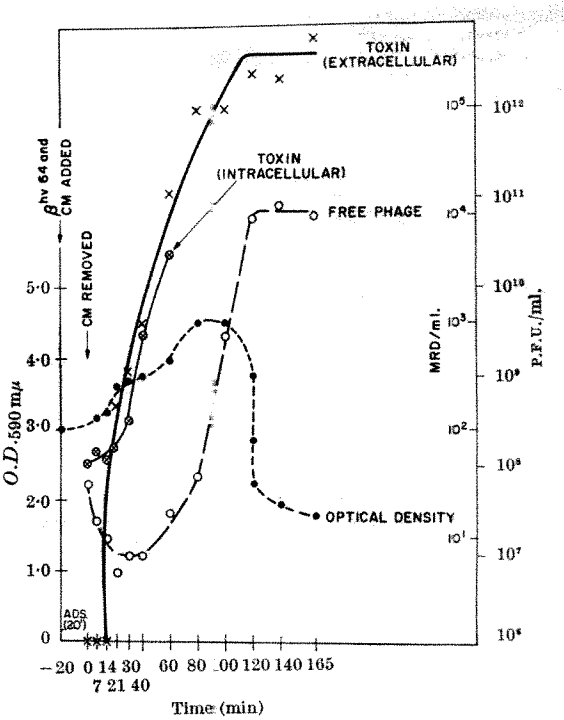

Fig. 1. The synthesis of diphtherial toxin by non-toxinogenic *C. diphtheriae*, strain $C7_s(-)^{tox-}$, infected with hypervirulent corynebacteriophage, $\beta hv64^{tox+}$. Phage and bacteria were combined to yield 288 ml. of a mixture containing: $2{\cdot}9 \times 10^9$ cells of $C7_s(-)^{tox-}$/ml., $2{\cdot}9 \times 10^{12}$ P.F.U. of $\beta hv64^{tox+}$/ml., 5×10^{-3} M calcium chloride and 125 μg/ml. chloramphenicol. Adsorption was allowed to proceed for 20 min at 36° C with gentle shaking. Mixture was then washed in chilled deferrated PGT medium, resuspended in 200 ml. of deferrated PGT medium containing 4 per cent maltose, distributed in 25 ml. portions in 1-l. Erlenmeyer flasks and incubated at 33° C with gentle shaking. Effective multiplicity of infection was 5·2. Samples for the assay of phage and extra-cellular toxin were taken at the intervals indicated, centrifuged and the supernates passed through 'Millipore' filters (*HAWP* 02400). For determining levels of intracellular toxin, 25 ml. samples were iced and centrifuged at 10,300*g* for 10 min at ±4° C; the packed cells were four times washed in chilled *tris*–Mg buffer (0·0 M *tris*, 10 mM magnesium acetate, *p*H 7·4) containing 0·01 per cent mercuhiolate and stored deep frozen. Afterwards, cells from the frozen state were suspended to original volume in *tris* buffer and twice passed through a Ribi cell fractionator at 3,000 p.s.i. at 5°–10° C. The disintegrated cells were twice centrifuged: at 6,000*g* for 20 min and at 10,300*g* for 20 min and the supernatant rendered sterile by passage through a 'Millipore' *HAWP* 02400 filter. CM, Chloromycetin; MRD, minimum skin reacting dose as assayed in the skin of rabbits; P.F.U., plaque forming units; ADS, adsorption period

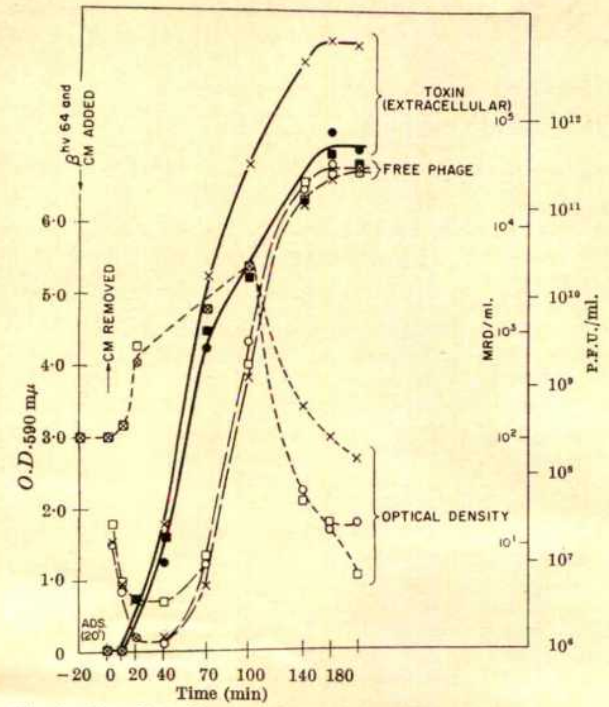

Fig. 2. The effect of iron on the synthesis of diphtherial toxin by *C. diphtheriae*, strain $C7_s(-)^{tox^-}$, infected with hypervirulent corynebacteriophage, $\beta^{hv64tox^+}$. Portions of a culture of $C7_s(-)^{tox^-}$ (grown to an optical density of 4·7 in deferrated medium supplemented with 0·1 μg iron/ml.) were diluted in (1) deferrated medium to which no iron was added and in (2) deferrated medium supplemented with 3·0 μg iron/ml., in both instances to give an optical density of 0·3, and 30 ml. samples of each were incubated in 300 ml. flasks. These 'low iron' and 'high iron' cells were allowed to grow to *O.D.* 2·85 ($3·7 \times 10^9$ cells/ml.); then each was combined with 17·5 ml. of a suspension of β^{hv64} ($4·3 \times 10^{10}$ P.F.U./ml.) Adsorption was allowed to proceed for 20 min in the presence of 5×10^{-3} M calcium chloride and 125 μg chloramphenicol/ml. Infected cells were then washed as described in the legend accompanying Fig. 1 and resuspended as follows: (×) infected 'low iron' cells were resuspended in deferrated medium; (○) a portion of infected 'high iron' cells was resuspended in deferrated medium; (□) a second portion of infected high iron cells was resuspended in medium containing 3·0 μg iron/ml. Samples were taken for optical density, P.F.U. and extracellular toxin at the indicated times. Effective multiplicity of infection was 2·1

minute. Extracellular toxin rises from the 14th to the 20th minute. The plateaux of both phage and toxin are reached at about the same time—a time at which the optical density of the lysing population sharply declines.

In Fig. 2 are plotted data from an experiment in which cells of $C7_s(-)^{tox^-}$ were grown (×) in deferrated medium and (○) in medium containing 3·0 μg iron/ml. The cells grown in deferrated medium eventually showed the lag in division time characteristic of iron-deficient cells. The cells grown in 3·0 μg iron/ml. grew at a normal rate. Such 'high iron' cells, grown as they are in excess iron, if washed, will retain considerable amounts of bound iron[7]. After these 'low iron' and 'high iron' populations had reached an optical density of 2·85, they were infected with $\beta^{hv64tox^+}$ in the presence of chloramphenicol. Following adsorption, the cells were washed. The 'low iron' cells were resuspended in deferrated medium. The 'high iron' cells were treated in two ways: some (○) were resuspended in deferrated medium and others(□) were resuspended in medium containing 3·0 μg iron/ml. The effect of iron on the course of viral infection and on the synthesis of toxin is shown in Fig. 2, where it can be seen that the 'high iron' cells produced less toxin than the 'low iron' cells, whether they were rich in bound iron (○) or, in addition, were supplied exogenous iron in the medium in which they were infected with phage.

In Fig. 3 is shown the immunochemical reactions of toxin produced under the direction of the $\beta^{hv64tox^+}$ gene and of a ten-times crystallized form of diphtheria toxin—kindly supplied by Dr. C. G. Pope[8] of the Wellcome Research Laboratories, Beckenham, Kent. The neat fusion of the antigen-antibody line formed between $\beta^{hv64tox^+}$-toxin and antitoxin with those formed between standard toxin and antitoxin would seem to be reasonable evidence that the two toxins are identical. This conclusion is further strengthened by the fact that standard antitoxin completely neutralizes the toxicity of $\beta^{hv64tox^+}$-toxin *in vivo*.

In a recent review, van Heyningen and Arseculeratne[9] pointed out the differences of opinion which exist regarding the mechanism of diphtherial toxin production. Although it is clear that toxin production depends (*a*) on the genetic information carried in the genome of a bacteriophage, and it has been generally agreed (*b*) that this information is expressed only under conditions in which the bacterial population is iron-starved, the exact relation between these two observations has been difficult to establish. Most of the studies concerned with toxin production so far have been based on the behaviour of a single strain, strain number 8 of Park and Williams[10], which we have designated $PW8_r(Pdi)^{tox^+}$; *r* indicates roughness in the usual sense, and in addition the loss of receptors for corynebacterial phages; *P* indicates that the strain carries a phage, *P*, which while defective (*d*) is inducible (*i*). It is an excellent producer of toxin and for that reason is used throughout the world for the manufacture of diphtherial toxoids and, to a lesser extent, for investigations of the mechanism of toxin production. It differs from most lysogenic, toxinogenic *C. diphtheriae* in that, since it carries a defective phage, there is no way of measuring the number of its cells which succumb to phage-induced lysis. A culture of $PW8_r(Pdi)^{tox^+}$ will, under conditions of iron starvation, produce toxin, but the relation of toxin production to the expected change from prophage to phage cannot be directly assessed. Induction of the vegetative multiplication of *Pdi*-phage by ultra-violet irradiation leads to the prompt production of toxin by $PW8_r(Pdi)^{tox^+}$, but in no greater amount per cell than in a non-irradiated culture allowed to become exhausted of iron. So far, it has not been possible to measure the yield of defective phage in terms of the amount of toxin formed. The situation is further complicated by the fact that the bacterial population appears to be heterogeneous with respect to its response to ultra-violet light.

In the system described here all the non-lysogenic, non-toxinogenic cells of strain $C7_s(-)^{tox^-}$ are brought into

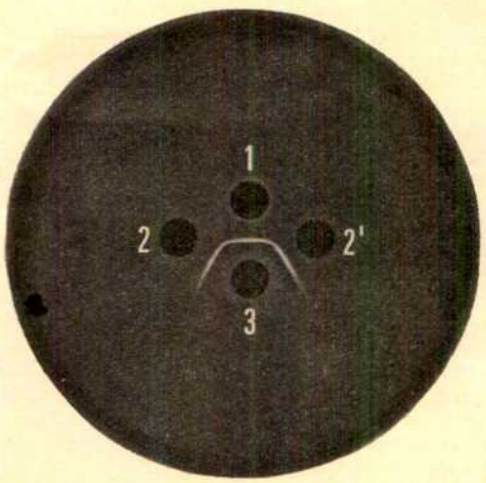

Fig. 3. Fused antigen-antibody bands resulting from diffusion in agar of antitoxin (see below), crystalline diphtherial toxin (Pope) and toxin produced under the direction of corynebacteriophage, $\beta^{hv64tox^+}$, during one cycle of growth in non-toxinogenic *C. diphtheriae*, strain $C7_s(-)^{tox^-}$. The cells labelled 1, 2, 2′, and 3, contained the following reactants in volumes of 0·2 ml.: (1) $\beta^{hv64tox^+}$. $C7_s(-)^{tox^-}$ lysate (24 × concentrated as 0–80 per cent saturated ammonium sulphate fraction); (2) and (2′), 20 Lf of 10 × crystallized diphtherial toxin, Pope. (3), 20 U. of diphtherial antitoxin (rabbit) produced with toxoid derived from crystalline toxin. Contact print was made after 3-days' incubation at 37° C. Prolonged incubation resulted in some thickening of the bands; no spurs were formed

synchrony with respect to toxin synthesis by having the *tox*+ gene injected into them as a part of the genome of an obligately lytic bacteriophage. Once the infected cells are removed from the presence of chloramphenicol (an agent used for establishing synchrony), the biosynthesis of phage and toxin ensues. The two syntheses appear interrelated. Toxin is made early both intra- and extracellularly. Iron does not inhibit the expression of *tox*+ though it does exert a limiting effect on the final yields of toxin. Experiments designed to exploit this lytic system to clarify the relation of toxin to the *tox*+-carrying corynebacteriophage and its host cell are in progress.

We thank our colleagues in this department for helpful suggestions in the preparation of this manuscript and the U.S. Public Health Service for a grant from the Institute of Allergy and Infectious Diseases.

PROLIFERATION OF HUMAN LYMPHOCYTES IN CULTURE

By M. S. SASAKI and PROF. AMOS NORMAN
Department of Radiology, Center for the Health Sciences, University of California, Los Angeles

PHYTOHAEMAGGLUTIN (PHA), bacterial antigens and other foreign proteins cause lymphocytes to undergo an abrupt increase in RNA synthesis, a progressive cell enlargement (transformation), DNA synthesis, and cell division (proliferation)[1–10]. The frequency of cells synthesizing DNA reaches a maximum 60–72 h after exposure to PHA; it is generally assumed that most of the cells involved are synthesizing DNA for the first time in culture[11,12]. Recently, however, Buckton and Pike[13,14], from investigations of the effect of time in culture on chromosome aberrations in lymphocytes obtained from irradiated patients, concluded that the majority of cells in metaphase at 72 h are in at least their second division in culture. Since the interpretation of cytological and biochemical data depends on whether the population of lymphocytes at the time of observation is transforming, proliferating, or both, we have studied the beginning of proliferation in some detail. The results show that not more than 30 per cent of the original mononuclear cells begin DNA synthesis by 72 h, that the transformation of the cells is essentially completed in 24–48 h, that after transformation the cells proliferate with a generation time of 22 h, that the increase in the frequency of cells synthesizing DNA from 48–72 h is due almost entirely to cell proliferation, and that 70–80 per cent of the cells in metaphase at 72 h are in at least their second division in culture. X-ray doses of up to 500 rads given before culture do not delay the onset of the first DNA synthesis, nor do they alter the duration of the G_1 (6 h), S (11 h), G_2 (3 h) and M (2 h) phases of the cell cycle.

Leucocytes were separated from peripheral blood without the aid of PHA and incubated at 37° C in a medium containing 80 per cent *NCTC* 109, 10 per cent autologous plasma, 10 per cent inactivated foetal calf serum, and 0·4 ml. of rehydrated PHA, type *M* (Difco), per 10 ml. of medium. Chromosomes were labelled by exposing cells to tritiated thymidine (specific activity 6·7 c./mmole) at a concentration of 1 μc./ml. The X-ray irradiations were done in whole blood prior to the separation of the leucocytes[15].

In the first set of experiments chromosomes were labelled with tritiated thymidine added to the cultures at various times after the start of incubation. The labelling was terminated by washing the cells with medium containing cold thymidine (100 μg/ml.) and the cells were resuspended in the standard incubation medium supplemented with cold thymidine (30 μg/ml.). After a total of 72 h incubation, the final 1·5 h in the presence of colcemide, the cultures were gathered and processed for autoradiography. The metaphase cells were identified as being in either the first or second division after labelling on the basis of the chromosome labelling pattern: at first division both chromatids are labelled, at second division only one of the two chromatids of the metaphase chromosome is labelled. Fig. 1 represents the results by a plot of the percentage of total cells in metaphase at 72 h that is in the first (solid line) or second (dashed line) division since the addition of tritiated thymidine. From the peak of the dashed curve we conclude that not less than 54 per cent of the metaphase cells are in at least their second division in culture; from the area under the curve we estimate that about 70 per cent of the metaphase cells are in at least their second division.

From the data we also estimate that the duration of the S phase, $T(S)$, is 11 h and that the generation time, T, measured from the mid-points of the two S phases, is about 22 h. Thus about half the cell cycle is occupied by DNA synthesis, the other half being split about equally between G_1 and the sum of G_2 and M.

In the second series of experiments, cells were incubated for 20 h and then treated with colcemide and tritiated thymidine at a final concentration, respectively, of 4·0 μg/ml. and 0·5 μc./ml. The cultures were collected at various times and processed for autoradiography. The labelling index and mitotic index were determined from counts of 1,000–3,000 mononuclear cells. Fig. 2 shows the percentage of labelled mononuclear cells, curve *A*,

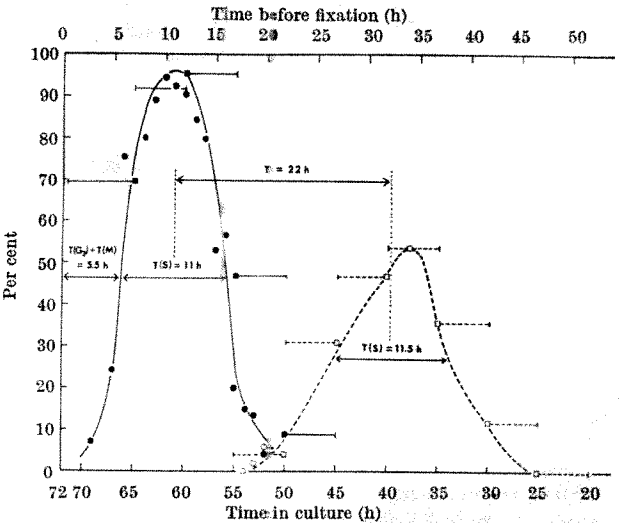

Fig. 1. Percentage of metaphase cells at 72 h in the first (solid line) or second (dashed line) division after labelling. Tritiated thymidine was added for either 5 h (horizontal lines), or 15 min (circles). Cells received 500 rads, circles, or 300 rads, squares

and of metaphase cells, curve B, as a function of time in cultures containing colcemide. Since colcemide does not affect the duration of DNA synthesis or of the cell cycle[16], curves A and B represent, respectively, the entry of cells into the first S phase and arrival at the first metaphase. As can be seen there is no significant difference in the data obtained with irradiated and unirradiated cells; apparently doses as high as 500 rads delivered before exposure to PHA do not cause a significant delay either in the time required for transformation or the time required to reach the first metaphase.

The cells appear in metaphase 14 h after the start of DNA synthesis. Taking this time as the duration of the sum of G_2 and S phases and using the data in Fig. 1 allows us to estimate the duration of each of the four phases in the 22 h cell cycle. The results for G_1, G_2, S and M are 6, 3, 11 and 2 h, respectively, in good agreement with results reported for mammalian cells[17].

If all the cells entering DNA synthesis, curve A, were accumulated in metaphase we would expect curve C (dashed line). The departure of the experimental curve, B, from the expected curve, C, after the 53 h shows that there must be a loss of mitotic figures after this time due to degeneration or escape from arrest.

Curve D was constructed from curve A under the assumption that every cell entering S phase for the first time (curve A) would divide and enter the S phase a second time exactly 22 h later. Since curve D represents reasonably well the experimental data (crosses) obtained with cells labelled in the absence of colcemide, we can conclude that the increase in frequency of cells synthesizing DNA found between 48 and 72 h is due primarily to cell proliferation. The cells in metaphase at 72 h entered DNA synthesis 14 h earlier, 58 h after the start of culture. From the ratio of curves D to curve A we estimate that 69 per cent of the cells are in their second S phase in culture at 58 h, in agreement with the previous estimate for the percentage of metaphase cells in second division at 72 h.

The third set of experiments is based on the observation that the small fraction of acentric chromosomes produced by X-rays that survive cell division appears in the daughter cells as double sets of identical acentric chromosomes. The proportion of cells in at least the second metaphase can be estimated, therefore, from the ratio of the number of cells containing such double sets to the total number of cells with acentric chromosomes. The results of these experiments are shown in Table 1. It can be seen that the fraction of cells in second division at 72 h, when no colcemide is present, averages about 80 per cent. Moreover, this ratio is independent of X-ray dose over the range of 100–600 rads, and this further supports the conclusion that such X-ray doses do not cause significant mitotic delays. Finally, it should be noted that both the frequency of cells with doubled acentric chromosome sets and the frequency of tetraploid cells is reduced almost to zero when the culture is stopped at 50 h; both frequencies are reduced to zero when 4 μg/ml. of colcemide is added to the culture at 20 h and the cells are collected at 50 h.

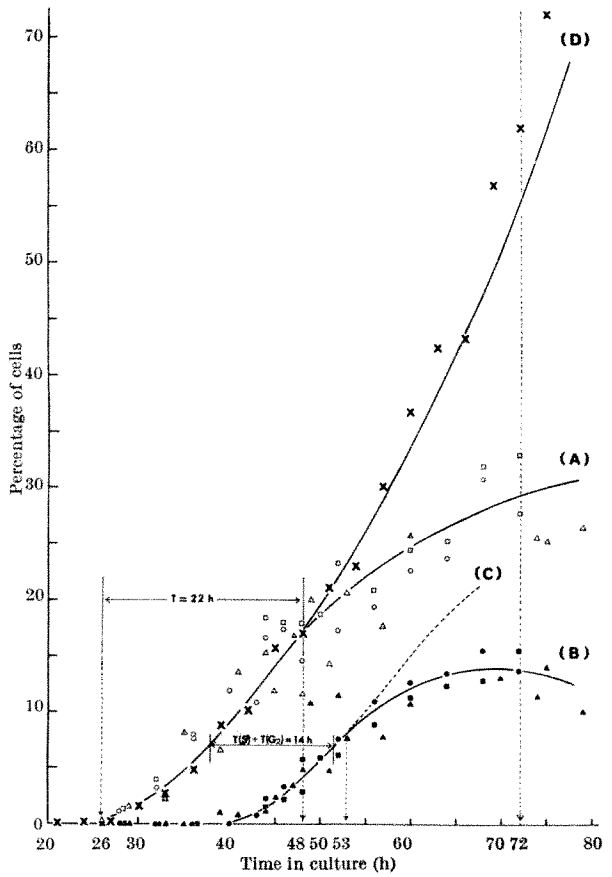

Fig. 2. Percentage of mononuclear cells labelled with tritiated thymidine in the presence (curve A) or absence (curve D, computed) of colcemide; and per cent of mononuclear cells in metaphase (experimental, curve B; expected, curve C). * Colcemide added after 20 h in culture.

Our data indicate, thus, that the small lymphocyte finishes its transformation in 24–48 h, then begins a period of cell proliferation with a generation time of 22 h. As a result the majority of cells are in their second division at the end of 72 h, the standard culture time in cytogenetic work with human lymphocytes. For cytogenetic work, therefore, we have adopted the procedure of adding colcemide after 24 h at a concentration of 3–4 μg/ml. and collecting the cells between 48 and 60 h. The yield of cells in metaphase and the quality of chromosome preparations are very similar to those obtained with the standard 72 h cultures.

This work was supported in part by the U.S. Air Force.

HAEMOGLOBIN KÖLN (β–98 VALINE → METHIONINE): AN UNSTABLE PROTEIN CAUSING INCLUSION-BODY ANAEMIA

By R. W. CARRELL* and DR. H. LEHMANN

Medical Research Council Abnormal Haemoglobin Research Unit, Department of Biochemistry, Cambridge

AND

DR. H. E. HUTCHISON

University Department of Haematology, Western Infirmary, Glasgow

IN 1964 an unstable human haemoglobin was described which was associated with Heinz body anaemia[1]. It had been found in a Glasgow family with some German ancestry. Unlike in other haemoglobinopathies, such as sickle-cell anaemia or haemoglobin C disease, this inclusion-body anaemia was not a homozygous condition, nor were the patients doubly heterozygous for two abnormal haemoglobin genes—the major proportion of their circulating haemoglobins was normal adult haemoglobin (haemoglobin A) (Fig. 1). At about this time, a haemoglobin from a German family was investigated which had been considered to be an abnormal haemoglobin A_2 (ref. 2). It had been sent from Cologne and had been denoted as haemoglobin Köln. This haemoglobin seemed to be identical with that from the Glasgow family as regards clinical manifestation, haematological features, tendency to denature on mild heating, electrophoretic behaviour, products of hybridization with canine haemoglobin, and the results of fingerprinting of the soluble peptides after tryptic hydrolysis. The fingerprints were indistinguishable from those of haemoglobin A, and it was concluded that haemoglobin Köln was an abnormal variant of haemoglobin A and not haemoglobin A_2. Because on electrophoresis at alkaline *p*H haemoglobin Köln moved more slowly than haemoglobin A, it was assumed that the part of the molecule carrying the additional positive charge did not appear in the fingerprint of the soluble tryptic peptides, but formed part of the insoluble 'core'—that portion of the haemoglobin molecule which does not go into solution on tryptic digestion. Hybridization showed that the α-chains of haemoglobin Köln formed the normal $\alpha_2^{human}\beta_2^{canine}$ hybrid, but that the β-chains of haemoglobin Köln did not form a hybrid with canine α-chains. It was concluded that the abnormality of haemoglobin Köln rested in its β-chain. Of the 146 residues of the β-chain of human haemoglobin the core comprises residues 83–120, and it was assumed that one of these residues had been substituted in haemoglobin Köln[1,3].

To confirm that the electrophoretic abnormality in haemoglobin Köln was situated in the β-chain, globin of pure haemoglobin Köln was prepared and the α- and β-chains were separated and compared with those of globin from haemoglobin A by electrophoresis at *p*H 8·6 in 8 M urea according to Chernoff and Pettit[4]. It was surprising to find that there was no electrophoretic difference between the α- and β-chains of globin Köln and globin A. Because the polypeptide chains became dissociated in 8 M urea and lost their tertiary structure, a possible explanation was that the difference in charge between the two haemoglobins was dependent on their tertiary structure and not primarily on a difference in charge of one of their amino-acid residues, as had so far been the case with all other abnormal haemoglobins (see Fig. 2).

* Supported by a grant from the Wellcome Trust and on study leave from the Pathology Department, Christchurch Hospital, New Zealand.

The possibility was considered that, on electrophoresis, haemoglobin Köln was moving more slowly than haemoglobin A because due to polymerization it was a larger molecule. However, on ultracentrifugation, the sedimentation constant proved to be the same as that of haemoglobin A.

An analysis of the haemoglobin was undertaken by fingerprinting and also an amino-acid analysis of tryptic peptides using methods recently summarized[5]. Fingerprints of the tryptic peptides were prepared for the whole molecule, including the core which had been made soluble by amino-ethylation of the cysteine residues according to the method of Jones[6]. No difference could be detected in the position of any of the tryptic peptides, which now included βTpX (residues 83–95), βTpXI (96–104), and βTpXII (105–120), that is, the core peptides.

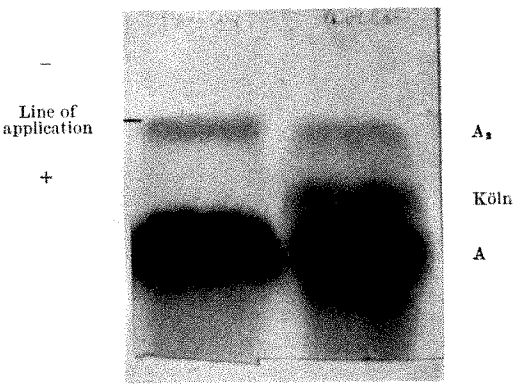

Fig. 1. Paper electrophoresis at *p*H 8·9 of a control (left) and haemoglobin from a patient with haemoglobin Köln disease (right). Electrophoretic separation of haemoglobin Köln from haemoglobin A is clearly shown

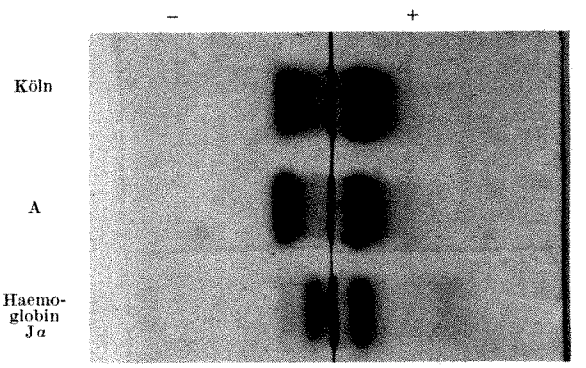

Fig. 2. Starch-gel electrophoresis at *p*H 8·6 in 8 M urea of the globins of haemoglobin Köln, A, and a fast-moving α-chain abnormal haemoglobin (the latter has been included to demonstrate that the method usually shows up electrophoretic differences of abnormal haemoglobins in one of their chains). It will be seen that by this method the separated globin chains of A and Köln show no electrophoretic differences

The α- and β-chains of haemoglobin A and haemoglobin Köln were then examined separately. Chain separation was effected on carboxymethylcellulose columns according to the method of Clegg, Naughton and Weatherall[7]. Samples of the separated chains were then hydrolysed in 6 N hydrochloric acid at 105° C for both 24 h and 48 h. Amino-acid analysis of the hydrolysates showed no difference between the two α-chains, but the β-chains of haemoglobin Köln consistently showed a higher content of methionine. The β-chain of haemoglobin A contains one residue of methionine. In order to confirm the difference in methionine content, both β-chains were oxidized with performic acid which converts methionine to the stable sulphone[8]. The ratio of methionine sulphone from haemoglobin Köln to that of haemoglobin A was exactly 2 : 1. All the other residues were present in near equal amounts, except for valine, which was significantly reduced in haemoglobin Köln. Fingerprints of the amino-ethylated β-chains of haemoglobin Köln and haemoglobin A, both after electrophoresis at *p*H 3·5 and *p*H 6·5, showed no difference in the position of the tryptic peptides (see Fig. 3). This confirmed that there was no difference in charged residues. Colour tests for specific amino-acids were sequentially carried out on the fingerprints as described by Putnam and Easley[9]. Both β^{A}T*p*XI and $\beta^{Köln}$TpXI gave positive reactions on staining for histidine and arginine. On staining for divalent sulphur a positive reaction was obtained in the case of haemoglobin Köln only. This suggested that in haemoglobin Köln a neutral amino-acid of βTpXI of haemoglobin A (residues 96–104 of the β-chain) had been replaced by methionine. From the peptide maps of both β-chains, βTpXI was now isolated using the techniques described by Clegg, Naughton and Weatherall[7]. After hydrolysis for 20 h in 6 N hydrochloric acid at 105° C, amino-acid analysis was carried out. At the same time, a blank area of the paper near βTpXI was eluted and hydrolysed, and on analysis the results were used as a blank correction for the peptide itself. The results are shown in Table 1. It will be seen that in βTpXI of haemoglobin A methionine was absent, and that in haemoglobin Köln methionine replaced a corresponding amount of valine. We consider, therefore, that the sample of haemoglobin Köln from Glasgow is $\alpha_2\beta_2^{98\ Val \rightarrow Met}$.

Residues	96	97	98	99	100	101	102	103	104
β^{A}TpXI	Leu	His	**Val**	Asp	Pro	Glu	Asn	Phe	Arg
$\beta^{Köln}$TpXI	Leu	His	**Met**	Asp	Pro	Glu	Asn	Phe	Arg

From the fact that haemoglobin Köln is highly unstable and denatures on a mild heating which does not affect haemoglobin A, it is concluded that the substitution of methionine for valine in position 98 of the β-chain has a profound effect on the stability of the haemoglobin molecule.

The instability of the haemoglobin Köln molecule *in vivo* and *in vitro* might well be related to a change in tertiary structure in an area which is in close proximity to the haem. The valine in position 98 is present in all the known haemoglobin chains, though in sperm whale myoglobin its counterpart is isoleucine. It is conceivable that valine in this position is an essential requirement for the stability of the haemoglobin molecule.

Table 1. AMINO-ACID ANALYSIS OF βTpXI FROM HAEMOGLOBIN KÖLN AND HAEMOGLOBIN A

	Haemoglobin Köln		Haemoglobin A	
	Moles	Residues	Moles	Residues
Aspartic acid	0·079	1·9	0·034	2·0
Glutamic acid	0·044	1·0	0·019	1·1
Proline	0·040	1·0	0·015	0·9
Valine	0·007	0·2	0·015	0·9
Methionine	0·030	0·7	Nil	Nil.
Leucine	0·043	1·0	0·015	0·9
Phenylaline	0·044	1·0	0·018	1·1
Histidine*	+	1	+	1
Arginine*	+	1	+	1

* A positive specific colour test was considered to represent one residue.

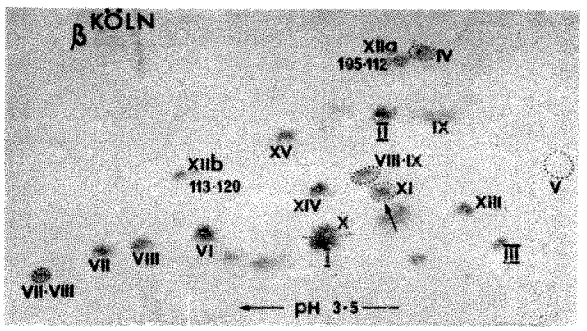

Fig. 3. Fingerprint of the amino-ethylated β-chain of haemoglobin Köln. The various tryptic peptides are indicated. βTpXI (arrowed) is in exactly the same position as it would be in a fingerprint of the amino-ethylated β-chain of haemoglobin A. The only difference is that in the case of haemoglobin A only the colour tests for histidine and arginine are positive, while for haemoglobin Köln there is also a positive test for methionine

There are at least six residues invariantly present in corresponding positions in the polypeptide chains of all functioning haemoglobins and myoglobins which have so far been investigated. They are represented in the β-chain of human haemoglobin by the residues of glycine in position 24, proline 36, phenylalanine 42, leucine 88, histidine 92, and tyrosine 145. Dr. H. C. Watson has pointed out to us that the valine residue in position 98 is in direct contact with the haem, and that there is a continuity of contact between 145tyrosyl—98valyl—haem—42phenylalanyl. It might be expected that replacement of the 98 valine residue by a larger one could interfere with the stability of the tertiary structure of the β-chain. The increased positive charge of the haemoglobin Köln molecule becomes apparent at *p*H 8·6. At this alkaline *p*H, it is possible to exclude a secondary decrease in charge of the neighbouring aspartic acid residue in position 99 (Table 2).

Table 2. THE NEIGHBOURING RESIDUES OF 98-METHIONINE IN THE β-CHAIN OF HAEMOGLOBIN KÖLN

End of helical segment F		Non-helical segment forming corner between segments F and G					Beginning of helical segment G	
92	93	94	95	96	97	98	99	100
His (haem-linked)	Cys[H]	Asp⁻	Lys⁺	Leu	His	Met	Asp⁻	Pro

The observation could, however, be in keeping with an increase in the positive charge of a nearby histidine residue. Dr. M. F. Perutz has suggested to us that it is possible that in the tightly packed area of the molecule around the residue 98, methionine might displace the neighbouring histidine in position 97, thus bringing it nearer to an aspartic acid residue at 99 or possibly 94. The greater proximity of the negative charge would then produce an increase in positive charge of the 97 histidine residue—and such an increase in positive charge would depend, however, on the tertiary structure of the molecule being maintained, which is what, in fact, has been observed.

It still remains to be ascertained that all samples of haemoglobin Köln are identical in their amino-acid constitution. This is of some importance because in addition to the original German family other families with haemoglobin Köln have been observed in Britain.

PRESENCE IN LIPOPROTEINS FROM HUMAN SERUM OF A CRYSTALLINE BLUE FLUORESCENT SUBSTANCE OF UNKNOWN STRUCTURE ISOLATED FROM BOVINE LIVER

By P. LALAND, J. O. ALVSAKER, F. HAUGLI, PROF. J. DEDICHEN, PROF. S. LALAND and N. THORSDALEN
Research Division, Nyegaard and Co. A/S, Oslo, and Department of Biochemistry, University of Oslo, Blindern, Norway

THE preparation of a bluish fluorescent polypeptide (protein) fraction from bovine liver has previously been described[1–4]. This fraction, which was given the name 'urgocyton', was shown to inhibit the breakdown of bradykinin by kininases[4]. On acid hydrolysis, the fluorescent polypeptide fraction liberated a bluish fluorescent substance of low molecular weight[4]. This substance, which seems to be a novel one, has now been prepared in the crystalline state and the present publication describes its method of preparation together with data of characterization. The same substance has also been isolated after acid hydrolysis of a lipoprotein fraction from human plasma.

To obtain crystalline material, the crude low-molecular-weight fluorescent fraction, prepared after acid hydrolysis of urgocyton by a method described previously[4], was subjected to the following additional purification. The fraction was dissolved in water and the *p*H adjusted to 8·0 with sodium hydroxide. The solution was then passed through a DEAE-'Sephadex *A* 25' coarse grade (3-cm × 41-cm) column previously equilibrated with 0·1 N sodium bicarbonate and washed with water. The column was then treated with 0·005 M sodium bicarbonate until no more material absorbing at 250 mμ was eluted. The bluish fluorescent substance was eluted with 0·05 M sodium bicarbonate solution. The *p*H of the solution was adjusted to 3·5 by the addition of 2 N hydrochloric acid and the solution extracted twice with 90 per cent aqueous phenol. The phenol extracts were combined and added to three times their volume of ether. The aqueous phase was removed and the phenol–ether phase extracted once with water. The two aqueous phases were combined, extracted with ether to remove phenol and concentrated to dryness. The solid was crystallized from water in prismatic needles (see Fig. 1) and had a melting point at 152°–153° (uncorrected). It is soluble in water at room temperature but insoluble in ether. It gives a negative ninhydrin reaction and a pinkish colour with ferric chloride. It was dried at 75° C *in vacuo* over phosphorous pentoxide. Analysis gave its composition as: carbon, 51·14; hydrogen, 4·64; nitrogen, 6·71; and sulphur, 15·16 per cent.

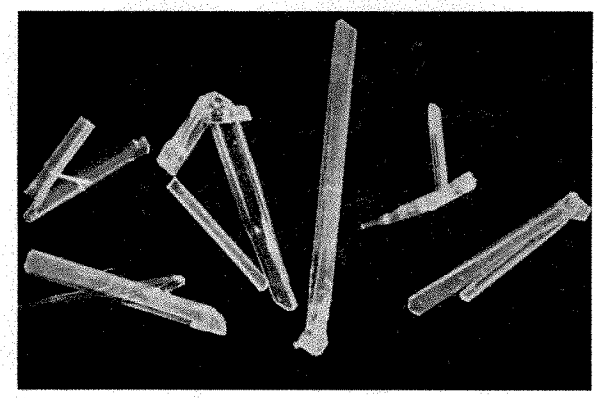

Fig. 1. Crystals of the bluish fluorescent substance photographed under the fluorescent microscope (× 10)

When titrated electrometrically with 0·01 N sodium hydroxide it was shown to possess a dissociating group with a pK'_a of 5·2. Its equivalent weight was calculated to be 212. The results suggest $C_9H_9NSO_3$ as the simplest formula. It is optically active with $[\alpha]_D^{20} = -106{\cdot}2°$ (carbon, 0·18 in water). Its electrophoretic properties were determined on Whatman No. 1 paper at 17 V/cm for 2 h. The buffers used were: 0·2 M acetic acid (*p*H 2·8), pyridine–acetic acid–water (10 : 100 : 90 v/v, *p*H 3·5) and pyridine–acetic acid–water (200 : 8 : 1,800 v/v, *p*H 6·5). At *p*H 6·5 and 3·5 the fluorescent substance moved 5·5 cm and 0·8 cm respectively towards the anode. At *p*H 2·8 it moved 1·2 cm towards the cathode. These results suggest that it exists in aqueous solution with a net negative charge and possesses an acidic group. The *p*H of a 0·025 per cent aqueous solution was 4·1. Furthermore, the nitrogen seems to become protonized at low *p*H.

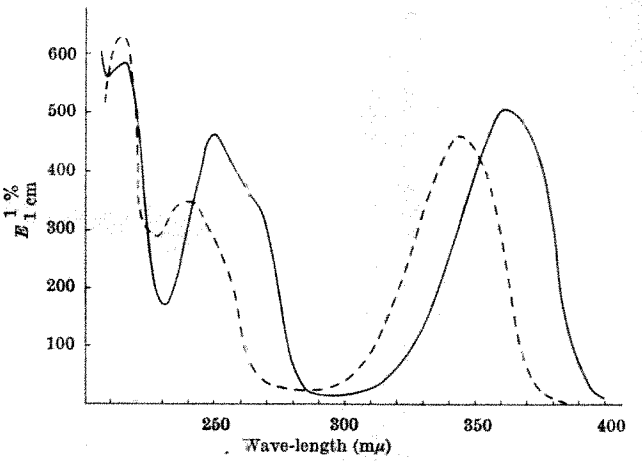

Fig. 2. Ultra-violet absorption spectra of the bluish fluorescent substance in 0·1 N hydrochloric acid (— — —) and 0·1 M phosphate buffer, *p*H 7·6 (——)

The ultra-violet absorption spectra measured in a 'Beckman *DU*' spectrophotometer at *p*H 1·0 and 7·6 are recorded in Fig. 2. The shift in the spectrum when going from *p*H 7·6 to 1·0 is reversible. The three sets of absorption maxima at *p*H 7·6 and 1·0 respectively are 360, 249, 214 mμ and 343, 239, 214 mμ. The absorption spectrum at *p*H 13, which has not been included, has maxima at 360, 248 and 218 mμ and is very similar to that at *p*H 7·6. The near identity of these two spectra suggests that there is no group dissociating between *p*H 7·6 and 13·0. The fluorescence and excitation maxima at *p*H 1·0, 7·4 and 13 were measured in a Farrand fluoro-spectrophotometer

Table 1. FLUORESCENCE AND EXCITATION MAXIMA IN 0·1 N HYDROCHLORIC ACID (*p*H 1·0), 0·1 M PHOSPHATE BUFFER (*p*H 7·4) AND 0·1 N SODIUM HYDROXIDE (*p*H 13) OF THE SUBSTANCE OF LOW MOLECULAR WEIGHT

*p*H	Excitation maximum (mμ)	Fluorescence maximum (mμ)
1·0	340	435
7·4	360	435
13·0	360	435

(uncorrected values with filters 7–54 and 3–73 are shown in Table 1). This instrument (and filters) was used in all subsequent measurements of fluorescence. In all cases, 435 mμ is the maximum of the fluorescence light. Excitation at *p*H 1 occurs at 340 mμ and at *p*H 7·5 and 13 at 360 mμ. The intensity of the fluorescence in water is sufficient to detect 0·1 μg/l. by the naked eye.

The substance is quite stable to acid hydrolysis. 0·076 mg was heated under reflux in 0·6 ml. of 6·3 N hydrochloric acid at 105° C for 20 h. The slightly yellow hydrolysate was concentrated to dryness over potassium hydroxide in vacuum, and the unchanged material was calculated from its ultra-violet absorption (at 360 mμ, *p*H 7·5). 90 per cent of the material remained unchanged.

The presence in ox serum of fluorescent proteins has previously been reported[4]. Some of these proteins in human serum have now been identified. Fig. 3 shows that, when human plasma is filtered on 'Sephadex *G*-200' gel, two fluorescent protein fractions (dotted line) appear in the beginning of the elution diagram. These are designated α_1 and α_2 and exhibited a blue fluorescence which was easily recognizable by the naked eye. A number of sera from healthy donors have also been examined. They all contain the α_1-peak with distribution coefficient 0·11–0·14. In some, peak α_2 with distribution coefficient 0·24–0·28 is much less pronounced and in others almost absent. Both peaks had a neutral *p*H fluorescence maximum at 440 mμ and an excitation maximum at 360 mμ. The large fluorescent peak seen in the last part of the elution diagram in Fig. 3 had a bluish turquoise fluorescence and will be the subject of a subsequent publication by some of us. According to Gelotte, Flodin and Killander[5], the lipoproteins are some of the proteins eluted in the fractions included in peaks α_1 and α_2. Dextran sulphate and calcium chloride added to the serum should precipitate the low-density lipoproteins[6]. However, when examined by agar immuno-electrophoresis[7], the precipitate contained as much high-density lipoprotein as low-density lipoprotein. Small amounts of β_1- and β_2-globulins were also present. When filtering the supernatant through gel after precipitation with dextran sulphate on 'Sephadex *G*-200', the fluorescent α_1-peak was absent and the α_2-peak was substantially reduced. Thus, the results seemed to indicate that the fluorescent substance was part of the lipoproteins. In order to isolate and identify it, the following experiment was carried out.

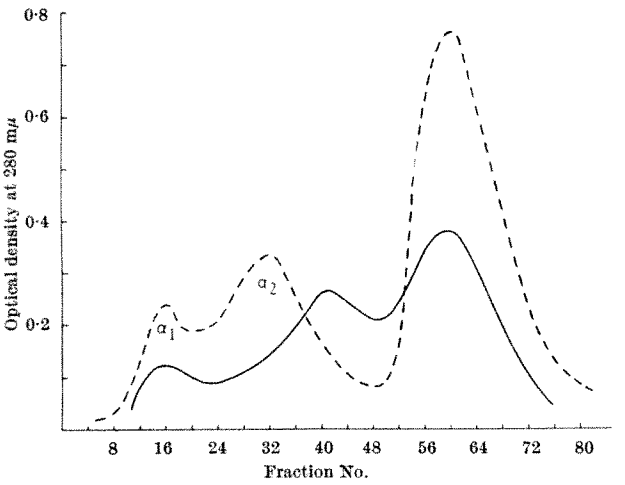

Fig. 3. Gel filtration of 20 ml. serum on 'Sephadex *G*-200' column (6 cm × 60 cm, diam. × height). The blood was drawn (from a fasting, healthy male), left at 20° C for 32 h followed by 6 h at 4° C and then centrifuged at low speed for 30 min at 0° C. The serum was fractionated on the column using as eluant a 0·2 M phosphate buffer (*p*H 7·3) containing 1 M sodium chloride (ref. 5). The flow rate was 40 ml./h and 10 ml. fractions were collected. The optical density (——) of the fractions was measured at 280 mμ after ten-fold dilution with the eluant. The fluorescence (— — —) was measured directly in the fractions at 440 mμ after excitation at 360 mμ. In all fractions beyond fraction No. 48, fluorescence was measured at 460 mμ after excitation at 340 mμ. The fluorescence is given in arbitrary units

For convenience the lipoproteins were isolated by mixing 180 ml. of serum with 7·2 ml. of a 10 per cent solution of dextran sulphate (Nutritional Biochemicals Corporation, clinical grade, molecular weight 16,200) and 18 ml. of a solution of 1 M calcium chloride. The precipitate was purified by dissolving it in 20 ml. of a 5 per cent solution of sodium chloride and reprecipitating it by the addition of 100 ml. of water and 15 ml. of a solution of M calcium chloride. The precipitate was hydrolysed with 5 ml. of 6 N hydrochloric acid at 100° C for 22 h. The filtrate was treated with 0·5 g charcoal. The charcoal was eluted and the eluted fraction[4] purified in water on a polyamide (Woelm) column. The fluorescent fraction was then further purified on thin-layer silica plates (medium *H* according to Stahl. E. Merck *AG*, Darmstadt, Germany) in the solvent system butan-1-ol–acetic acid–water (100 : 22 : 50) and finally in the isopropan-2-ol–butan-1-ol–water (10 : 7 : 10) where it had R_F values of 0·40 and 0·48 respectively. These were identical to those found for the low-molecular-weight fluorescent substances isolated from liver. The fluorescent band was extracted from the silica plates using 50 per cent aqueous ethanol. The final extract (50 per cent ethanol) was concentrated to dryness and the ultra-violet absorption spectra and fluorescence characteristics determined. These were in all respect identical to those of the crystalline substance already described. The characteristic shifts in the ultra-violet absorption and the excitation spectrum when going from neutral to acid solution were exactly the same. When compared electrophoretically at *p*H 2·8, 3·5 and 6·5, the fluorescent substance isolated from the lipoprotein fraction behaved in an identical manner to that of the substance isolated from liver.

Having established the presence of the low-molecular-weight fluorescent substance in the serum-protein fraction, the following less-laborious method for detecting this substance in hydrolysates was used. 100 mg of the material to be analysed was hydrolysed at 100° C for 18 h with 1·5 ml. of 6 N hydrochloric acid. The hydrolysate was diluted with water to 3 ml., filtered and treated with 0·2 g 'Norit' for 2 h at room temperature. The charcoal was washed with water until filtrate was free of chloride ions and eluted at room temperature twice (2 h each time) with ethanol–ammonia (sp. gr. 0·91)–water (48 : 2 : 50), 4 ml. each time. The eluate was concentrated in vacuum and chromatographed on Whatman No. 1 paper in butan-1-ol–ethanol–aqueous ammonia (sp. gr. 0·91)–water (4 : 1 : 2 : 1, by volume) containing 0·2 per cent ammonium chloride. If present, the substance could easily be detected by its blue fluorescence and its approximate R_F of 0·25. The fluorescent band was eluted and its identity confirmed by its fluorescence characteristics, that is, excitation maxima at 360 mμ and 340 mμ at *p*H 7·4 and *p*H 1·0 respectively, and fluorescence maximum at 435 mμ.

To decide whether the lipid part of the lipoprotein contained any of the low-molecular-weight fluorescent substance, the following experiment was carried out. The fluorescent fraction obtained after gel filtration on 'Sephadex *G*-200' was extracted by the method of Scanu, Lewis and Bumpus[8] to remove lipid. The dialysed and freeze-dried lipoprotein fraction was added to 25 ml. of a mixture of ethanol–ether (1 : 1, by volume) and kept at −20° C for 4 h. The precipitated protein was treated with 50 ml. of ether for 24 h at −20° C. The lipid and protein fractions, which weighed 327 mg and 340 mg respectively, were both subjected to the procedure described for detecting the presence of the low-molecular-weight fluorescent substance. A hydrolysate of the lipid contained no such substance, whereas the protein hydrolysate did.

The hydrolytic procedure used in liberating the low-molecular-weight fluorescent substance is fairly drastic, but it is convenient, since proteins are completely broken down to amino-acids. It is conceivable that this hydrolytic procedure could change the fluorescent substance some-

what. There are, however, two reasons why this is probably not the case. When hydrolysing the lipoprotein fraction and urgocyton, respectively, with N-hydrochloric acid at 100° C for 1 h, the same fluorescent substance could be isolated. The fluorescence and excitation maxima (440 and 360 mμ) of the lipoprotein fraction at *p*H 7·3 are very similar to that of the low-molecular-weight fluorescent substance at *p*H 7·6 (fluorescence maximum 430 mμ and excitation maximum 360 mμ).

Certain preliminary conclusions regarding the structure of the fluorescent substance may be drawn. Its strong fluorescence and multi-banded ultra-violet absorption spectrum indicate some unsaturated cyclic structure, an aspect which is also reflected in its low hydrogen content. The presence of one nitrogen molecule per molecular equivalence excluded the presence of purine and pyrimidine ring systems.

The optical activity of the substance makes it more interesting, since it seems unlikely that carbohydrates and amino-acids are present. The presence in it of sulphur is also worth noticing.

What is the biological significance of the bluish fluorescent substance of low molecular weight? Is it required for the proper function of the high-density lipoprotein or is it merely transported by lipoproteins and liberated in the body as such (or attached to peptides) when and where its presence is called for? Furthermore, is it attached to other proteins? What is the relationship between the lipoproteins and the fluorescent polypeptide fraction (urgocyton) isolated from liver?

The biological properties as well as the chemical structure of this substance are under investigation.

X-Ray Crystal Data on Fluorescent Substance from Bovine Liver

A PRELIMINARY X-ray crystallographic investigation has been carried out on the fluorescent substance of unknown structure described in the preceding communication. Weissenberg diagrams were taken about the *a* and *c* axes. The crystals are orthorhombic, elongated in the *c* direction, with $a = 12{\cdot}60$ Å, $b = 17{\cdot}64$ Å, $c = 8{\cdot}51$ Å (all $\pm 0{\cdot}5$ per cent). The space group is $P\,2_12_12_1$, as reflexions $h00$, $0k0$ and $00l$ are absent for odd values of h, k and l. No other systematic absences occur. By flotation in mixtures of benzene and carbon tetrachloride the density was found to be 1·54 g cm^{-3}. This gives a weight of 439 for the asymmetric unit in the crystals. Two equivalents of weight 211 and one water molecule correspond to a weight of 440, in good agreement with the experimental value. The existence of half a molecule of water per equivalent weight was verified in drying experiments.

The space group indicates that the molecules might be optically active. They were tested directly for this, and strong activity in aqueous solution was found.

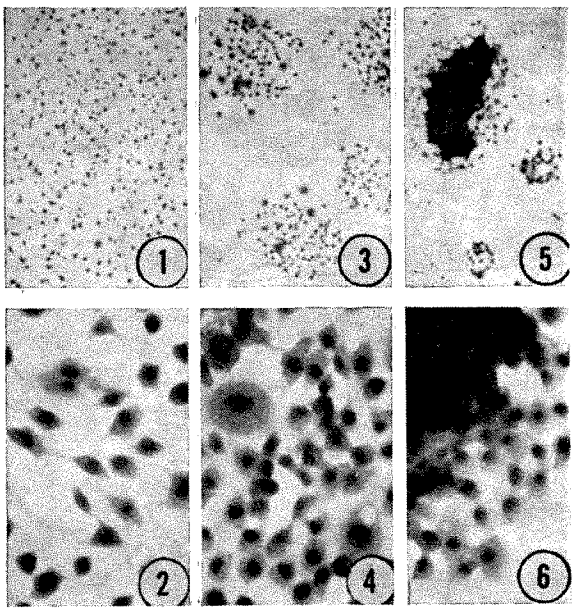
EFFECTS OF PHYTOHAEMAGGLUTININ *IN VITRO* ON CELLS OTHER THAN LYMPHOCYTES

By DR. HARRY L. IOACHIM*

Department of Pathology, College of Physicians and Surgeons of Columbia University and Francis Delafield Hospital, New York

IN 1960, Nowell demonstrated that phytohaemagglutinin (PHA), an extract of *Phaseolus vulgaris*, known for its haemagglutinating activity[1], possesses the remarkable property of being able to initiate mitoses in normal human lymphocytes *in vitro*[2]. Since this observation was made, a great number of reports from different laboratories have analysed the various facets of this phenomenon. It was found that PHA constantly produces leucoagglutination and that mitoses occur only within the clumps of white blood cells[3]. An increase in both DNA[4–7] and RNA[6–8] synthesis was demonstrated. In addition, the greater content of cytoplasmic ribosomes seen in electron micrographs indicated active protein formation[9,10]. The newly synthesized protein was identified as a γ-globulin[11]. Similarly, after PHA stimulation, the cells had increased pyroninophilia[12], acid phosphatase activity[13] and affinity for periodic acid–Schiff stains (PAS)[14].



The final result of these cellular alterations is the appearance of a different cell, larger in size, more basophilic, nucleolated and capable of mitosis having the features of a lymphoblast[10,14]. This unusual cellular transformation was interpreted in general as a response to non-specific stimulation produced by PHA[11] and as positive proof for the potentiality of lymphocytes to transform, rejuvenate and divide[15].

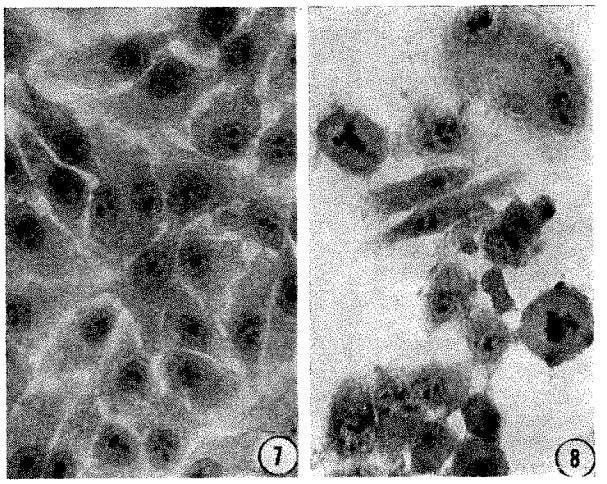
No data are available as to what effect, if any, PHA may have on other types of cells in culture.

To investigate the possibility of an effect, PHA, of both types *M* and *P*, with a control of simple diluent, were added to matched subcultures of different cell types and the morphological alterations induced were studied. The types of cultured cells used are shown in Table 1. All were serial, long-term cultures, grown in Petri dishes with a constant flow of 5 per cent carbon dioxide in air, and regularly subcultured. 'Bacto-phytohaemagglutinin *M*' (code 0528, Difco Laboratory, Detroit, Michigan) was used in a concentration of 0·025 ml. per ml. medium. 'Bacto-phytohaemagglutinin *P*' (code 3110, Difco), 0·006 ml. per ml. medium, and 'Bacto-haemagglutination Buffer' (Difco), the reconstituent of lyophilized PHA, 0·025 ml. per ml. medium, were also used. PHA was added to the cultures at different times and observations were made after periods of 24–96 h, with the phase contrast microscope and on preparations fixed and stained with haematoxylin and eosin, Giemsa and PAS.

When PHA was added to cells in suspension immediately after seeding the plates, an apparent and constant agglutination occurred in all types of cultures. PHA-*P* had a more intense and rapid effect than PHA-*M*, inducing formation of larger and denser clumps (Figs. 4, 6). In contrast to control cultures where cells sedimented and attached to the glass in the following hours, in the



Figs. 1–6. Culture L_{929} with PHA added initially and observed 24 h later. 1, Control culture. Haemagglutination buffer added (× 100); 2, the same (× 360); 3, PHA-*M* added (× 100); 4, the same (× 360); 5, PHA-*P* added (× 100); 6, the same (× 360)

PHA-*P* cultures the cells did not attach and at 48 h remained in clumps floating in the supernatant. However, the agglutinated cells were viable and after 3–4 days formed an incipient monolayer at a time when control cultures had already died, if they had not been subcultured.

The cellular morphology was also altered and, similarly, more intense with PHA-*P* than PHA-*M*. At 24 h the cells in control cultures spread out and displayed characteristic shapes (Figs. 1, 2), whereas in the cultures to which PHA was added all cells were rounded, smaller and more basophilic. In the PHA-*M* cultures the cells remained rounded for a variable time even when attached to the glass, and gradually regained their characteristic features (Figs. 3, 4). The cells in the PHA-*P* cultures remained morphologically altered (Figs. 5, 6).

If PHA was added 8 h later, when most cells were already attached to the glass, and the cultures observed 24 h later, a change in growth pattern was noted. The PHA-treated cultures displayed separate colonies that differed from the uniform monolayers of cells that were formed in the control cultures. These colonies in the PHA-*M* cultures were formed by loosely connected, spread-out cells. In the PHA-*P* cultures the colonies were smaller, formed by closely packed cells that often were piled up in multi-layers. As a result of cytoplasmic condensation the cells were rounded, smaller in size and more basophilic (Figs. 7, 8).

Figs. 7 and 8. Culture D_{98} with PHA added at 8 h and observed 48 h later. 7, Control culture. Haemagglutination buffer added (× 400); 8, PHA-*P* added (× 400)

In a third set of experiments, PHA was added after 24 h when most of the control cultures displayed an organized monolayer. However, even at this time, when PHA was added the growth pattern, as well as the cellular morphology, was altered. The cells, particularly in the PHA-*P* cultures, appeared to be re-arranged in separate or coalescent islands with multilayered areas (Figs. 11–13). A great number of cells in the PHA-treated cultures had lost their characteristic shape, were rounded, with a narrow rim of cytoplasm and more intensely stained. Many cells displayed a granular nucleoplasm and a characteristic chromatin structure. Mitoses in different stages were frequent (Figs. 9–13) and the mitotic indices were higher in the PHA-treated cultures than in the controls (Table 2). PAS-positive material was significantly increased in PHA-treated *HEp* No. 2 cultures.

Table 1. CELL TYPES TESTED FOR PHA EFFECTS

Culture	Animal	Origin: Tissue	Growth pattern	Medium	Mode of subculture
L_{929}*	Mouse	Connective	Fibroblastic	MEM Eagle + 10 per cent calf serum	Trypsinization
HEp No. 2*	Human	Laryngeal carcinoma	Epithelial	,, ,, ,,	Trypsinization

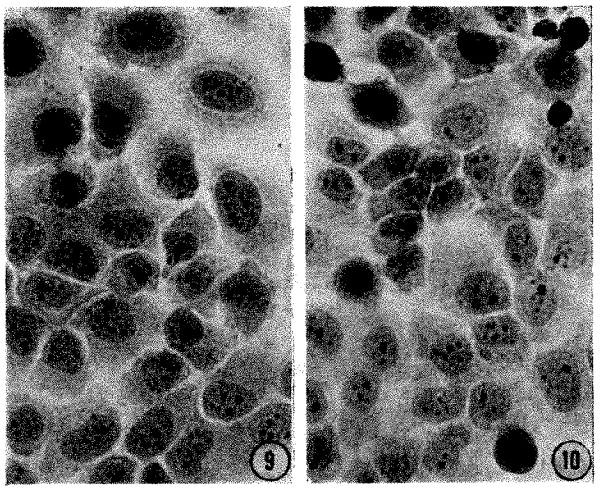
Table 2. MITOTIC INDICES FOR ONE OF THE EXPERIMENTS*

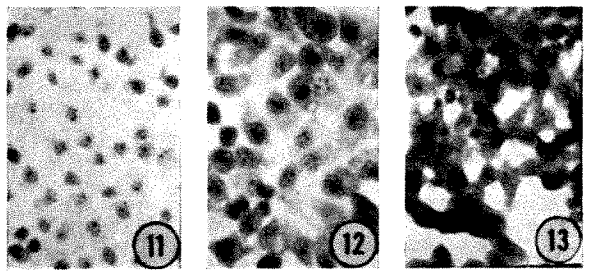
Cell type	Time of exposure: Added to cultures 24 h: Diluent	24 h: PHA-*M*	24 h: PHA-*P*	48 h: Diluent	48 h: PHA-*M*	48 h: PHA-*P*	72 h: Diluent	72 h: PHA-*M*	72 h: PHA-*P*
L_{929}	6	9	9	3	6	5	1	2	1
HEp No. 2	4	13	11	9	10	21	8	11	15
D_{98}	12	26	17	10	31	22	3	3	9
J_{111}	0	22	15	6	20	24	8	9	19
LT_9	5	5	4	3	4	8	4	6	7

* Numbers indicate mitotic figures per 500 cells.



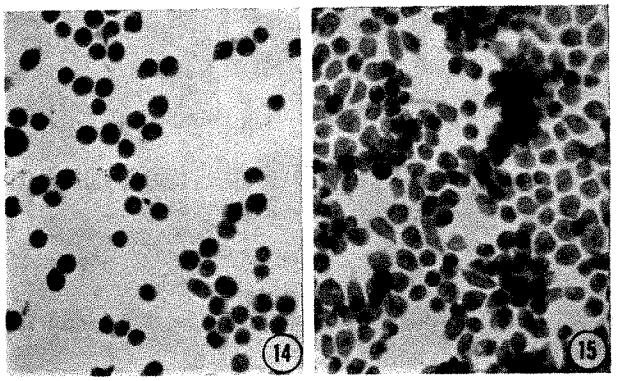
In the LT_9 cultures treated with PHA the changes were different. In contrast to the rounded floating lymphoblasts in control cultures, more cells were immobile and attached to the glass. They were spread out, larger and polyhedral. The cytoplasm appeared more abundant and less basophilic, the nuclei had a granular structure and mitoses were more frequent (Figs. 14, 15).

Specific cellular alterations are known to occur when PHA is added to human lymphocytes *in vitro*. The present experiments demonstrated that PHA induced comparable transformations in other types of cells. These cultures were originated from three different species, of normal and neoplastic, and of epithelial and mesenchymal tissues.



The mechanism by which PHA induces profound metabolic and morphologic changes in cells is not known and a number of explanations have been offered.

Because the effects of this substance were studied exclusively on lymphocytes, the prevalent interpretation is based on an immunological mechanism. According to this interpretation, PHA acts as an antigenic stimulus and elicits an immunologic response[16–18]. Similar alterations occur to lymphocytes from sensitized individuals with the addition to cultures of tuberculin[16], various vaccines[11,19], drugs[20] and by mixing lymphocytes from two unrelated persons[18]. However, while only 5–35 per cent of the lymphocytes in culture were stimulated by these specific antigens, PHA induced alterations in 95 per cent of the total number of cells[11].



With the demonstration of PHA effects on a variety of cells, most of them unrelated to immunologic phenomena, a mode of action based on a presumed antigenic nature becomes more unlikely. The broad range of cell types affected, as well as the intensity of this effect, indicate

Figs. 9 and 10. Culture J_{111} with PHA added at 24 h and observed 24 h later. 9, Control culture. Haemagglutination buffer added (× 400); 10, PHA-*M* added (× 400)

Figs. 11–13. Culture *HEp* No. 2 with PHA added at 24 h and observed 48 h later. 11, Control culture. Haemagglutination buffer added (× 350); 12, PHA-*M* added (× 350); 13, PHA-*P* added (× 350)

Figs. 14 and 15. Culture LT_9 with PHA added at 24 h and observed 48 h later. 14, Control culture. Haemagglutination buffer added (× 400); 15, PHA-*M* added (× 400)

rather a non-specific nature of this stimulation. A capacity to act on the cell surface as previously suggested[6,11] could possibly explain some of the effects of PHA as cell agglutination and induction of mitoses. This would be in accord with the finding that the leucoagglutinogenic and mitogenic properties of PHA could not be separated by adsorption with leucocytes[21].

Human leukaemic leucocytes in cultures of peripheral blood were reported as non-responsive[22,23] or responsive in a much lower degree[24] to PHA than normal lymphocytes. In the present experiments leukaemic lymphoblasts of rat origin, obtained from long-term cultures, were sensitive to PHA and responded with marked morphologic alterations.

The transformation of lymphocytes under stimulation by PHA to lymphoblastoid forms was interpreted as a cellular activation under immunologic stimuli and used to support the idea of a potentiality of lymphocytes to transform to other types of cells. It seems that some conclusions regarding the rejuvenation of the lymphocyte as well as its metamorphosis to plasmocytes and other types of cells are still questionable.

The leucoagglutinogenic and mitogenic properties of PHA may prove useful as practical laboratory procedures. More work is necessary to understand its mode of action. This appears worth while, as the effects PHA has on cells seem to have implications bearing on some basic problems of cellular biology.

I thank Miss Marlene Sabbath for technical assistance.

SITE OF LETHAL DAMAGE BY IONIZING RADIATION IN *Escherichia coli B/r* GROWING EXPONENTIALLY IN MINIMAL MEDIUM

By DR. R. J. MUNSON and DR. B. A. BRIDGES
Medical Research Council Radiobiological Research Unit, Harwell, Berkshire

SOME 30 years ago it was shown that the ultra-violet action spectrum for lethal damage to bacteria coincided with the ultra-violet absorption spectrum of nucleic acids. Equally direct evidence that the principal sites of lethal damage by ionizing radiations are also the nucleic acids has not yet been found, although some experimental findings are consistent with this hypothesis[1–5].

Much of the early work on the action of ionizing radiations was centred around the ideas developed by Crowther[6], Lea[7], Zimmer[8], Timoféeff-Ressovsky[8] and others, and which became known as the 'target hypothesis'. Indeed, Lea suggested that lethal damage could be regarded as a particular type of genetic damage, namely a lethal mutation[7]. In recent years, however, it has become apparent that the sensitivity of bacteria to ionizing radiation is dependent on their physiological state before, during and after radiation. It has also been shown that there is more than one possible type of damage in *Escherichia coli* for example[9], and the presence or absence of enzymatic repair systems is known to make an important contribution to observed radiosensitivity in this species[5].

During these developments the target hypothesis has tended to fall into disrepute in bacterial radiobiology because of the view, perhaps mistaken, that observable changes at the genetic level are always induced with the same efficiency irrespective of the physiological state of the cell. There is, however, at least one bacterial system where target hypothesis may be applicable, namely *Escherichia coli B/r* growing exponentially in glucose-salts medium. Brownell[10] found that the survival curve for such cells was sigmoid with an extrapolation number[11] of 4·02. On the assumption that an organism which has two or more similar sensitive sites (targets) will survive if at least one site is undamaged after exposure, Atwood and Norman[12] had previously shown theoretically that the extrapolation number for a population of organisms each containing one, two, three or more equally sensitive targets was equal to the average number of targets per organism. When Brownell observed an average of 3·5 stainable nuclei per organism, he suggested that these nuclei were the radiobiological targets. Munson and Maclean[13] later investigated the survival curves for populations of *E. coli B/r* growing in minimal media in continuous culture and showed that their shapes were correlated with the average length of the bacteria over a wide range of lengths. They concluded that radiosensitive targets were distributed along the length of the organisms at average intervals of between 1 and 1·5μ, while the nuclear bodies shown by staining had an average spacing of 1·2μ in good agreement with the hypothesis that each nucleus contained about one radiosensitive target.

It is now known that each nucleus in an exponentially growing population at 37° C in minimal medium contains a continuously replicating chromosome in which each part of the genome may be represented either once or twice[14,15]. Thus, if lethal damage were genetic in origin it would be expected that the average number of targets per nucleus would lie between one and two; near one when the radiosensitive genes were replicated last and near two when they were replicated first. If all genes were equally sensitive the number of targets per nucleus would be 1/ln2 or 1·44. For genetic damage, a target would therefore be one unreplicated genome containing one copy of every gene which, by a loose analogy with the genetic material of higher organisms, we may call a 'chromatid'.

Besides the multi-target hypothesis of the inactivation of bacteria there are two other likely hypotheses for explaining extrapolation numbers greater than one[5]. They are: (1) the 'multi-hit' model in which n 'hits' anywhere within a hypothetical sensitive volume of the organism results in lethality; (2) the repair model in which enzymatic reactivation mechanisms reduce the slope of the survival curve at low doses but are inhibited or saturated at high doses. The multi-target hypothesis differs from these hypotheses in that it predicts that damaged targets (chromatids ?) will segregate from undamaged targets (chromatids ?) at cell division. This will result in an increase in the proportion of non-viable cells during the first generation time or so of growth after irradiation while the viable targets are segregating (Fig. 1).

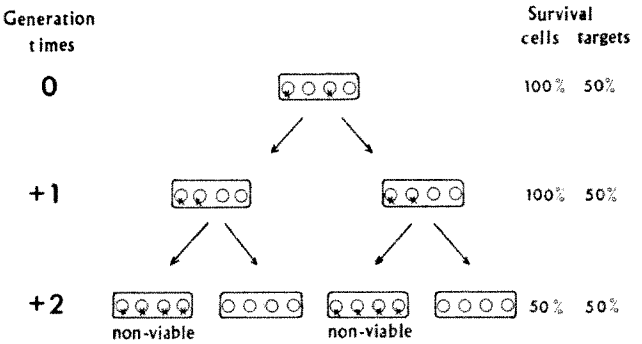

Fig. 1. Illustration of the segregation of viable from non-viable targets from an organism containing four targets of which two are inactivated at zero time. Once segregation is complete the ratio of the number of viable organisms to the number in a similar undamaged clone which has undergone the same number of divisions is equal to the proportion of viable targets at zero time

Segregation of organisms containing viable and non-viable targets. Fig. 2 shows the results of an experiment to test this prediction. A culture of *E. coli B/r* growing exponentially at 37° C in Davis minimal medium[16] was chilled to 0° C and separated into three parts—the average number of nuclei per bacterium at this time being 1·9. Part *A* was irradiated with various doses of cobalt-60 γ-radiation and viable counts on minimal agar plates at 37° C were performed to yield a survival curve. Part *B* was given a dose of 3,500 rads aerobically and together with part *C* (unirradiated) was returned to the 37° C water bath. Viable counts (on pre-warmed minimal agar plates), total counts (using a Hawksley 'Thoma' counting chamber), and nuclear counts (using the acridine orange fluorescence technique[17]) were made on both *B* and *C* at frequent intervals. It can be seen that total and viable counts rose exponentially from zero time in the unirradiated culture (*C*) with a doubling time of 44 min. In the irradiated culture (*B*), the proportion of non-viable organisms at zero time was very small as would be expected from the shape of the survival curve. The total number of organisms rose at about the same rate as in the unirradiated culture for at least one generation time. The

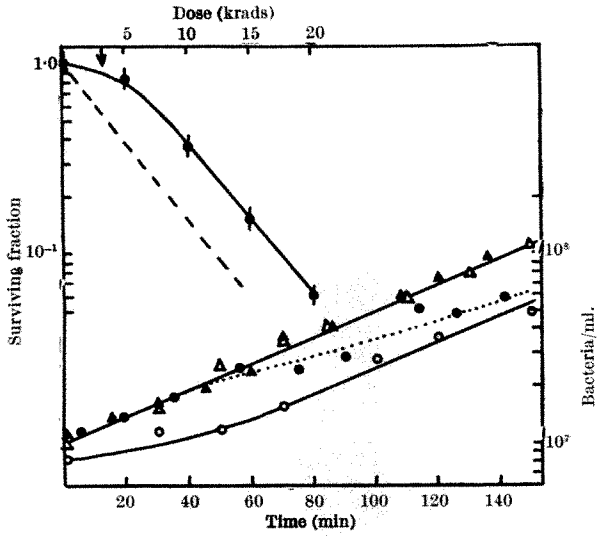

Fig. 2. Post-irradiation segregation of viable and non-viable bacteria (*Escherichia coli B/r*) growing at 37° C after irradiation under oxygen. Uppermost curve indicates survival for total population, broken line is theoretical survival curve for individual targets (chromatids ?). Arrow indicates dose of radiation given for the segregation experiment. Lower curves indicate rise with time of total unirradiated bacteria (▲), viable unirradiated bacteria (△), total irradiated bacteria (●) and viable irradiated bacteria (○). Dotted line is the expected count of total irradiated bacteria (see text)

number of viable cells, however, rose very slowly during the first generation time, indicating that many of the organisms resulting from the first division were non-viable. From between one and two generation times onwards the viable count in the irradiated population rose at the same rate as that in the control culture. This, together with the fact that the total counts in both cultures increased at the same rate during the first generation time, showed that no immediate measurable decrease in growth rate resulted from the dose of 3,500 rads. The total count in the irradiated population rose less steeply than that in the control population after about one generation time—the experimental points being well fitted by a curve (dotted line in Fig. 2) calculated on two assumptions: (*a*) that when a daughter bacterium containing no viable chromatids arises by cell division this daughter undergoes no further division; (*b*) bacteria containing at least one viable chromatid divide at intervals of 44 min.

On the multi-target model, the survival curve for the sensitive targets is a straight line through the origin parallel to the linear portion of the cellular survival curve (broken curve in Fig. 2) and indicates that 56 per cent of the targets should have been viable after a dose of 3,500 rads. When these bacteria had later divided and the undamaged targets had segregated, the viable count should have become equal to 56 per cent of that in a similar unirradiated population. Our observed figure was 54 per cent.

It is possible to perform a number of experiments like that shown in Fig. 2 simultaneously on a suspension divided into aliquots each of which is given a different dose of radiation. This, however, is complicated at all but the lowest doses by unknown irradiation products arising in the medium which have a rapid bactericidal action when the suspension is warmed to 37° C. This difficulty may be overcome by making a ten-fold dilution into fresh warm medium after irradiation. The results of such an experiment are shown in Fig. 3, where the observed surviving fractions before and after segregation are plotted against dose. The former are fitted by a curve computed on a multi-target model (solid line); the latter do not differ significantly from a line through the origin parallel to the limiting slope of the multi-target curve (broken line). The observed and theoretical survival curves for the targets are therefore seen to be in complete agreement.

Thus, *E. coli B/r* organisms growing exponentially in minimal medium appear to contain (on average) more than one target sensitive to ionizing radiation and these targets segregate into independent cells at division. Furthermore, as expression of lethal damage only occurs after cell division in most cases it can be provisionally regarded as recessive lethal damage.

Correlation of targets with chromatids. Earlier workers, as already mentioned, tried to correlate the number of targets with the number of stainable nuclei. In Brownell's experiments there were 1·15 targets per nucleus. In our experiment shown in Fig. 2, analysis by computer of the survival data showed that the extrapolation number of the linear portion of the curve of 'best fit' was 3·05, so there were $3{\cdot}05/1{\cdot}92 = 1{\cdot}59 \pm 0{\cdot}28$ targets per nucleus. Table 1 shows results from eleven recent experiments with four different lines of *E. coli B/r* in which surviving fractions and nuclear numbers were found simultaneously. In all but two experiments the number of targets per nucleus exceeded 1·0, and the average number was $1{\cdot}36 \pm 0{\cdot}15$.

Table 1

Strain	Experiment	Mean nuclear No., *A*	Extrapolation No., *B*	*B/A*	
E. coli B/r WP2 try⁻	1	1·54	2·62	1·70 ± 0·31	
E. coli B/r WP2 try⁻	2	1·70	1·92	1·13 ± 0·47	
E. coli B/r WP2 try⁻	3	1·53	1·72	1·16 ± 0·17	
E. coli B/r RRU 5 meth⁻	4	1·59	2·76	1·74 ± 0·27	
E. coli B/r RRU 14 leu⁻	5	1·60	2·11	1·32 ± 0·23	
E. coli B/r RRU 14 leu⁻	6	1·80	1·69	0·94 ± 0·13	1·36 ± 0·15
E. coli B/r RRU 14 leu⁻	7	2·12	3·93	1·86 ± 0·29	
E. coli B/r	8	2·05	1·62	0·79 ± 0·10	
E. coli B/r	9	1·66	2·29	1·38 ± 0·35	
E. coli B/r	10	2·79	3·71	1·33 ± 1·45	
E. coli B/r	11	1·92	3·05	1·59 ± 0·28	

Ratios of extrapolation number to mean nuclear number for logarithmic phase cultures at 37° C of various strains of *Escherichia coli B/r*. Individual errors of *A* and *B* were not available from the computer print-out but were used to compute the errors shown for *B/A*.

It therefore seems likely that there are more targets than nuclei per cell, in accordance with the hypothesis that inactivation of these cells by ionizing radiation is due to the inactivation of their genetic material and that the minimum amount of this which can organize a living cell (that is, a chromatid) is present on average about 1·4 times in any nucleus.

Survival curve for single mutant chromosomes. A further distinction between the multi-target hypothesis and the 'multi-hit' and 'repair' hypotheses can be made by investigating the survival both of unselected bacteria and of those bacteria which in the same exposure mutate at a particular gene locus. On the 'hit' and 'repair' hypotheses, the chance of survival of an induced mutant would be the same as that of a non-mutant, that is, the survival

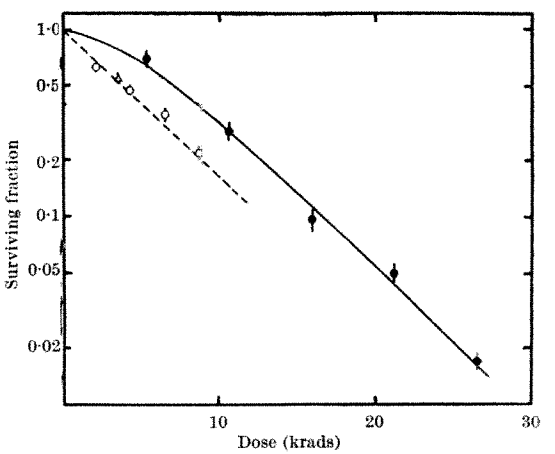

Fig. 3. Surviving fractions of *Escherichia coli B/r* with (○) and without (●) segregation following various doses of γ-radiation under oxygen. The solid line is fitted to the experimental points on a multi-target model. The broken line is the theoretical survival curve for individual targets (chromatids ?). The value after segregation calculated from the experiment of Fig. 2 is also shown (△)

curves of mutants and of the whole population would be identical. On the target hypothesis, the survival of the mutant would depend only on the survival of the single chromatid which contained the mutant gene or of one of the two mutant chromatids in the case of a chromosome in which the particular gene had not replicated at the time of irradiation. The survival curve of mutants should then show a small shoulder corresponding to an extrapolation number between one and two depending on the position of the gene in the replication order.

Survival curves for genetically 'labelled' (mutant) chromosomes of *E. coli* may be obtained by recording the number of mutants induced by various doses of radiation and plotting mutation frequency per nucleus per rad against the radiation dose. This method, which has been used before at low doses to determine by extrapolation the mutation rate under conditions of no killing[18], depends on the assumption that the induced mutation frequency is proportional to dose. Such survival curves have now been extended to higher doses for prototrophic revertants of the tryptophan-requiring strain *E. coli B/r WP2* and compared with those obtained concurrently for the whole population. The linear portions of the survival curves for mutants and for the whole population are parallel, confirming that the induction of mutations is linearly proportional to the dose under these conditions. The survival curve for unselected bacteria had an extrapolation number of 2·62 (average nuclear number 1·54) while the mutant fraction gave a curve with an extrapolation number of not more than two (Fig. 4).

Unfortunately the rather large errors involved in determining mutation frequency and survival at low doses prevented a convincing demonstration of a real difference in the shape of the two curves. Such a difference in shape, if real, could be more readily seen if it were possible to increase the number of chromatids per bacterium. This should have the effect of increasing the extrapolation number for the population as a whole, without affecting that for the mutant fraction. Unfortunately, it has not been possible to increase the number of nuclei per cell and in this way achieve a higher extrapolation number with *E. coli WP2* at 37° C. An alternative approach was suggested by earlier work with this strain which had indicated that at 16° C a large proportion of nuclei contain chromosomes which have replicated but not separated[18,19]. They would, therefore, be in a state analogous to *G2* in higher organisms, each

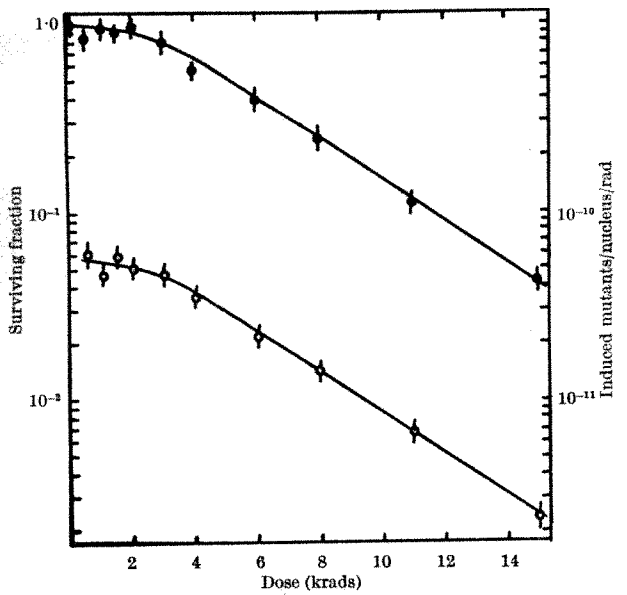

Fig. 4. X-ray survival curves under oxygen for unselected bacteria (●) and newly induced prototrophic revertants (○) of *Escherichia coli B/r WP2 try*⁻ grown at 37° C

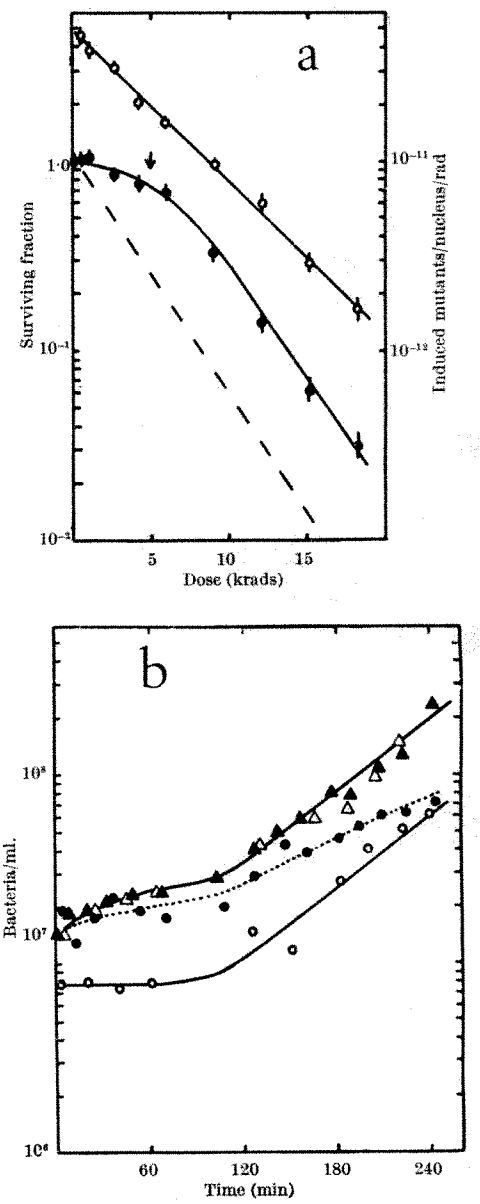

Fig. 5. *a*, Survival curves (γ-radiation under oxygen) for the total population of bacteria (●) and newly induced revertants (○) of *Escherichia coli B/r WP2* grown before irradiation at 16° C; broken line is theoretical survival curve for individual targets (chromatids ?). *b*, Segregation at 37° C of viable and non-viable bacteria (*Escherichia coli B/r WP2*) grown before irradiation at 16° C. Arrow in (*a*) indicates dose of radiation given at zero time. Curves indicate rise with time of total unirradiated bacteria (▲), viable unirradiated bacteria (△), total irradiated bacteria (●, dotted curve, see text) and viable irradiated bacteria (○)

chromosome consisting of two complete chromatids. If this were so, the survival curve for the whole population should have an extrapolation number of nearly twice the nuclear number while that for the mutants should be close to unity. There should also be a greater delay in the segregation of non-viable cells.

These predictions have been verified experimentally (Fig. 5*a*). A population grown at 16° C with an average of 1·82 nuclei per bacterium gave a survival curve with an extrapolation number of 5·00, while the curve for the mutant fraction was exponential. The number of targets per nucleus in this experiment was $5{\cdot}00/1{\cdot}82 = 2{\cdot}75 \pm 0{\cdot}54$. This value may be compared with the number of mutable units of the tryptophan gene per nucleus in a comparable population by two different methods, namely 2·06 and 2·23 (refs. 18 and 19). If targets are to be identified with chromatids and mutable units with single genes on chromatids, numbers per nucleus greater than two may

indicate that some nuclei go through a second replication cycle before separation of the chromatids when bacteria are grown at 16° C.

The rather surprising fact that the linear portions of the two survival curves are not strictly parallel could mean either that mutants (revertants) are more resistant to radiation than the non-mutants (auxotrophs) or that mutation induction is not a linear function of dose for bacteria grown under these rather special conditions.

Total and viable counts after irradiation at 0° C (Fig. 5*b*) show that in these experiments there was a delay in achieving the full growth rate appropriate to 37° C when samples were inoculated into fresh medium at 37° C. Since this delay occurred with irradiated and unirradiated populations and could be reduced by a slower temperature rise between 0° C and 37° C, it was probably a result of temperature shock.

Comparison of the viable counts for the irradiated and unirradiated populations shows that after nuclear segregation the viability of the irradiated population was 29 per cent compared with the value 24 per cent expected from the survival curve. This is consistent with the segregation of undamaged targets or chromatids in bacteria each containing four or five. As with 37° C-grown bacteria, the observed increase in the total count of the irradiated population can be entirely attributed to division of bacteria containing viable chromatids.

In conclusion, we have demonstrated that the inactivation by ionizing radiation of *E. coli B/r* growing exponentially in minimal medium is due to the inactivation of discrete units (targets) within the organism, which segregate from one another at cell division. A bacterium which possesses only inactivated targets is unable to undergo further division. Evidence has been presented that the target is the bacterial chromatid which is itself inactivated with 'one-hit' kinetics. The inactivating lesion must therefore prevent both strands of the DNA from passing on 'viable' information during replication. A similar effectively 'double-stranded' event has also been observed with mutational damage[18,19]. Under the conditions of growth and irradiation used in our experiments the radiosensitivity of *E. coli B/r* is probably at its greatest. Obviously under conditions where radiosensitivity is less, there must be some mechanism for the prevention or repair of lethal chromosomal damage. Under such conditions it is quite conceivable that non-chromosomal damage may make a significant contribution to the observed lethal effect.

EMPEROR PENGUIN COLONY AT BEAUFORT ISLAND, ROSS SEA, ANTARCTICA

By Dr. BERNARD STONEHOUSE

Department of Zoology, University of Canterbury, Christchurch, New Zealand

THE existence of a colony of Emperor Penguins (*Aptenodytes forsteri*) at Beaufort Island was first noted by Harrington[1]. His report was based on a letter from Mr. S. O. Wilson of the U.S. Antarctic Research Programme, who saw the colony from a passing ship on November 5, 1956. The colony was reported to occupy part of a 25-ft. bench on the north side of the island; no further details were given by Harrington.

Beaufort Island (76° 56′ S., 67° 03′ E.) is a small ice-capped island off the mouth of McMurdo Sound in the south-western corner of Ross Sea (Fig. 1). Often beset by pack ice in summer, it is difficult to approach by sea and received little attention from early explorers. A current of up to three knots setting westward between the island and Cape Bird helps to ensure early break-up of fast ice each spring. By mid-November a polynia some 20–30 miles across is usually found to the west of Beaufort Island and Cape Bird, extending southward into McMurdo Sound as far as Cape Royds. There are large colonies of Adelie Penguins (*Pygoscelis adelie*) at Beaufort Island, Cape Bird and Cape Crozier, the three together accommodating nearly half a million birds. A small colony of Emperor Penguins, at present numbering some 1,500 pairs[2], breeds each year on the sea ice below Cape Crozier.

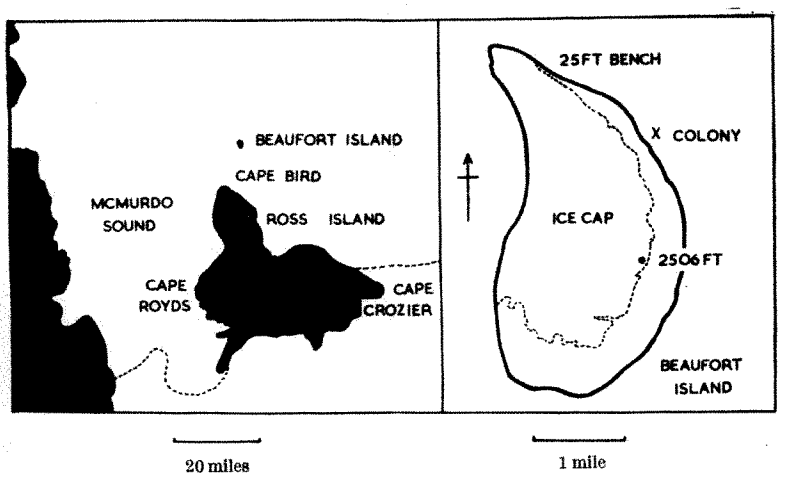

Fig. 1

The Beaufort Island Emperors were first examined and photographed on December 6, 1962, from a U.S. naval aircraft (Fig. 2). The size and situation of the colony were determined, and similar flying visits were made on November 26, 1963, and November 19, 1964, for annual comparisons. This work is part of a long-term conservation investigation sponsored by the University of Canterbury Antarctic Biology Unit.

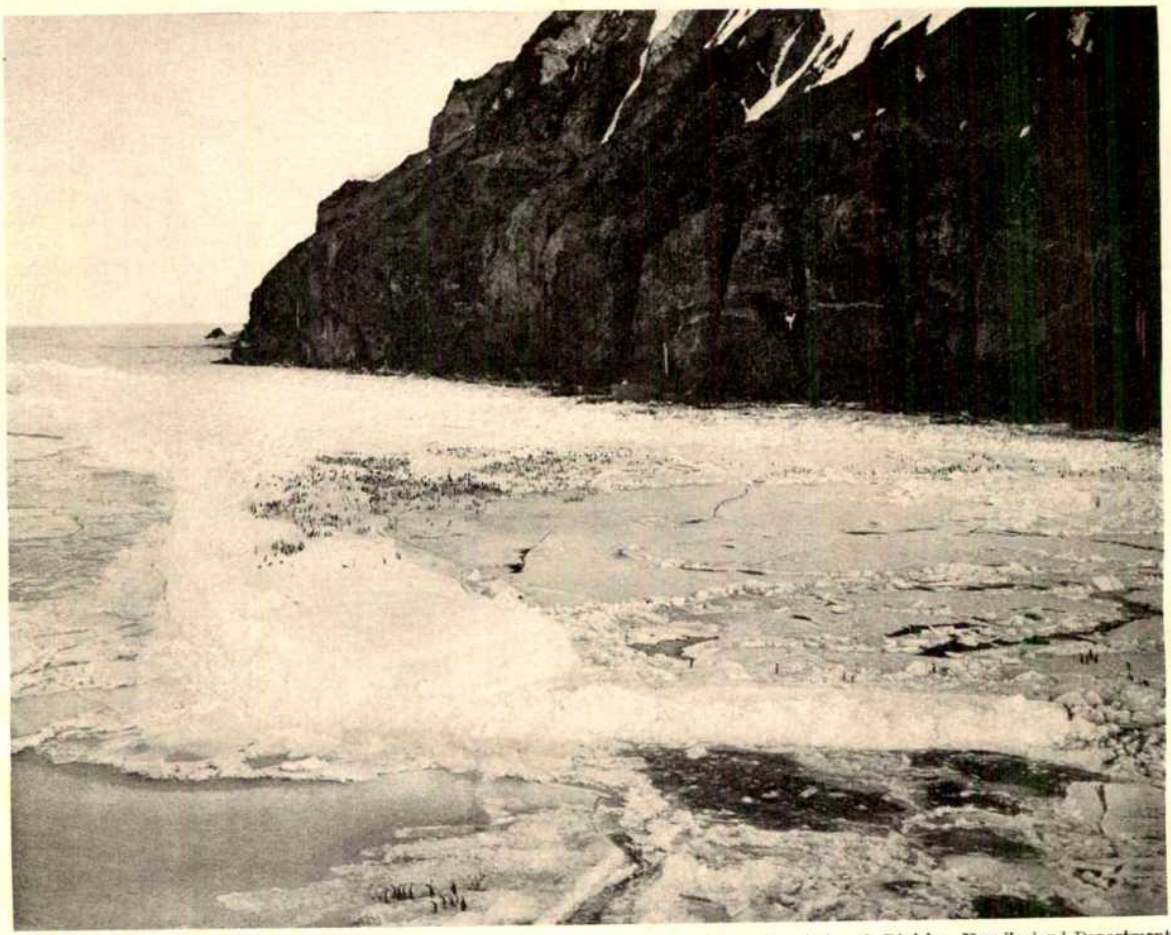

Fig. 2. Emperor Penguin Colony, Beaufort Island, December 6, 1962. (Photo by Guy Mannering, Antarctic Division, New Zealand Department of Scientific and Industrial Research)

The colony has been found each season on sea ice at the foot of a steep, ice-capped cliff off the north-eastern corner of the island, 0·75 mile south and east of the 25-ft. bench. The birds congregate on a narrow platform of winter ice, 100–200 yd. wide, fringing the cliff at this point. Open sea is usually close at hand; in 1962 a quarter-mile of rafted, newly formed ice separated the colony from several square miles of open water, and in 1963 and 1964 smaller pools, in which adults were swimming, lay within a hundred yards of the main group of birds. Extensive open water dotted with floes and frozen patches spread to south and west in all three seasons.

A line of brash ice at the edge of the platform in 1962 and 1964 gave evidence of very recent wave action within a few yards of where the birds were standing. The surface of the platform is usually rough, with many cracks and upheavals, as though subject to pressure and distortion. Frozen-in fragments of berg give protection to the colony; in 1964 a small tabular berg was present nearby, and guano-stains showed that the colony had spent some time in its lee. The roughness of the platform would screen the birds from ships passing more than a few hundred yards from the island.

Adults and chicks were usually assembled in three or four loose groups over an area of a few hundred square yards; the groups were always centred under the same point of cliff, with several large guano-stained areas visible on either side of them. Beaufort Island is a prominent landmark, and birds approaching from any direction would have little difficulty in finding the traditional colony site. Sastrugi suggests that local winds blow strongly along the cliff base, but some shelter would be afforded at ground level by hummocks and depressions in the ice platform.

Close examination from the air showed no evidence that the birds had ever occupied the 25-ft. bench, as the original discoverer of the colony suggested. However, this species is noted for its absence of nest sites and tendency to wander during incubation and chick rearing, and it would not be entirely uncharacteristic if incubation began on land and chick rearing were completed on the sea ice. Flights earlier in the season would help to determine this point. The fringing platform of winter ice, although more stable than that further out to sea, is clearly subject to disturbance during its formation, and might be unsuitable for courtship and laying in May and June.

Photographs taken in 1962 showed 1,069 chicks and 707 adults present in the colony; these figures were means from independent counts by two observers using binocular microscope under varying conditions of light and magnification, and were likely to be accurate within ± 5 per cent. The 1963 and 1964 photographs suggest very similar colony sizes, possibly within 10 per cent of the 1962 figures. Thus the colony is likely to have a breeding population of some 1,200–1,500 pairs, equivalent to or perhaps slightly smaller than that of Cape Crozier 5 miles to the south-east.

I thank Guy Mannering, whose excellent photograph made this work possible, and the Research Committee of the New Zealand University Grants Committee for financial support. The field assistance of *VX* 6 Squadron U.S. Navy, and the good offices of U.S.A.R.P. and Antarctic Division, New Zealand Department of Scientific and Industrial Research, are also acknowledged with thanks. Miss Felicity Cutten helped in checking photo counts and illustrated this paper.

LETTERS TO THE EDITOR

ASTROPHYSICS

Strength of Cosmic Radio Sources

THE discovery of quasi-stellar objects has brought with it the realization that bremsstrahlung radiation in the radio wave region as generated in a plasma has not been properly understood. The present communication represents an effort to account for the unusually high levels of radio emission from quasars and to explain, in particular, the spectral output from the sub-structures A and B of $3C$-273.

It was suggested earlier[1] that the intense radio-wave emission from quasi-stellar bodies might be explained in terms of radiation from tenuous plasmas. Subsequent calculations[2] based on a stimulated bremsstrahlung mechanism in optically thin plasmas revealed that for $3C$-273 B a self-consistent model confirming the Hubble law deduced location of the source (in the megaparsecs range) could be obtained. Indeed, the flat spectral power output in the neighbourhood of 10^3 Mc/s was reproduced.

The problem remained, however, to account for the power spectrum of $3C$-273 A, the spectral index of which $(-0{\cdot}9)$ had prompted speculation[3] that a synchrotron mechanism was indicated, although it was rather doubtful that sufficiently adequate magnetic fields were present; in point of fact, there was no evidence of strongly polarized radio waves from this portion of $3C$-273.

The following rational explanation is offered as a unified theory not only for parts A and B of $3C$-273 and quasars generally, but possibly for radio galaxies as well. Suppose the number of ions and electrons in a fixed volume be augmented. The power will at first grow as more and more free transition occurs; but soon the inverse bremsstrahlung will tend to cut down the radiative transfer to the surface of the plasma as the black-body limit is approached. In other words, a maximum output of bremsstrahlung radiation prevails at some intermediate plasma density. Presumably part B of $3C$-273 at $n = 10/\text{cm}^3$ lies close to this point with a small optical depth in effect, whereas part A at $n = 10^7/\text{cm}^3$ manifests a larger optical depth, so that self-absorption gives rise to a fall-off of radio power at higher frequencies.

Galaxies at still higher densities are further from the optimum region and are then characterized by varying degrees of power drop-off at high frequencies. Combining this aspect with the fact that quasi-stellar sources have lower temperatures (10^4 °K compared with 10^5 °K or greater), the enhancement factor m_0c^2/kT for the latter provides added cause for quasars to emit proportionately larger amounts of radio waves. In essence, then, the combination of stimulated emission and low opacity for a plasma can give rise to unexpectedly large quantities of emitted electromagnetic radiation, particularly in the longer wave-length region of the spectrum.

It is not surprising that very dense, hot plasmas are notoriously poor sources of steady radio emission. The Sun, for example, exhibits low levels of steady thermal radiation.

The effect of optimal density plasmas should be looked for in the laboratory and more systematically investigated. Theoretical effort is being directed toward characterizing the build-up of radiated power from a plasma as the carrier density runs the gamut from the low- to the high-density region.

This work was supported in part by a grant from the National Aeronautics and Space Administration and is based on a Sigma Xi address delivered at Fordham University on December 15, 1965.

GEOPHYSICS

Remote Cyclotron Resonance Phenomenon observed by the *Alouette* Satellite

A NOVEL cyclotron resonance phenomenon associated with the second harmonic of the electron gyrofrequency $2f_H$ is sometimes observed on *Alouette* topside ionograms. The phenomenon occurs remote from the satellite and will consequently be called the 'remote resonance'. The cyclotron resonances which occur in the vicinity of the satellite, and which are responsible for the cyclotron spikes, have been discussed by previous authors[1,2].

A topside ionogram showing the trace produced by the remote resonance ('resonance trace') is presented in Fig. 1. The presence of substantial range-spreading of the echoes, commonly known as 'spread F', tends to obscure some of the features on this ionogram; for clarity, a somewhat idealized schematic diagram of this same ionogram is presented in Fig. 2. In Fig. 1 the lowest observed frequency of the resonance trace occurs at a delay time corresponding to an apparent range of about 1,450 km. At slightly higher frequencies it appears at rapidly decreasing range and subsequently joins the extraordinary wave trace. The frequency at which the resonance trace meets the extraordinary reflexion trace is defined as the 'cut-off frequency' f_c (see Fig. 2). The second harmonic cyclotron spike ($2f_H$ spike) caused by a local resonance at the satellite is also indicated on the ionogram.

Fig. 3 shows the real height of reflexion of the extraordinary wave (obtained from the ionogram of Fig. 1) plotted as a function of frequency. Also shown is the variation with height of $2f_H$ calculated from the Jensen

May 28, 1963, 1506 G.M.T. (68° N. 159° W.)

Fig. 1. Ionogram recorded by the *Alouette* topside sounder, illustrating the remote resonance trace

and Cain spherical harmonic coefficients[3]. The observed cut-off frequency obtained from the ionogram is found to occur where the extraordinary wave reflexion curve and the $2f_H$ curve intersect. The height at which these curves intersect is defined as h_r.

In Fig. 4, the observed cut-off frequencies f_c from eleven ionograms are plotted against the corresponding calculated values of $2f_H$ at height h_r. These heights (h_r) were obtained from electron number density-height profiles calculated from the ionograms and are indicated in brackets in Fig. 4. For equality between the observed cut-off frequencies and the calculated value of $2f_H$ at h_r the experimental points should fall on the straight line drawn at 45° to the axes of the graph. Uncertainties in the calculated values of $2f_H$, using the Jensen and Cain coefficients[3], are negligible compared with the uncertainties in scaling and real height reduction. The inner error bars indicate the accuracy to which the cut-off frequencies were scaled. The outer bars are an estimate of probable error due to uncertainties in the real height reductions because of spread F on the ionogram traces. Additional errors in the real height reductions due to ionospheric tilts and gradients are also possible. Fig. 4 demonstrates that

$$f_c = 2f_H(h_r) = f_x(h_r) \quad (1)$$

where $f_x(h_r)$ is the frequency of the extraordinary wave reflected at h_r. Since h_r is the extraordinary wave reflexion height for frequency $f_x(h_r)$, the Appleton–Hartree equation for the index of refraction in the ionosphere gives:

$$f_N^2(h_r) = f_x(h_r)\,[f_x(h_r) - f_H(h_r)] \quad (2)$$

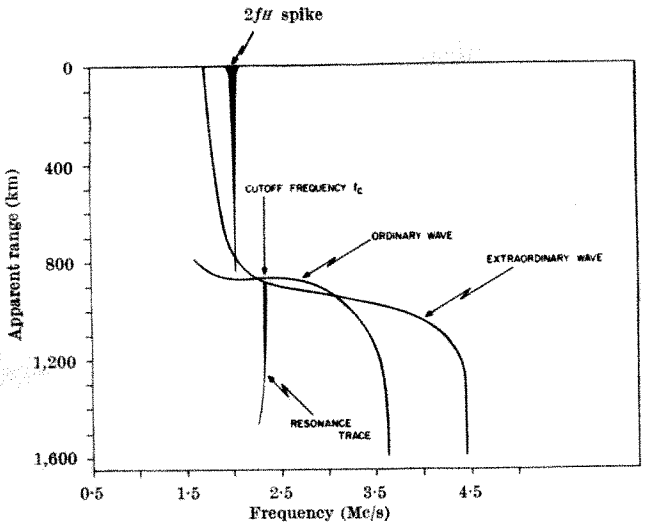

Fig. 2. Schematic diagram of ionogram in Fig. 1

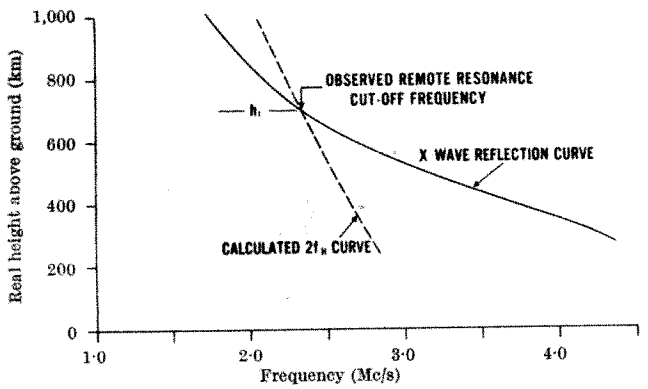

Fig. 3. The relationship of the observed remote resonance cut-off frequency (from the ionogram in Fig. 1) to twice the gyrofrequency and to the extraordinary wave reflexion height

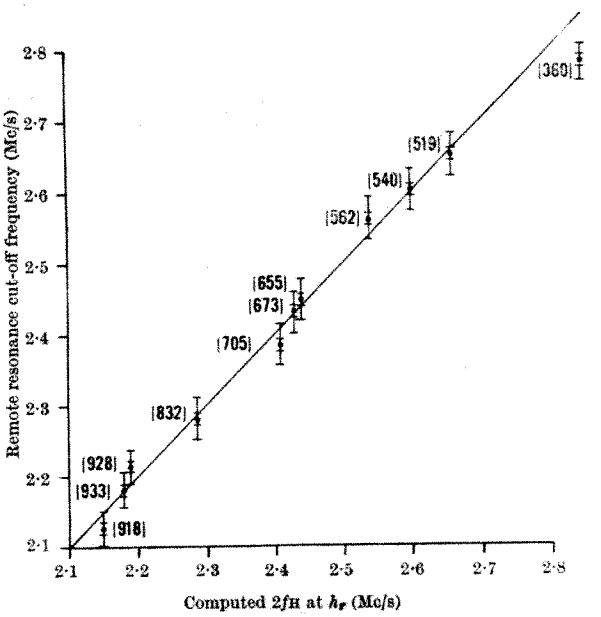

Fig. 4. Comparison of remote resonance cut-off frequencies obtained from ionograms, with computed values of $2f_H$ at height h_r. The numbers in brackets beside the data points are h_r values

where $f_N(h_r)$ is the plasma frequency at h_r. From equations (1) and (2):

$$f_N(h_r) = \sqrt{2}\,f_H(h_r) = \frac{f_c}{\sqrt{2}} \quad (3)$$

The variation of f_H with height is known quite accurately[3] so that h_r can be determined from f_c; from equation (3) the electron density at this height h_r can be obtained. A single measurement of frequency (f_c) determines both the real height and electron density. This method of obtaining the electron density at h_r is completely independent of the usual assumptions made in the calculation of electron number density as a function of height from ionograms.

The remote resonance trace is only observed on high-latitude ionograms which show moderate to extreme spread F and spread echoes at the height of the satellite[4]. About 4,000 high-latitude ionograms (recorded during the period May 2–11, 1963, at the Resolute Bay, North-West Territory, and College, Alaska, telemetry stations) were examined and resonance traces were observed on about 1,050 (26 per cent) of these ionograms. The resonance traces were observed most frequently on ionograms recorded above about 70° N. geomagnetic latitude, although on occasion they were observed down to about 50° N.

Remote resonance traces have not been observed to be associated with the third or higher harmonics of the cyclotron frequency.

Several thousand bottomside ionograms recorded at Baker Lake and Resolute Bay, and at Thule, Greenland, have also been examined; no resonance phenomena associated with twice the gyrofrequency were found on these.

In summary, an ionospheric cyclotron resonance is found to occur remote from the satellite at the height at which the extraordinary wave frequency is equal to $2f_H$. From the resonance cut-off frequency, the plasma frequency at a particular height in the ionosphere can be obtained. This technique is independent of the usual assumptions made in obtaining electron number density profiles from ionograms. The remote resonance trace is a common feature on high-latitude topside ionograms that show substantial spread F.

A more detailed discussion of the remote resonance trace is given by Muldrew and Hagg[5,6].

I thank Mr. D. B. Muldrew for useful discussions.

Prediction of the Intensity of the Present Sunspot Cycle

King-Hele[1] predicted that the intensity of the present sunspot cycle (beginning about late 1964) may resemble the relatively high activity cycles with maxima in 1870 and 1949 and that the solar activity of the forthcoming maximum would reach the level which prevailed in late 1959. This prediction of a fairly high level of sunspot activity for the present cycle can be supported by circumstantial evidence from three periods A.D. 1100–1203, 1724–98 and 1914–64, which have remarkable similarities in various aspects of solar activity, and in terrestrial climate, glacial activity and tree growth.

The 1100–1203 period apparently had a mean sunspot cycle length of about 10·2 years, an interval less than the average cycle length and one which probably indicated a high level of sunspot activity[2]. The mean sunspot number (Wolf number of '*R*' *sensu* Waldmeier[3]) for the maximum years of the ten cycles from the period 1100–1203 was about 113 (including the maximum year of 1098, presumably the same maximum as the year 1100 in Bray[2]) as calculated from the estimates in Schove[4]. This high mean sunspot maximum number again suggests a fairly high cycle strength during the period.

The 1724–98 period had a cycle length of 10·7 years and a mean yearly sunspot number of 54. The lengthy interval following the sunspot maximum of the last cycle of this period somewhat increased its mean cycle length[2]. The mean sunspot number for the maximum years of the seven cycles from the period 1724–98 was about 117 calculated from the estimates in Schove[4] and 113 from the measurements in Waldmeier[3].

The mean cycle length for the 1914–64 period was 10·2 years and the mean yearly sunspot number was 62. The mean sunspot number for the maximum years of the five cycles from the period 1914–64 was about 116 calculated from the estimates in Schove[4] and 127 from the measurements in Waldmeier[3].

The foregoing results show that the three outlined periods had a relatively high mean yearly sunspot activity and a moderately high to high activity for the cycle maximum. A comparison of these periods with other sequences of high sunspot activity in Schove indicates that the years 1100–1203, 1724–98 and 1914–64 were among the most active of the past millennium. Further evidence of high solar activity in the first two periods (no reliable data for 1914–64) is their below-normal level of carbon-14 activity (1100–1203 = −0·5 per cent; 1724–98 = −0·1 per cent) (ref. 5). Such lower carbon-14 activity may be an indication of higher than average sunspot activity[6,7].

All three of the outlined periods were intervals of warm and apparently comparable terrestrial temperature[6–13] and represent maximum temperature intervals during the past millennium[7,10,14]. These periods were also intervals of agricultural expansion into cooler areas[10,14] and recession or stagnation in volume of glacial and sea ice[2,10,13–19]. During the last two periods, tree growth over the past four centuries was at a maximum in the Canadian Rocky Mountains[2] and in the polar Ural Mountains[20]. If there tend to be warmer terrestrial temperatures and glacial recession during periods of high solar activity[2], then these observations are additional evidence for a relatively high solar activity during the three indicated periods.

If the length of the present high sunspot activity period, which began in 1914, is analogous to the length of the high activity periods of 1100–1203 and 1724–98 (that is, 7–10 cycles), it is conceivable that the present interval of high activity may extend for seven or more cycles. If this occurs and if the present high-activity period can be dated as beginning with the 1914 cycle, then the present cycle which began in 1964 should be of moderately high to high activity. The similarity in solar activity and in terrestrial climate, glacial activity, and tree growth between the 1724–98 and 1914–64 periods suggests that future sunspot cycles of the present period may be similar in pattern to the latter part of the eighteenth century. Mean yearly sunspot number per cycle for 1914–64 has shown the same general tendency to increase with each succeeding cycle as occurred in 1724–98 (Table 1, calculated from Waldmeier[3]). If this tendency continues, the present cycle may be of similar magnitude to the record cycle 1954–64 and may conceivably exceed it in mean yearly sunspot number.

Table 1. Aspects of Sunspot Activity for the Periods 1700–1798 and 1890–1964

Sunspot cycle	Mean yearly sunspot No.	Sunspot cycle	Mean yearly sunspot No.
1700–1711	18	1890–1901	38
1712–1723	28	1902–1913	31
1724–1733	54	1914–1923	45
1734–1744	52	1924–1933	41
1745–1755	40	1934–1944	55
1756–1766	43	1945–1954	75
1767–1775	59	1955–1964	96
1776–1784	69		
1785–1798	60		

The high sunspot activity from the period 1914–64 has been identical in sunspot cycle length (10·2 y) to that estimated for the ten cycles of the twelfth century[2]. The climate and glacial activity for these two periods also correspond. This again suggests that the present period of high sunspot activity may continue for several more cycles. Bray and Struik[17] noted the possibility of the present level of relatively high sunspot activity extending to near the close of the twentieth century.

Slow-speed Tape Recordings of Seismic Signals

Seismic interpretation at the University of Tasmania has been enhanced by using very-low-speed magnetic tape recordings in conjunction with the normal pen recordings. When played back with a time compression of 250, the outputs from the short period 'Willmore' seismometers become audible. By comparing the tape and

the pen recordings for earthquakes easily identifiable on the pen recordings it has been found, once the various tones are memorized, that it is not only possible to hear seismic activity which is lost in background noise on the pen records, but also to tell approximately the region from which they originated. Since a 2,400 ft. reel of 0·25 in. magnetic tape lasts approximately 3 months if used continuously, this slow-speed recording also affords an economical way of permanently storing the records in an electrical form.

Recording is achieved by passing analogue signals from the Tasmanian telemetered seismic net[1] by way of low-pass filters directly on to the heads of a commercial stereo tape recorder. A recording speed of 0·00375 in./sec, which allows signals in the frequency range 0·1–10 Hz to be recorded with a dynamic range of approximately 40 dB, has been achieved by driving the capstan flywheel with a hinged motor and a rubber driving pulley.

To enable four channels to be recorded at once, the erase head has been replaced by another record head. By means of a six-position switch any two channels may be reproduced in stereo. Timing is achieved by recording speech at normal tape speeds once per day to give the date and time, while hour marks are automatically recorded by saturating the tape for approximately 15 sec on each hour.

Each day the previous day's recordings are listened to at a tape speed of $\frac{15}{16}$ in./sec, so that one hour is analysed in fourteen seconds. Any seismic activity can thus be pinpointed to within two minutes, making a detailed examination of the pen recordings for the relevant time interval feasible.

Table 1, which covers the period, April 24–May 16, 1965, a period of twenty-three days, shows the effectiveness of this method of recording:

Table 1

No. of earthquakes found on tape	88
No. of earthquakes found on pen recorder	59
No. of earthquakes which would otherwise have been missed	14

The discrepancy between the tape and pen recordings (that is 29 events) are events which are indistinguishable from background noise on the pens.

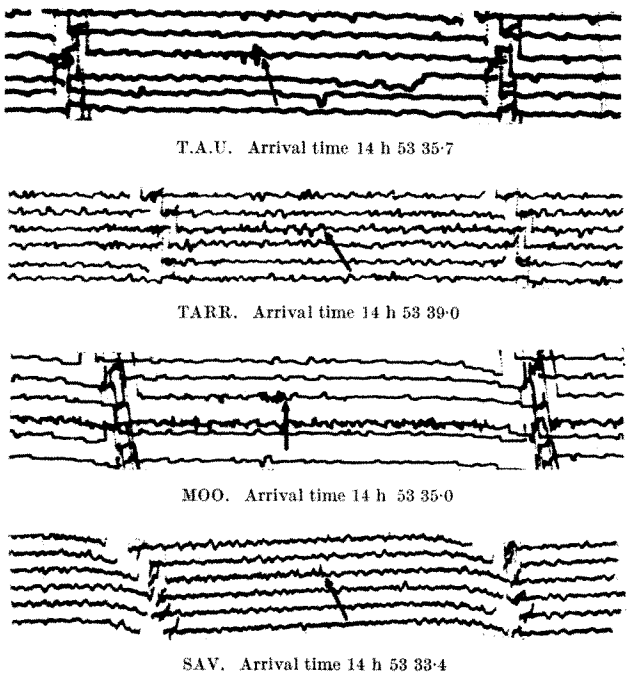

Fig. 1. Pen recordings of an earthquake which occurred south of Fiji Island, lat. 24·1 S., long. 179·5 W., on April 27, 1965. Pen travel is from right on a 1-h per revolution drum recorder. The vertical pen deflexions are minute marks

An example of an event which was first found by listening to the tape and afterwards located on the pen recording is shown in Fig. 1. The reality of this event is shown by the fact that it was recorded on all four stations and its occurrence has also been listed by the U.S. Coast and Geodetic Survey.

PHYSICS

Spherically Symmetric Motions in General Relativity

I HAVE recently obtained certain exact solutions of Einstein's equations of general relativity which, so far as I can trace, have not been noticed before. They refer to a spherically symmetric mass of material in radial motion which may either be collapsing on to the central point (gravitational collapse) or be exploding from that point (spherical blast). The solutions are determined from three general conditions: (1) from a certain pre-assigned form for the coefficients of the metric; (2) from the existence of co-moving co-ordinates; (3) from the assumption that the stress is spatially isotropic. The results have analogies with the spherical blast waves of classical gas-dynamics[1], but with the additional feature that the gravitational self-attraction of the material is a controlling element of the motion. A by-product of the investigation is the discovery of the class of solutions of Einstein's equations to which belongs a particular case[2] obtained in 1933 by a different method.

The form for the coefficients of the metric is indicated by the formula:

$$ds^2 = y^2 dt^2 - R_0^2 S^2 \{e^{\eta}\, dr^2 + e^{\zeta} f^2 (d\theta^2 + \sin^2\theta\, d\varphi^2)\}/c^2 \qquad (2)$$

where R_0, c are constants, $f(r)$ and $S(t)$ are functions of r and t, respectively, and y, η, ζ are functions of a variable z, which is defined by $z = \ln\{Q(r)/S(t)\}$, Q being a function of r. It then follows from Einstein's equations with zero cosmical constant, namely:

$$R^{ij} - \frac{1}{2} g^{ij} R = -(8\pi G/c^2)\, T^{ij} \qquad (2)$$

that co-moving co-ordinates exist if

$$\zeta = \eta,\ y = 1 - \frac{1}{2}\frac{d\eta}{dz}.$$

Physically this means that the material described by the energy-tensor T^{ij} has a uni-directional motion at each point of space and at each instant of time. The material is moving radially either inwards or outwards. It then also follows from equation (2) that the energy-tensor reduces to its four diagonal components: one of these is the generalized density; the other three components describe the stress. Of these the radial component is different from the two cross-radial components which, however, are equal to one another. The assumption of an isotropic stress, describable by a single pressure-function, yields three ordinary differential equations of the second order which involve two arbitrary constants a and b. Two of the equations determine f and Q in terms of elementary functions of r; the third equation is:

$$\frac{d^2y}{dz^2} + (a - 3 + y)\frac{dy}{dz} + y\,(b + a - 2 - (a - 3)y - y^2) = 0. \qquad (4)$$

It cannot, in general, be integrated in terms of elementary functions and resort must be had to numerical computa-

tions. But if certain relations exist between the values of a and b, particular integrals, involving one constant of integration only, can be found. In addition, it proves to be the case that the result discovered in 1933 arises if $a = 3$ and $b = 0$.

The density and pressure can be expressed in terms of the known functions f, Q, y and η through the appropriate Einstein equations (2). However, the as yet undetermined function $S(t)$, and its first and second derivatives, also occur in the expressions for the density and the pressure. The function can be found by imposing an additional requirement, for example, a boundary condition. Thus if there is a vacuum outside the spherical mass, the pressure must be zero at the outer boundary. The function S can thus be found and it involves, among other constants, the boundary value of the co-moving co-ordinate r. It is, of course, the case that S determines the speed of the motion, the time to reach a given size, and other similar properties. Speeds up to the local velocity of light are possible.

The detailed analysis of special cases based on the particular integrals of equation (4), and which correspond to collapsing configurations, shows that a wide variety of motions is possible. In general, there are pressure and density gradients within the material. In some cases, a spherical surface on which the pressure is infinite moves outwards through the material[3]—rather like a shock wave. In other cases, singularities of this kind are absent. The effective times of collapse tend, on the whole, to be short—by astronomical standards at least. The exploding configurations can be dealt with in a similar manner.

On the Theory of Layer Structures

Recently, Shinada and Sugano[1] and also Ralph[2] have published theoretical calculations on the optical absorption in layer structures. These calculations are based on a two-dimensional effective mass approximation and the implications are that conclusions drawn from such an approach apply to the actual physical situation met with in layer structures. In our opinion, this view is at variance with the basic principles of quantum mechanics. Indeed, any two-dimensional representation fails to satisfy the requirements of completeness necessary to describe the states of a physical system and, therefore, is liable to miss physically significant facts. Although the electron wave-functions in layer structures may often be represented with sufficient accuracy as products:

$$\varphi(x,y,z) = \chi(x,y)\zeta(z)$$

of two separate components[3,4], this does not imply that the two-dimensional component $\chi(x,y)$ alone covers the whole situation. The proper representation of the system involves both components and they must appear explicitly in the definition of any physical parameter. In particular, we note that the optical properties of layer structures are subject to selection rules which depend on the mutual orthogonality properties of the two components, and which cannot, *a priori*, be ignored. This example illustrates that it is necessary to make a careful assessment of the physical significance of two-dimensional approximations as applied to layer structures.

The implications of the ideas outlined here will be discussed in some detail in a forthcoming paper[5]. Here we add that the discrepancy noted by Ralph between his results and those of Shinada and Sugano is due to Ralph's omission of the energy dependence appearing in the matrix elements of the dipole interaction. Although permissible in isotropic crystals, this omission is no longer justifiable in layer structures.

Current Transients in Potassium Chloride

A preliminary investigation has been carried out of current transients in potassium chloride at 150° C. The specimens used were single crystals of AnalaR grade, supplied by Hilger and Watts, Ltd.—the slab size being about 2·5 cm square and 0·4 cm thick. Into each slab a flat-bottomed cylindrical recess of 0·5 cm diameter was drilled and the thickness reduced by polishing on a Selvyt cloth moistened with water. Final thicknesses of specimens lay in the range 0·01–0·02 cm. Silver paint was used as electrodes, and the specimen and its spring-loaded contacts were enclosed in a well-insulated thermostatically controlled chamber in which the temperature was maintained at 150° ± 1° C. The pulse generator used provided linearly rising voltage transients of variable rise time and amplitude. The displacement current to the crystal was balanced by adjusting a variable air condenser in parallel with the specimen and feeding the output voltages from the measuring resistor in series with the crystal and from the balancing resistor in series with the condenser to the differential amplifier of a Tektronix type 502*A* oscilloscope. The following is a summary of our observations.

(1) Fig. 1 *A* (lower traces) shows the current in a potassium chloride specimen resulting from the application of two voltage pulses having the form indicated in the upper trace. The second pulse was applied about 2 sec after the first (both are superimposed on the photograph). Before the first pulse was applied, the specimen had not been subjected to high voltage. It can be seen that the magnitude of the first current pulse considerably exceeds the second. At a particular value of the field the current departs from a linear field dependence, increases steeply and then decays.

(2) The second and further successive pulses decrease the magnitude of the current and the position of the decreased current maximum shifts to higher voltages.

(3) The initial high current pulse cannot be repeated by either short-circuiting the specimen after application of voltage or by interchanging the connexions to the electrodes so as to apply the same magnitude pulse in reversed polarity. Regardless of the polarity the high-current pulse is only seen on the first application of voltage.

(4) The initial current can, however, be partially or totally recovered by heating the crystal to a higher temperature (for example, 200° C) and leaving it at this temperature for an hour or two.

(5) The faster the application of voltage the steeper and the higher is the initial current.

(6) If after having applied several pulses of given maximum voltage a pulse of magnitude higher than this series is applied, the current once again shoots up at a threshold voltage exceeding that previously observed, and its magnitude is greater at this higher field. This settles down as before to a very low value on application of further pulses of this magnitude. It is usually found that the residual current at lower fields is now less than before, that is to say, the application of a higher voltage increases

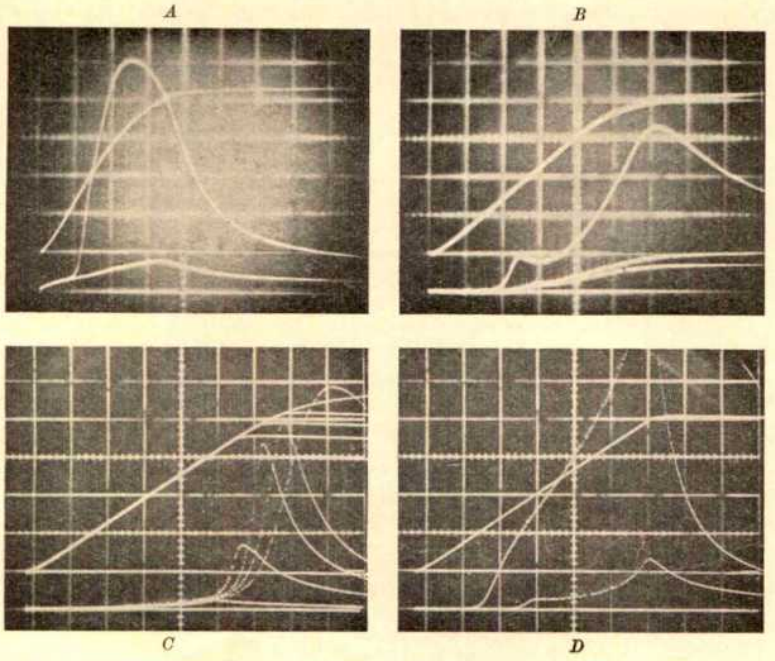

Fig. 1. Transient current in potassium chloride at 150° C (lower traces) and pulse voltage (upper traces). *A*, Voltage/large division = 1 kV; current/large division = 5 μamp; time/large division = 0·5 msec; thickness = 0·013 cm; area = 0·138 cm². *B*, Voltage/large division = 2 kV; current/large division = 10 μamp; time/large division = 0·5 msec; thickness = 0·014 cm; area = 0·196 cm². *C*, Voltage/large division = 2 kV; current/large division = 10 μamp; time/large division = 0·5 msec; spherical recess, minimum thickness 0·0127 cm, diameter = 0·8 cm. *D*, Voltage/large division = 2 kV; current/large division = 10 μamp; time/large division = 0·5 msec; same specimen as *C*

the resistance of the crystal at lower voltages. (See Fig. 1 *C*, in which successive pulses of increasing amplitude were applied.)

(7) It is sometimes found that if the voltage is progressively increased so that the current pulse moves to higher and higher fields, some recovery at lower fields occurs. This can be seen in the double humped oscillogram in Figs. 1 *B* and *D*, second pulse.

(8) It is generally found that the higher the current the shorter the time taken for it to decay.

(9) If a sample is allowed to recover as described in (4), all the foregoing phenomena can be repeated. Differences exist in absolute magnitude of current from sample to sample of the same area and thickness, but the phenomena observed are the same qualitatively.

(10) All the aforementioned characteristics are also observed if the recess is made spherical instead of flat and if evaporated electrodes of silver or aluminium are used.

(11) Figs. 1 *C* and *D* refer to the same specimen. After application of the voltage shown in Fig. 1 *C*, the specimen was allowed to recover and then subjected to two voltage transients of greater amplitude than that mentioned in paragraph (1) (see Fig. 1 *D*). The current due to the first pulse is seen to rise at the low threshold voltage and it continues to rise with increasing voltage until the latter reaches its maximum (the decay of this current can be seen on the right in the oscillogram). The current at fields above the threshold voltage is some 1,000 times that recorded at the same field using direct current.

(12) Breakdown when it occurred was always abrupt.

The foregoing results indicate that the current in potassium chloride at 150° C is dependent on the thermal and electrical history of the specimen and on the rise time of the applied voltage. Similar phenomena have also been found in semiconductors[1]. Von Hippel[2] and Konorova[3] have suggested that high-field conduction is mainly electronic due to field emission from the cathode and that the current decay with time is due to space charge formed by electrons trapped at crystal defects. Our observations can be accounted for on this hypothesis. The sudden increase in current at a threshold voltage can be attributed to electron injection into the conduction band due to field emission from the cathode. These electrons gradually settle into traps and form negative space charge near the cathode, which acts to diminish the field at the cathode, to limit further emission and to slow down electron movement.

An increase in the rate of rise of the voltage will result in greater acceleration of free electrons and in addition will maintain emission from the cathode if the trapping rate—and thus the build-up of space charge at the cathode—is less than, or at least comparable with, the voltage rise. The current under these conditions should be steeper and higher as is observed.

As the initial current may be recovered after some time has elapsed with moderate heating of the crystal, it would seem that shallow traps are involved. It may be that at higher fields electrons can be ejected from these traps resulting in a partial removal of the space charge near the cathode and allowing, on subsequent application of voltage, injection at lower fields. This could then account for the double humped curves seen in Fig. 1 *B*.

The rate of settling into traps will, in part, be determined by the free electron density. This would account for our observation that the decay of current is more rapid the greater the magnitude of the current observed, and also that the resistance of the crystal at low fields is increased by the application of higher voltages.

Relation between the Poincaré Group and the Exceptional Lie Group G_2

THERE is a correspondence, $L_3 \leftrightarrow P_5$, between the line geometry on a three-manifold M_3 and that of planes on M_5 (ref. 1). Because, essentially, of the role of quaternions and octonions as co-ordinate rings here, this correspondence is unique[2]. It can be expressed in terms of the groups which act on manifolds, with dimensions, respectively, of the following elements:

$$\begin{aligned} &M^2{}_{3(5)}, \text{ lines (planes) restricted to a linear complex} \\ &M^2{}_{4(6)}, \text{ lines (planes)} \\ &R_{5(7)}, \text{ linear complexes of lines (planes)} \end{aligned} \qquad (1)$$

and is (the middle group being in each case the conformal group):

$$(B_1, D_3, B_2) \leftrightarrow (G_2, D_4, B_3) \qquad (2)$$

Thus, instead of B_2 (de Sitter group and, by restriction to four-space, Poincaré group), on the right-hand side one finds the exceptional G_2. Behind this is the fact that B_3, D_4, though classical groups, admit exceptionally an outer automorphism of order three, generally known as 'triality'[3].

In view of the known representations of the electromagnetic field $F = (E,B)$ by quadratic[4] or linear[5] com-

plexes in L_3, it is important to see with what physical interpretation the generalization to P_5 corresponds.

In a constant isotropic medium the radiation field $F = (E,B)$ with $E \cdot B = 0$ is determined by five parameters and can therefore be represented by the linear complex:

$$F_{\mu\nu}\, p^{\mu\nu} = F_{\mu\nu}\, x^{\mu}\, y^{\nu} = \hat{F}^{\mu\nu}\, p_{\mu}\, q_{\nu} = 0 \qquad (3)$$

in L_3 where x^{μ},p_{μ} are homogeneous point and plane co-ordinates on the light cone $M_3{}^2$. In the non-isotropic case, one has a non-trivial constitutive tensor K given by:

$$F^{\mu\nu} = K^{\mu\nu\sigma\varepsilon}\, G_{\sigma\varepsilon} \qquad (4)$$

where $G = (D,H)$. In L_3, K defines a quadratic complex:

$$\Omega = K^{\mu\nu\sigma\varepsilon}\, G_{\mu\nu}\, G_{\sigma\varepsilon} = 0 \qquad (5)$$

of which the singular surface $F_{\mu\nu}\, x^{\nu} = G_{\mu\nu}\, x^{\nu} = 0$ is well known to be the wave surface of geometrical optics. As a local property of space K must, according to the philosophy of general relativity, be a function of the fields used to describe the structure of that space. In the Born–Infeld theory[6] $K_B = K(g_{\mu\nu},F_{\mu\nu})$ and, so far as dependence on F is concerned, can be reduced[7] by a four-parameter Lorentz transformation to the identity times a complex gauge factor $e^{\theta+i\varphi}$. The unitary part of this is a duality rotation[8]:

$$(E + iH)(\varphi) = e^{i\varphi}\,(E + iH)(0) \qquad (6)$$

so that $\hat{F}(0) = F(\pi/2)$. The remainder is a real gauge transformation:

$$e^{\theta} = (F_0{}^2 - F_R{}^2)\, F_0{}^{-2} \qquad (7)$$

where F_R is the remaining, purely magnetic, component of F in the reduced frame, and F_0 is a constant in the Born theory, but in general must depend on the metric like $g^{-1/2} = |-g_{\mu\nu}|^{-1/2}$ times an invariant density ρ. In any case K now depends on seven parameters and this, from (1), indicates the possibility of representation by a linear complex in P_5. Furthermore, since K in general depends on 21 parameters, one expects representation in this case by three complexes which are interchanged by a triality rotation.

One can show this very briefly by taking, for a 'field-with-gauge', $F = g^{1/2}\, F_{\mu\nu}$, $g^{1/2}$, ρ) an octonion with components as homogeneous co-ordinates in R_7. This already implies that F can be represented as a linear complex in P_5 because G_2 is the largest group that leaves invariant the multiplication law of octonions[9]. The scalar part, $S(F_1(F_2F_3))$ say, then of any product of three fields F_1,F_2,F_3 is invariant under the conformal group D_4 (ref. 10) acting on the component fields and also under B_3 acting on the product. It follows then that the twenty-one independent transforms can be taken under the latter as elements of K. Thus, B_3 is the analogue of the Lorentz group in the L_3-theory.

Using the definition:

$$(AX)(A^{*}Y) = A^{**}(XY) \qquad (8)$$

of triality, where $A^{***} = A$, one can define a triality rotation analogous to equation (6). Particular interest then attaches to the form in which this is parametrized by elliptic functions. This is the case if ρ is taken to be a (positive) scalar curvature density; then

$$\frac{\mathrm{d}^2 \log g^{1/2}}{\mathrm{d}s^2} = \rho\, g^{-1/2} \qquad (9)$$

has solution $g^{-1/2} = \mathfrak{p}((u) - e_i)$ in terms of the Weierstrauss elliptic function $\mathfrak{p}(u)$ of a formally complex proper time $s = \rho^{-1/2}\, u$ in the three neighbourhoods $e_i u \sim 0$, where e are the roots of $\mathfrak{p}'(u) = 0$, permuted by triality. Thus, $\varkappa_i = \rho^{1/2}\, e_i$ may be taken as the inverse 'lifetime' (if real) or 'range' (if imaginary) of the fields in each case; especially if $\varkappa_3$ is real, then $\varkappa_1 = -(\varkappa_2 + \varkappa_3) = \varkappa_2$ and F_1,F_2 may be taken conjugate in the sense, $F_2 = \bar{F}^{*}$, so that by (8) $F_1(F_2F_3) = N(F_1)(F_1{}^{**}F_3)$. The corresponding fourteen-parameter constitutive tensor K_G, say, is a generalization of the Born K_B in the sense that it reduces to the ten-parameter form:

$$K_E^{\mu\nu\sigma\varepsilon} = \tfrac{1}{2}\,(g^{\mu\sigma}\, g^{\nu\varepsilon} - g^{\nu\sigma}\, g^{\mu\varepsilon}) \qquad (10)$$

of general relativity[11] instead of equation (7) up to, that is, possibly a triality rotation. The fields $F_1,F_2 = \bar{F}_1^{*}$, then supply a non-trivial metric which suggests, as a particle interpretation, that the gravitational 'vacuum' consists of vector meson pairs, possibly the W-mesons of weak interaction theory.

Finally, each of the groups on the right of equation (2) has an invariant of degree six which is the determinant $|K|$ of K considered as a symmetric tensor on $M_6{}^2$, and is an intrinsic property of the medium. This action of G_2 is to be compared with that of the Poincaré group which leaves invariant the Lagrangian of the Born theory, that is essentially $|g_{\mu\nu} - F_{\mu\nu}|$ which is of degree four.

This work was done under a U.S. Air Force contract.

Avoidance of Growth-striae in Semiconductor and Metal Crystals grown by Zone-melting Techniques

It has recently been shown[1] that the growth striae found in semiconductor crystals grown by zone-melting techniques are caused by fluctuations in temperature in the melt from which the crystal is being grown. (The term growth-striae is used to describe a banded distribution of impurity revealed on etched crystal sections.) One of us has shown[2] that the temperature fluctuations were a characteristic property of a liquid metal contained in a horizontal boat on which was impressed an axial temperature gradient. At lower temperature gradients, but still above some critical gradient, the temperature varied sinusoidally with time.

Hurle *et al.*[3] carried out a spectral analysis of the temperature fluctuations and have shown that they are composed predominantly of a harmonic series, the fundamental of which is the sinusoidal oscillation obtained at low temperature gradients. Hurle[2] has postulated that the oscillations are an example of the phenomenon of overstability[4,5]—a form of convective instability. Hurle[2] has also shown that the fluctuations can be eliminated by the application of a transverse magnetic field and has proposed the use of a magnetic field during crystal growth as a means of eliminating growth striations.

This communication reports the results of experiments in which tellurium-doped indium antimonide has been zone-melted with the molten zone maintained in a horizontal, transverse magnetic field.

A conventional horizontal zone-melting apparatus was modified to permit the mounting of a water-cooled electromagnet on the carriage containing the zone-heater. The silica envelope was fitted with a small side arm angled at approximately 45° to the tube, which permitted the introduction of a fine chromel-alumel thermocouple into the molten zone. The tip of the thermocouple was protected by a thin coating of boron nitride. The thermocouple was fed, by means of a backing off circuit, to a potentiometric recorder.

The indium antimonide charge was doped to a concentration of 1×10^{18} atoms/c.c. of tellurium and was contained in a vitreous carbon[6] boat of 16 cm length and about semicircular cross-section of diameter 2 cm. Purified argon was flowed through the tube at a rate of 1 l./min.

The carriage was initially positioned so as to melt a zone of about 4 cm length at one end of the ingot. The ingot was positioned with respect to the side arm such that the thermocouple could be inserted into this zone. With zero magnetic field temperature fluctuations of $\sim 5°$ C amplitude peak-to-peak were recorded (Fig. 1*A*). On applying a magnetic field of 2·5 kG the fluctuations disappeared (Fig. 1*B*). The field was then steadily decreased until at a field of 1·96 kG sinusoidal oscillations of frequency 0·5 c/s were observed (Fig. 1*C*). The critical magnetic field at which the oscillations disappeared increased markedly with increasing length of zone. No quantitative measurements, however, of this effect were made.

After the preliminary experiments had been completed, the thermocouple was removed from the molten zone and the zone was passed along the bar at a rate of 4 cm/h. During passage of the zone through the first and last thirds of the ingot the field was zero, but during passage through the middle third, a magnetic field of 2·5 kG was applied. The bar was then removed, sectioned longitudinally and etched in a modified *CP*-4 etchant. Irregularly spaced striations were visible in the regions which had been crystallized without a magnetic field; there were no striations where the magnetic field had been applied.

In another experiment, a field of 1·96 kG, which was just sufficient to produce sinusoidal oscillations, was applied as before. A bar processed as in the foregoing experiment was found to have striae spaced equally at a distance equal to the crystallization velocity divided by the oscillation frequency. Fig. 2 is a micrograph of the crystal section taken at the point where the field was applied.

All the crystals grown were polycrystalline, no attempt having been made to obtain single crystals.

Both the observation that the striae disappear when the temperature fluctuations are suppressed and the correlation between striae spacing and oscillation frequency provide additional proof that the striae are directly due to the temperature fluctuations.

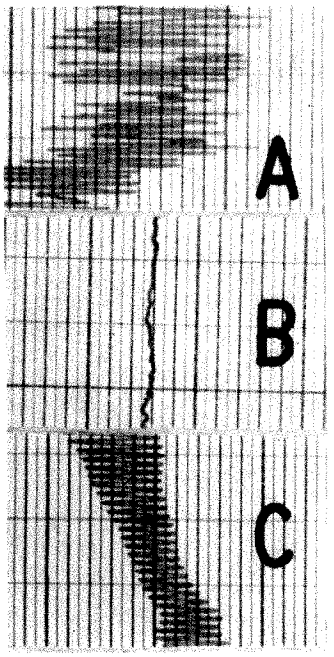

Fig. 1. Thermocouple records: Abscissa, one division = ~0·25° C; ordinate, one division = 15 sec. Magnetic field H: in *A*, 0; in *B*, 2·5 kG; in *C*, 1·96 kG. Frequency, 0·5 c/s

Fig. 2. Photomicrograph of etched crystal section. The region to the left of the arrow was grown with $H = 0$; that to the right with $H = 1{\cdot}96$ kG (×44)

The use of a magnetic field, as described here, for avoiding growth striae has definite advantages over the use of short zones and low-temperature gradients proposed by Müller and Wiehelm[1]. First, the use of low-temperature gradients is likely to result in the occurrence of constitutional supercooling, with its consequent inhomogeneities, in all but very dilute alloys. Secondly, it is technically difficult to maintain short zones. If the heat is applied to the zone externally (as distinct from being generated within the bar by, for example, joule heating), then the zone length cannot be made appreciably smaller than the ingot diameter. On the other hand, the magnetic fields required to suppress the fluctuations are modest and can readily be generated over the necessary volume for crystal growth.

Whether the striae observed in doped oxide crystals[7] are also due to overstable temperature oscillations has yet to be determined. If they are, then the application of a magnetic field may again be useful. However, the electrical conductivity of such melts is somewhat lower than that of liquid metals, and the magnetic fields required are likely to be proportionately higher.

CRYSTALLOGRAPHY

Ordered Structure of Titanium Oxide

THE TiO phase in titanium–oxygen alloys is known to have an extraordinarily wide range of composition, that is, from $TiO_{0{\cdot}7}$ to $TiO_{1{\cdot}25}$, and its crystal structure has varying proportions of both titanium and oxygen vacancies. Density and X-ray lattice parameter measurements[1,2] have shown that a third of the oxygen sites are vacant in $TiO_{0{\cdot}7}$, a quarter of the titanium sites are vacant in $TiO_{1{\cdot}25}$ and even in stoichiometric TiO about a seventh of both sites are vacant. According to the X-ray examina-

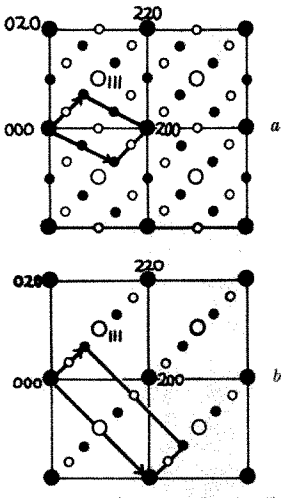

Fig. 1. Reciprocal lattices. Indices refer to the NaCl-type cell. ●, Reflexion on $l=0$ plane; ○, reflexion on $l=1$ plane

tions, these vacancies are arranged randomly at temperatures above the equilibrium temperature, 990° C, giving the diffraction patterns typical of a cubic NaCl-type structure. On the other hand, many weak superlattice lines have been observed on the X-ray powder patterns[3,4] after annealing below 950° C, suggesting the formation of an ordered arrangement of vacancies. However, many attempts to determine this ordered structure in terms of an NaCl-type lattice with a periodic vacancy arrangement have been unsuccessful.

In the present investigation, the ordered structure was examined by transmission electron microscopy/diffraction using alloy foils thinned chemically from bulk. The main advantage of this method of examination over conventional X-ray methods is that it is possible to obtain single crystal diffraction patterns by means of the 'selected-area' diffraction technique. Prior to thinning, all specimens were quenched from above 1,500° C or the melt to retain the cubic NaCl-type structure followed by isothermal annealing below 950° C. Within the composition range $TiO_{0\cdot9}$ to $TiO_{1\cdot1}$ numerous superlattice spots in addition to the fundamental NaCl-type reflexions were observed in the electron diffraction patterns. In the electron microscope images an array of small domains ($\sim 3\mu$ diameter), each containing one set of parallel sub-bands (~ 300–1000 Å wide), was observed. Selected area diffraction patterns of the domains were taken for many crystal orientations, but most of them were actually the superposition of two or more patterns. In extracting diffraction patterns due to single domains from these complex ones, the sub-bands were revealed as twins on a {110} plane of the NaCl-type lattice. A reciprocal lattice was constructed (Fig. 1*a*) from which a monoclinic cell (shown by thick lines) was chosen to describe the ordered structure.

The space group C_{2h}^3-A2/m (No. 12 with A, B interchanged) was obtained from the extinction rules given by the reciprocal lattice. All the observed reflexions are explained by assuming that of the twelve titanium and twelve oxygen sites in the ordered unit cell there are a sixth of each site vacant, that is, two titanium and two oxygen atoms are missing. This assumption is consistent with the previous observations that a seventh of both kinds of atoms are absent at the stoichiometric composition. In the structural model, atoms have been assigned to the following positions:

2 Ti in 2 (*c*): $\frac{1}{2}, 0, 0 : \frac{1}{2}, \frac{1}{2}, \frac{1}{2}$.
2 O in 2 (*b*): $0, \frac{1}{2}, 0 : 0, 0, \frac{1}{2}$.
4 Ti in 4 (*i*): $(0, 0, 0 : 0, \frac{1}{2}, \frac{1}{2}) + x, y, 0 : \bar{x}, \bar{y}, 0$.
With $x = \frac{1}{6}, y = \frac{1}{3}$.
4 Ti in 4 (*i*): with $x = \frac{2}{3}, y = \frac{1}{3}$.
4 O in 4 (*i*): with $x = \frac{1}{3}, y = \frac{1}{6}$.
4 O in 4 (*i*): with $x = \frac{2}{3}, y = \frac{1}{6}$.

At the moment these positions are being refined by computation using a least-squares method on intensity data obtained from X-ray diffractometer measurements on powdered samples.

The structure can be described in terms of vacancy ordering; that is, in every third plane parallel to the (110) plane of the original NaCl-type lattice, half the titanium and half the oxygen atoms are missing alternately (see Fig. 2). The spacing of these (110) planes is slightly larger than that of the other {110} planes. As a result, the symmetry of the original cubic structure is lowered to monoclinic. From previously published X-ray powder data[3,4] and the X-ray diffractometer data obtained in the present investigation, the lattice parameters of $TiO_{1\cdot00}$ have been calculated as follows:

$a = 5\cdot855 \pm 0\cdot003$ Å.
$b = 9\cdot340 \pm 0\cdot005$ Å, $\gamma = 107°\ 32' \pm 3'$.
$c = 4\cdot142 \pm 0\cdot002$ Å.

This proposed structure accounts adequately for all the X-ray powder lines reported previously[3,4].

The structural model described here corresponds to the stoichiometric composition TiO, but the observation that this structure is stable from $TiO_{0\cdot9}$ to $TiO_{1\cdot1}$ implies that a small excess or deficiency of titanium and oxygen vacancies can be tolerated. However, within the composition range $TiO_{0\cdot7}$ to $TiO_{0\cdot9}$ for non-equilibrium conditions of cooling there appears to be a transition structure formed which is different from the structure just described. The superlattice unit cell in the reciprocal lattice is orthorhombic (thick lines in Fig. 1*b*) and from the extinction rules the space group I222 (No. 23) was chosen for the structure. While the orthorhombic unit cell involves six titanium sites and six oxygen sites, it is considered that there are more oxygen vacancies than titanium vacancies in this structure since it has been observed only in the oxygen-deficient alloys. The structure can be described by the ordering of oxygen vacancies with random titanium vacancies such that all the oxygen atoms are missing from every third atomic plane parallel to the (110) plane of the original NaCl-type lattice. This structure model accounts adequately for all the observed superlattice spots obtained on the electron diffraction patterns.

In conclusion, it is to be noted that when the TiO alloys were quenched from above 1,500° C the electron diffraction patterns contained strangely shaped diffuse scattering effects, in addition to the fundamental spots due to the NaCl-type lattice. It seems that these effects are due to short range order in the arrangement of vacancies. Work on this aspect of the ordering reaction is being continued.

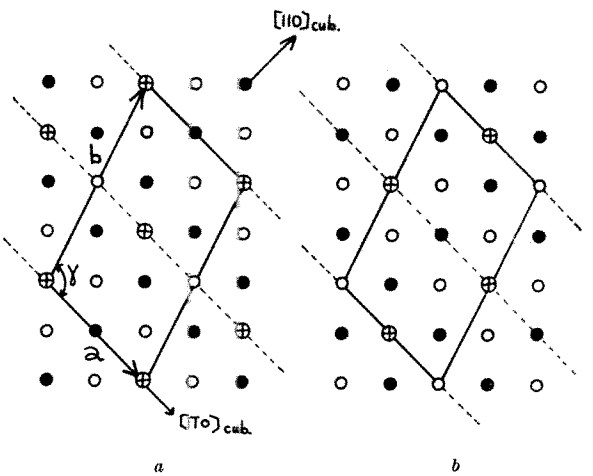

Fig. 2. Structure of ordered TiO. (*a*) Shows $z=0$ plane and (*b*) shows $z=0\cdot5$ plane. Thick lines represent unit cell and dotted lines the planes containing vacancies. ●, Titanium; ○, oxygen; ⊕, vacancy

Rapid X-ray Diffraction Studies using Image Intensification

A METHOD of quickly making observations by X-ray diffraction is needed for investigation of unstable phases and of structural rearrangements in crystals : it is also desirable in order to expedite the orienting of normal specimens for crystallography. The required direct observation and rapid recording have now been achieved by use of electronic intensification of the image of the diffraction pattern. It has proved possible to correct approximate settings of the crystal by inspection, and transient diffraction patterns have been observed. Exposure times for photographic recording range between 0·5 sec and 5 sec.

Image intensifiers[1] are supplied commercially for medical and industrial radiography. The pattern is visible through a lens which produces an image at infinity. These experiments were made with a unit having an input window 15 cm in diameter. As the protective cover was found to cut the intensity of copper $K\alpha$ radiation by a factor of 10^3, it was replaced by black paper. An 'intensification camera' was constructed incorporating the intensifier instead of a film-holder, a 35 mm camera which could be swung into position when required, provision for a 'vertical circle' for universal orientation of the specimen, and a normal collimator. Provision was made to record reflexions at higher angles, but front reflexions were more useful. Cross-wires placed across the window facilitated adjustment of the crystal. To reduce the exposure of the worker's hands to radiation the goniometer head should be operated through flexible leads or by keys attached to long rods. The device was calibrated by photographing the diffraction pattern from a standardized quartz powder.

The resolution of the intensifier is stated to be 30 lines/cm. This has been found adequate for most purposes. Though the sensitivity is poor for wave-lengths above about 1·5 Å, good Laue and characteristic patterns have been obtained with molybdenum radiation.

When polychromatic radiation is used an important zone axis can be recognized by the way the spots move when the crystal is rotated slightly. Whereas the analysis of conventionally recorded Laue patterns is limited because the wave-length causing each reflexion is not known, here various planes can be brought to the angle at which they diffract the characteristic ($K\alpha$) wave-length. This is recognized by the sudden increase in intensity and confirmed by introducing the β-filter. The low wave-lengths can be determined approximately by reducing the excitation potential on the generator until the reflexion disappears. Similarly, the diffraction pattern given by $K\alpha$ radiation can be quickly recorded in successive photographs with a stationary crystal. As with a diffractometer the diffraction angle is known from the photograph and the crystal orientation is read from a scale on the apparatus; but as in the photographic method several reflexions (for example in different layer lines) can be recorded simultaneously. In this situation the crystal can be set very precisely. In following the progress of a structure change it is an advantage that a representative diffraction pattern of both structures can be observed rather than only one peak as with a diffractometer, and transient effects due to stresses can be detected.

The method has facilitated several investigations. Phase I of rubidium nitrate exists between 284° C and the melting point 310° C. Conventional powder photographs showed it to have essentially the NaCl structure (a fact of interest in relation to melting), but experiments to confirm this by moving film methods remained incomplete because the crystal decomposed during the long exposure. The crystal has to be grown from the melt and does not necessarily appear single and in a convenient orientation. By using this technique it was possible to monitor the growth, remelting as required, and to take a series of photographs. By watching the diffraction pattern while changing the temperature it was seen that there is a progressive and completely reversible fading of some reflexions and change in the relative intensity of others. This indicates a gradual order–disorder change which explains a known specific-heat anomaly in this

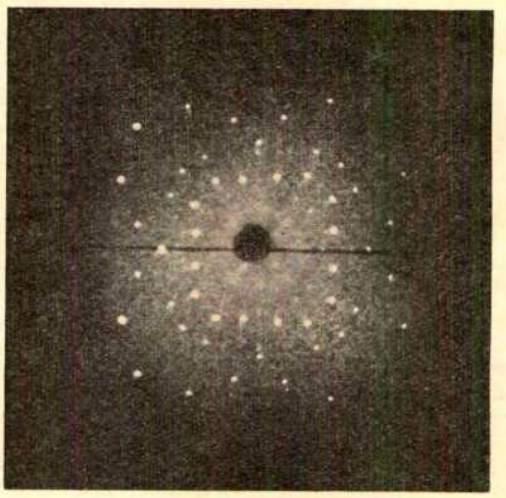

Fig. 1. Intensification photograph of Laue pattern from an ammonium iodide crystal, with [100] about 1° off the beam. Exposure 4 sec

phase. When on careful cooling the specimen changed to phase II, a strict orientation relation was maintained in a way which strongly suggested that the general arrangement of cations remained unaltered. This inference about the unknown structure of phase II goes far to rationalize the complex polymorphism of this compound.

Plastic deformation and relaxation are expected to be important in the kinetics and thermodynamics of some types of structure-change[2], but no information has been available on the rate at which stresses are released during and just after transformation. Direct viewing showed that ammonium iodide could be taken through the transformation cycle NaCl-type⇄CsCl-type at about −16° C with maintenance of an apparently definite orientation relation. While strain effects in the low-temperature form were great and the pattern poor, the pattern from the room-temperature structure appeared immediately on reversing the transformation, but annealing continued and reflexions became sharper over a period of 40 min. The rate of annealing on gentle heating, shown by reduction of asterism, was also followed and was initially rapid. By contrast, at the reconstructive transformations III→II at 219° C in rubidium nitrate and IV→III at 32° C in ammonium nitrate, when the diffraction pattern of the first phase disappeared it was replaced initially by the picture due to a very strained and disordered specimen. The pattern of the somewhat strained new structure then appeared gradually over a period of 1 min. Microscopy showed that the newly formed phase II of rubidium nitrate actually recrystallizes. One concludes that consideration of defects and free-energy differences in the treatment of phase growth[2] should include relatively large allowance for temporary disorder not recorded by conventional methods.

Image intensification[3] promises to provide an additional technique for crystallography of value particularly for study of reactions involving structural rearrangements, especially when combined with new techniques for precise measurement at the equilibrium temperature.

MINERALOGY

Substitutions for Phosphate Ions in Apatite

IN the course of recent investigations of the geology and mineralogy of the phosphate deposits of Christmas Island, Indian Ocean, numerous samples of apatite (optical varieties, collophane and dahllite) were analysed chemically. The purity of the samples was established by X-ray diffraction and differential thermal analysis. A typical analysis is shown in Table 1.

The ionic proportions for apatite were computed both on a basis of ten Ca^{+2} etc. ions and 26 (F, O, OH) ions per two formula units, namely, 2 $(Ca_5(PO_4)_3$ (F, OH)). It was assumed that the Ti^{+4}, Al^{+3}, Fe^{+3}, Na^{+1}, K^{+1} and Li^{+1} ions substitute for Ca^{+2} in the same manner as the divalent ions Mg^{+2}, Mn^{+2} and Zn^{+2}. These substitutions, with the exception of Ti^{+4}, have already been demonstrated[1]. The relative proportions of the sesquioxides in samples from all the phosphate deposits of Christmas Island are remarkably constant, the ratio of Al_2O_3/Fe_2O_3 being approximately 2·5. This ratio is also maintained in the crandallite and millisite-bearing overburden.

The sum of the F^{-1} and OH^{-1} ions was plotted against the number of carbon atoms on a basis of 26 (F, O, OH) ions as shown in Fig. 1. In addition to the twelve analyses of apatite from Christmas Island, the complete analyses of carbonate apatite recorded by Deer, Howie and Zussman[1], McConnell[2] and Palache, Berman and Frondel[3] are also included. Two, and possibly three, linear relations

Table 1. TYPICAL APATITE FROM CHRISTMAS ISLAND, INDIAN OCEAN

(Analysis by D. K. Rowley, the Australian Mineral Development Laboratories, Adelaide, South Australia.)

for carbonate and fluorine are indicated. The first accords with the substitution:

$$CO_3 \cdot F \rightleftarrows PO_4 \qquad (1)$$

This conforms with the formula of carbonate apatite proposed by Borneman–Starynkevich and Belov[4], $xCa_{10}P_6O_{24}F_2 + yCa_{10}P_5CO_{23}F_3$. The correspondence of values with this relationship is not close. McConnell[2] has indicated that there is no straightforward relationship between $(CO_3 \cdot OH)$ and PO_4 groups in francolite.

The gradients of the other two relationships in Fig. 1 are parallel and suggest substitutions of the type:

$$2(CO_3 \cdot F_{2 \cdot 5})^{-4 \cdot 5} \rightleftarrows 3(PO_4)^{-3} \qquad (2) \text{ and } (3)$$

Apatites represented by relationship (3) contain 3 (F, OH) ions in the non-carbonate end member. They also contain an average of three times more monovalent metal ions ($Na^{+1} + K^{+1} + Li^{+1}$) than those represented by relationship (2), and show a corresponding decrease in the divalent metal ions. It is likely that as well as substitution of fluorine, hydroxyl and carbonate ions for phosphate ions occurring, fluorine and/or hydroxyl can substitute for oxygen with the attendant replacement of sodium, etc., ions for calcium to balance the charge.

These results are in accordance with the theory advanced by McConnell[5], Simpson[6] and Winand[7] that the carbonate ions, together with fluorine or hydroxyl ions, substitute for PO_4^{-3} ions and do not conform with substitutions of carbonate for the $2F^{-1}$ ions in the apatite structure.

GEOLOGY

Detection and Location of a New Underwater Volcano

THE irregular appearance of an unusual component of the sea-noise spectrum in the waters to the east of the North Island first attracted attention in 1963. Measurements carried out over a period of several months showed that these signals invariably came from one direction, and led to the conclusion that the source was probably geophysical rather than biological in origin. Cross-bearing measurements ultimately pointed to the source lying some 160 miles east-north-east of Great Barrier Island.

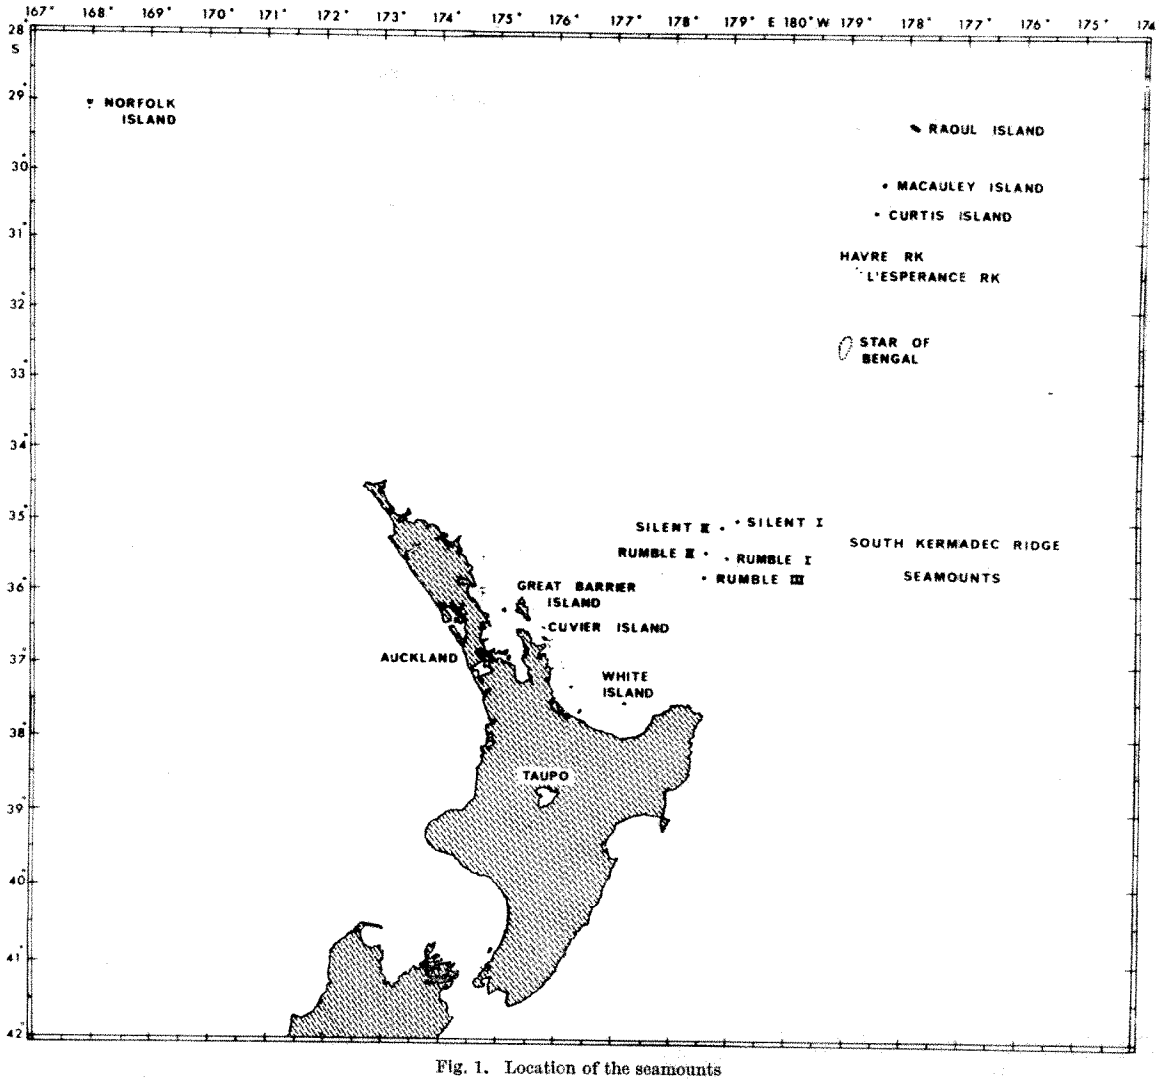

Fig. 1. Location of the seamounts

According to existing charts the sea bed in this area was quite featureless. However, subsequent bathymetric surveys have revealed, so far, six large topographical features rising up to 8,000 ft. from a surrounding sea floor at 1,500 fathoms. Because of the position of these peaks in relation to the Kermadec Ridge they have been called the South Kermadec Ridge Seamounts. The positions of the five most significant peaks are shown in Fig. 1.

Although limited towed nuclear precession magnetometer measurements have suggested that all the seamounts are of volcanic origin, extensive acoustic investigations have pointed finally to Seamount Rumble III, at 35° 42′ S., 178° 29′ E., being the source of the acoustic signals and the site of the present volcanism. The soundings available so far show Rumble III to be a seamount rising to produce a minimum sounding of 120 fathoms from an ocean depth of 1,500 fathoms. It is some 10 miles across at the 1,250-fathom contour, and slightly elongated in the north–south direction.

Only limited dredging has been carried out on the various seamounts, but by far the most significant sample, recovered from Rumble III, confirms the volcanic origin suggested by the magnetic measurements.

Although one series of acoustic measurements has been made close to the seamounts, most of the information relating to the acoustic signals has been obtained from recordings made with a hydrophone at a position close to Great Barrier Island. Several distinct forms of the acoustic signal have been identified, and these indicate that the volcano behaves in several characteristic ways.

By measuring the transmission loss between Great Barrier Island and Seamount Rumble III, it has been possible to establish fairly accurately the charge weight required to produce an equivalent signal level. For some of the strongest activity recorded so far the equivalent charge weight appears to be 10^6 lb. of TNT. Estimates of the total acoustic energy released during prolonged outbursts give values which are higher than those deduced for other volcanic activity[1]. It is felt that, as the transmission loss is accurately known in the present case, the acoustic energy output produced by underwater volcanoes may be much higher than previously estimated.

The occurrence of a region of volcanic activity in the position of the South Kermadec Ridge Seamounts is not surprising considering the geology of the region. Rumble III lies on the line of present volcanic activity passing through Taupo, White Island and Raoul Island. Although Rumble III has been active intermittently for several years, it was marked by a particularly intense outburst in November–December 1964, a period during which Raoul Island erupted violently[2].

The low-frequency rumbling heard in the present case is obviously similar to that reported by others[1,3,4]; but, as Rumble III displays various modes of activity, has been continuously monitored for several years, and its location is known, it has provided an excellent opportunity for studying the acoustic properties of underwater volcanic activity.

Colour Variations in Bituminous Coal with Thickness of Sections

The colour of bituminous coal has been variously attributed to large polynuclear condensed aromatics[1–3], free radicals[4–6], charge-transfer complexes[3,7] and free π-electrons[8]. The chemical-physical causes of colour remain matters of conjecture and will not be treated here; the optical aspects and simulation of colour in coal will be discussed. Thick sections of coal vitrain are black, or opaque in the visible region of the spectrum. For thin sections, however, the transmitted colour progressively changes from brown to red to yellow with decrease in thickness[9,10]. The yellow colour is characteristic of the thinnest sections that can be successfully made by the normal procedure. The recent success at this laboratory with the grinding of a thin section to form a wedge suggests that, at thicknesses represented by regions near the tip of the wedge, white light is transmitted; that is, the vitrain is clear and colourless[11]. Similar variations in colour with thickness are observed for carbonaceous derivatives such as some heavy oils, asphalts and pitches from coal and petroleum. This communication presents an explanation for these colour changes, and the production of identical colour-changes with thickness is demonstrated with pure compounds that are lightly coloured or colourless.

Published absorption spectra for bituminous coals[4,5,12,13] —usually as thin vitrain sections, Fig. 1*a* (ref. 12)—show that there are no absorption bands, but only general absorption throughout the visible region of the spectrum. This absorption, which is greatest at the short-wavelength limit of the visible region, constitutes the 'wing' of stronger general absorption in the ultra-violet region. Thus vitrain transmits more light at the red end of the spectrum than at the blue. If absorption bands were present in this region little or no colour change would occur with thickness.

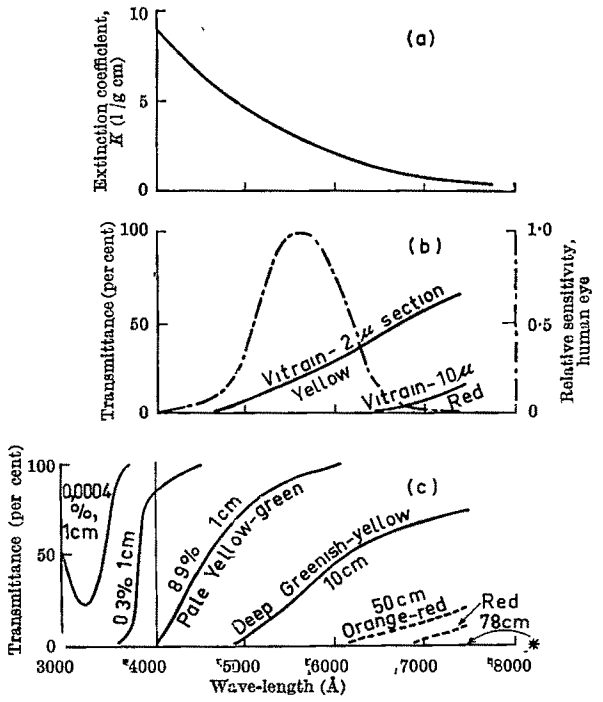

Fig. 1. *a*, Absorption spectrum of Pittsburgh vitrain (84 per cent carbon) determined with ground sections. *b*, Schematic curves for two bituminous vitrain sections, and response curve for the human eye. *c*, Curves for sodium salt of *p*-hydroxyacetophenone. ——, Transmittance curves, and colours for solutions - - —, Calculated curves, and colours observed through long cells. — · —, Response curve for human eye

* For a cell of 191 cm the calculated transmittance at 7500 Å is 0 2 per cent (dark brown to opaque).

The fact that absorption of vitrain thin sections at each wave-length in the visible region obeys Lambert's law of absorption (that is, the optical density is a linear function of the thickness) establishes that the observed colour-changes are of physical rather than chemical origin. In other words, these changes are not due to changes in the

chemical structure or to oxidation of the vitrain induced by grinding.

The observed colour of a substance is a function of the spectral response of the human eye and of the spectral distribution of the light transmitted, or reflected, by the substance[14,15]. The sensitivity of the eye is a maximum near 5550 Å, which is at the yellow end of the green, and it falls rapidly both to shorter and longer wave-lengths with cut-offs near 4000 and 7500 Å (Fig. 1*b*). Thus, for thin sections of vitrain the decreasing sensitivity of the eye towards the blue end of the visible region, below 5550 Å, is coupled with decreasing transmittance for vitrain (Fig. 1*b*); but decreasing sensitivity of the eye towards the red, beyond 5550 Å, is partly compensated by the increasing transmittance of vitrain. Therefore the eye receives greatest stimulus from the red end of the spectrum. To explain the variation with thickness from colourless through yellow and orange to red and brown the thin vitrain sections may be regarded as optical filters with broad shallow transmittance cut-offs at the short wave-length end of the spectrum. For very thin sections this cut-off becomes significant only at some wave-length below 4000 Å in the ultra-violet, and white light is transmitted with negligible attenuation; the section appears colourless. However, as the thickness increases, the absorption edge progressively passes through the visible, and the apparent colour changes from colourless to greenish-yellow to yellow to orange to red and then to brown. This effect is illustrated in Fig. 1*b* by schematic curves for vitrain sections; for 2μ and 10μ sections of a bituminous vitrain the predominant colours would be yellow and red respectively.

The foregoing explanation for the colour change in vitrains receives support from the fact that these changes can be simulated in a simple laboratory experiment using selected pure compounds. The sodium salt of *p*-hydroxyacetophenone, a colourless compound, was selected for this purpose on the basis that it possesses an absorption band with a maximum in the near ultra-violet at 3240 Å and a 'wing' that extends nearly into the visible region. The absorption spectra in the visible region of solutions of this sodium salt were measured with progressively higher concentrations and/or path lengths (for long cells, stainless steel tubes were used) (Fig. 1*c*); changes from colourless to opaque were noted. At the concentrations normally used to obtain accuracy in the measurement of the optical density at peak absorption the absorption in the visible region (Fig. 1*c*) was negligible and the solution was colourless. With increasing concentrations, absorption in the visible region became increasingly significant and progressed towards longer wave-length. In parallel, changes were observed from colourless to yellow-green, through yellow, orange, red and brown to opacity.

Similar colour changes through part of the visible region were observed for solutions of other compounds, both organic and inorganic, having 'wing' absorption in the visible spectrum. Compounds and the colours observed were as follows: 2-methylanthracene (colourless, green-yellow, yellow), picric acid (yellow, orange), sodium picrate and sodium dichromate (orange, red, brown, opacity). Because of low solubilities and steep absorption curves it was not practicable to produce colour changes to complete opacity in all cases.

Spectral absorption data and visual observations of colour must be reconciled. There is some variance in the published absorption spectra of thin vitrain sections. The data of Friedel[12], obtained for Pittsburgh vitrain (84 per cent carbon), using thin sections prepared by grinding, indicated that the transmittance at 6350 Å for a 10μ-thick section was 1·3 per cent (Fig. 1*a*). On the other hand, calculations based on the data for microtomed sections[13] of the same vitrain indicate that for a 10μ section at 6350 Å the transmittance would be only $1{\cdot}3 \times 10^{-11}$ per cent. The former value of 1·3 per cent is more compatible with the observed translucence of a 10μ section.

We thank Dr. G. H. Taylor for helpful discussions.

CHEMISTRY

Radiation-induced Synthesis of Ammonia from Nitrogen and Water

THIS communication reports on the synthesis of small amounts of ammonia by the irradiation of nitrogen and water either with ultra-violet light below 1800 Å or with gamma-rays.

Since the dissociation energy of nitrogen[1] (9·76 eV) is rather high, high-energy ultra-violet light is necessary to split the nitrogen molecules. Groth *et al.*[2] have shown that the krypton resonance lines (1165 and 1236 Å) which have a quantum energy of 10·03 and 10·64 eV are sufficient for photolysing nitrogen in the gas phase. A new source of ultra-violet light which may also be used for some photochemical processes has recently been developed by Okabe[3]. This lamp, filled with a mixture of 20 per cent nitrogen and 80 per cent argon (total pressure 1 mm of mercury), emits lines at 1495 Å (about 55 per cent) and 1745 Å (100 per cent), which originate from the excited nitrogen atoms. In this case the resonance lines of pure argon at 1048 and 1067 Å disappear.

In my photochemical experiments, a low-pressure mercury lamp filled with argon was used to excite the mercury vapour. Small quantities of nitrogen were present in the lamp. To obtain the lines at 1495 and 1745 Å, and in order to suppress the mercury lines at 2537 and 1849 Å, the lamp was operated at 0° C. Up to 50 per cent of light at 1745 Å is transmitted through quartz glass depending on its degree of purity. In my experiments the ultra-violet lamp was submerged in the solution in a specially designed apparatus. The solutions were prepared using three-times distilled water and reagent-grade chemicals. The cooled aqueous solution was kept saturated with nitrogen, during exposure to the ultra-violet light, by bubbling the gas through it. The irradiated solution was made alkaline and immediately distilled under nitrogen. The ammonia was collected in a vessel containing 0·01 M hydrochloric acid. Nessler's reagent was added to an aliquot and the ammonia was spectrophotometrically determined at 4100 Å (ref. 4). In order to prevent any back reaction of ammonia with hydroxyl radicals, methanol was added as a radical scavenger. Any aldehyde formed in this way was transformed back into methanol by reduction; thus it does not interfere with the

analysis. Thereafter the ammonia was distilled and determined. Blank determinations of unirradiated solutions were made using the same procedure.

Some typical results, representing the mean values of several experiments, are shown in Table 1. No ammonia could be detected after the irradiation of pure water saturated with nitrogen (see exp. 1), but small amounts of ammonia could be found in acidic media. The yield of ammonia was increased by adding ferrous ions. Our experiments showed: (1) that a maximum ammonia yield was reached after irradiation with ultra-violet light for 6 h (see exps. 3–5); (2) that the yield was lower when a 1 : 1 mixture of nitrogen and hydrogen was bubbled through the solution (see exps. 6 and 7); (3) that the yield was higher when methanol was added as a scavenger for the hydroxyl radicals (compare exps. 2 and 8).

Table 1. PHOTOCHEMICAL SYNTHESIS OF AMMONIA FROM NITROGEN GAS AND WATER AT 0° C

Exp. No.	Aqueous solution	pH	Duration of irradiation (h)	Ammonia yield (μmoles/l.)
1	Distilled water	6 7	6	Not detectable
2	10^{-3} M hydrochloric acid	2·9	5	14
3	5×10^{-3} M hydrochloric acid 10^{-2} M ferrous sulphate	2·5	4	16
4	10^{-3} M ferrous sulphate 5×10^{-3} M hydrochloric acid	2 5	6	25
5	10^{-2} M ferrous sulphate 5×10^{-3} M hydrochloric acid	2 5	12	12
6	5×10^{-3} M hydrochloric acid 10^{-3} M ferrous sulphate Nitrogen : hydrogen = 1 . 1	2 5	6	10
7	5×10^{-3} M hydrochloric acid 10^{-2} M ferrous sulphate Nitrogen . hydrogen = 1 1	2·5	6	12
8	5×10^{-3} M hydrochloric acid 10^{-3} M methanol	2·5	5	18

For the formation of ammonia using gamma-rays, a cobalt-60 source (14,000 c.; dose rate, $5{\cdot}5\times10^{19}$ eV/ml./h) was used. The preparation of the solutions and the analysis were carried out as described earlier. Some results are shown in Table 2. Here, too, the yield of ammonia was increased to a G-value of 0·24 by the use of methanol as a scavenger for the hydroxyl radicals.

Table 2. FORMATION OF AMMONIA INDUCED BY γ-RAYS FROM NITROGEN GAS AND WATER AT pH 2·5 AND ABOUT 25° C

Exp. No.	Aqueous solution	Dose (eV/ml.)	Ammonia yield (μmoles/l.)	G-value
1	5×10^{-3} M hydrochloric acid	$4\,1\times10^{19}$	14	0·02
2	5×10^{-3} M hydrochloric acid	$5{\cdot}5\times10^{19}$	6	0 01
3	5×10^{-3} M hydrochloric acid 10^{-3} M methanol	$0\,9\times10^{19}$	36	0·24
4	5×10^{-3} M hydrochloric acid 10^{-3} M methanol	$2{\cdot}8\times10^{19}$	22	0·05

It should be mentioned that some years ago ammonia was synthesized with a G-value of 0·67 by exposing a mixture of gaseous nitrogen and hydrogen to ionizing radiation[5,6]. However, these experiments were apparently not continued. (*Note added in proof.* It was brought to my attention that by irradiating water under a nitrogen pressure of 150 atmospheres, ammonia was formed with $G = 0{\cdot}76$ (Dimitriev, M. T., and Pshezhetskii, S. Ya., *Atomnaya Energiya*, 8, 59; 1960)).

The mechanism of the reaction involved in these syntheses of ammonia in aqueous solutions has not yet been clarified, but some tentative conclusions can be drawn from the results obtained.

When water is photolysed by ultra-violet light at 1849 Å, hydrogen and hydroxyl radicals are produced (quantum yield, $\Phi = 0{\cdot}6$) (ref. 7):

$$H_2O \rightsquigarrow H_2O^* \rightarrow H + OH \qquad (1)$$

This line (1849 Å) supplies an energy of only 6·7 eV and is essentially not absorbed by the nitrogen. The line at 1745 Å (7·1 eV) and at 1495 Å (8·2 eV) cannot excite the nitrogen molecules sufficiently, since there is no continuous absorption by nitrogen in the region from 1050 to 1600 Å with k-value greater than 0·01 cm^{-1} (ref. 12). However, ammonia could then be formed in the presence of hydrogen atoms and excited water molecules. It has been established that ferrous ions[8–10] as well as chloride ions[11] can take part in the formation of solvated electrons (e-aq), on exposure to ultra-violet light. My experimental results indicate that these solvated electrons may also take part in the formation of ammonia.

The mechanism of synthesis of ammonia under the influence of gamma-rays from cobalt-60 seems to be due both to the hydrogen atoms and the solvated electrons which are formed by the radiolysis of the water.

I have only obtained small yields of ammonia, but this is of considerable interest, especially in explaining the formation of organic substances under possible primitive earth conditions. My investigations are still in progress and a complete report will be given elsewhere.

I thank Prof. B. Karlik for her interest in this work, Dr. G. B. Cook for the use of the cobalt-60 source and Mr. A. Fritsch for technical assistance. Part of this work was carried out in the Institute of Chemistry at the Siebersdorf Reactorcentre.

This work was supported by the Bundeskanzleramt-Verstaatlichte Unternehmungen (Sektion IV) of the Federal Republic of Austria.

Hydration in Liquid and Solid Cation Exchangers

THE extraction of water and acids by the liquid cation exchanger dinonylnaphthalene sulphonic acid (HDNNS) dissolved in heptane has recently been investigated for two different concentrations of HDNNS and over a large range of concentrations for nitric, hydrochloric, perchloric and sulphuric acids[1]. The experiments have been performing by shaking samples of HDNNS dissolved in heptane with various water–acid mixtures. After centrifugation and separation of the two phases, both were analysed for acid by titration with alkali and the organic phase analysed for water, using the modification of the Karl Fischer method due to Axel Johansson[2,3].

In Fig. 1 the number of water molecules per sulphonic acid group (Z_{H_2O}) is plotted against $-\log\{H_2O\}$, where $\{H_2O\}$ is the activity of water in the aqueous phase for nitric (□), hydrochloric (■), perchloric (●) and sulphuric (○) acids and 5 per cent (by volume) of HDNNS in heptane. Correction has been made for the small amount of water extracted by the diluent itself and for the co-extraction of some water with nitric acid. From Fig. 1 it is clear that Z_{H_2O} reaches quite large numbers when approaching pure water and slowly tends towards zero with decreasing water activity. It is also clear from Fig. 1 that Z_{H_2O} is a unique function of $\{H_2O\}$ independent of the nature of the strong acid used.

In order to determine the composition of the possible species present, we start to consider the addition of the first water molecule. Application of the equilibrium law to the reaction:

$$HDNNS(org) + H_2O(aq) \rightleftarrows HDNNS{\cdot}H_2O(org) \quad (1)$$

gives, assuming that the organic phase behaves ideally,

$$[HDNNS{\cdot}H_2O] = K_1\,[HDNNS]\,\{H_2O\} \quad (2)$$

where square brackets denote concentration. According to the definition

$$Z_{H_2O} = [HDNNS{\cdot}H_2O]/([HDNNS] + [HDNNS{\cdot}H_2O]) \quad (3)$$

From (2) and (3) we get

$$Z_{H_2O}/(1 - Z_{H_2O}) = K_1\,\{H_2O\} \quad (4)$$

In Fig. 2, $Z_{H_2O}/(1 - Z_{H_2O})$ is plotted against $\{H_2O\}$ for 5 per cent HDNNS in heptane and sulphuric acid–water, the system in which the lowest water activities were obtained. In agreement with (4) a straight line through the origin can be fitted to the data. From the slope of the line we find

$$K_1 = 21 \pm 1 \text{ (dimensionless)} \quad (5)$$

Further analysis along the same lines indicates the possibility of the species $HDNNS(H_2O)_3$, $HDNNS(H_2O)_8$ and a remainder, which can be formally described as $HDNNS(H_2O)_{20}$ in addition to $HDNNS{\cdot}H_2O$.

This sort of treatment is also applicable to the sorption of water by ion exchangers. In Fig 3, Z_{H_2O} is plotted against $-\log\{H_2O\}$ for the sorption of water by sulphonic acid resins in the silver form. The upper curve (○) refers to a 0·5 per cent DVB resin investigated at 0° C by Glueckauf and Kitt[4], while the lower curve (●) refers to a 10 per cent DVB resin studied at 25° C by Gregor *et al.*[5]. From Fig. 3 it is seen that two parallel curves are obtained of a shape very similar to that found for the liquid ion exchanger (of Fig. 1). Finally, in Fig. 4, $Z_{H_2O}/(1-Z_{H_2O})$ is plotted against $\{H_2O\}$ for the lowest water activities investigated by Glueckauf and Kitt. Here also reaction (1) with the equilibrium law formulated according to (4) applies to the data. Further analysis along these lines seems to indicate that both investigations can be described by $AgR(H_2O)_3$ and a remainder $AgR(H_2O)_{10}$ besides $AgR{\cdot}H_2O$, with different constants for the two temperatures.

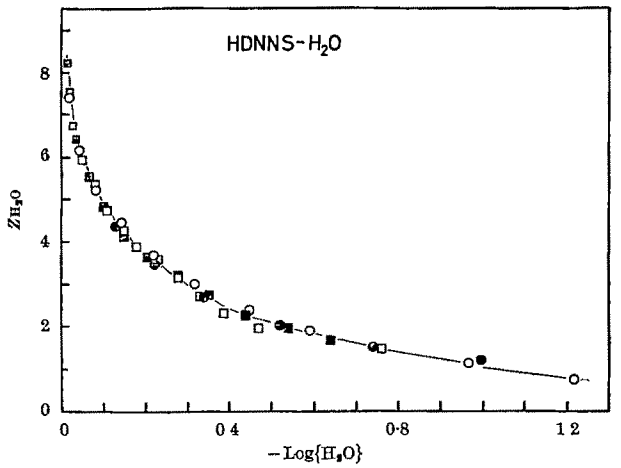

Fig 1. Z_{H_2O} plotted against $-\log\{H_2O\}$ for 5 per cent HDNNS in heptane and the following acid–water systems: □, nitric acid–water; ■, hydrochloric acid–water, ●, perchloric acid–water, ○, sulphuric acid–water

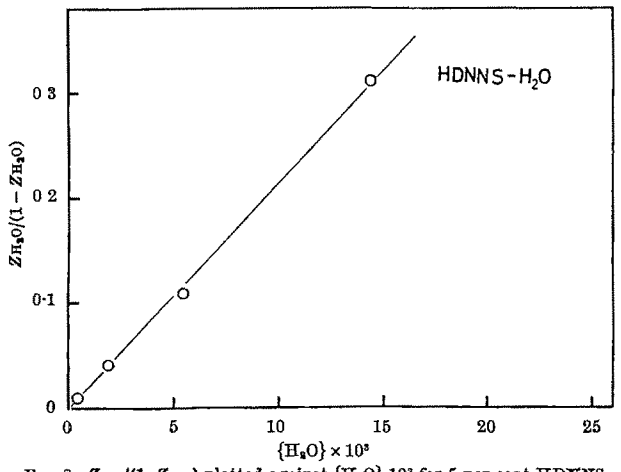

Fig. 2. $Z_{H_2O}/(1-Z_{H_2O})$ plotted against $\{H_2O\}\cdot10^3$ for 5 per cent HDNNS in heptane and sulphuric acid–water

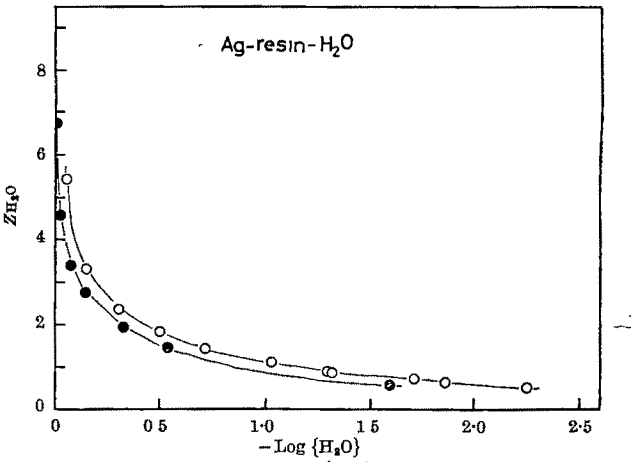

Fig 3 Z_{H_2O} plotted against $-\log\{H_2O\}$ for the systems: ○ AgR (0 5 per cent DVB)–water, $t = 0°$ C (ref 4); ●, AgR (10 per cent DVB)–water, $t = 25°$ C (ref. 5)

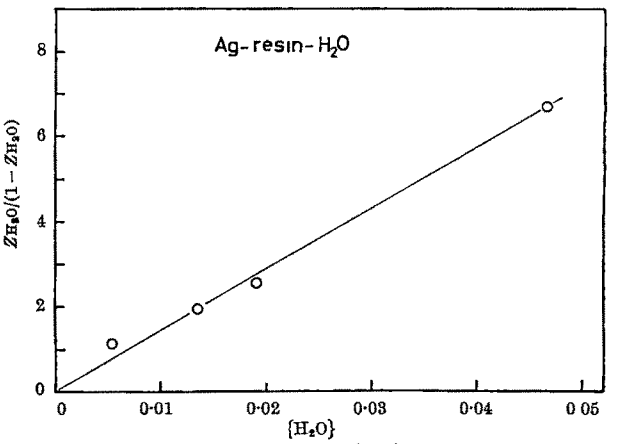

Fig. 4. $Z_{H_2O}/(1-Z_{H_2O})$ plotted against $\{H_2O\}$ for the system AgR (0 5 per cent DVB)–water, $t = 0°$ C

The system presented here offers at low water activities an alternative and simpler description than that given by Glueckauf[4], who suggests that the first water molecule goes to the sulphonic acid group and causes complete dissociation, while all the others go to the cation. Until experimental evidence is obtained in favour of one or the other system, the simpler one is to be preferred. At high water concentrations, dissociation has to be taken into account.

I thank Dr. R. Gardner King, Norwalk, Connecticut, for samples of DNNS used, the Swedish Natural Research Council for supporting the experimental work, and the Ford Foundation for making possible the visit to the Middle East Technical University.

Yields and Rate Constants of the Precursors of Hydrogen in the Radiolysis of *n*-Propanol

PRESENT-DAY interest in the radiolysis of aliphatic alcohols has been centred on the identification of the precursors of hydrogen. In the case of methanol and ethanol, investigations of pulse radiolysis[1,2] have led to the identification of the solvated electron in agreement with kinetic–mechanistic deductions[3–5]. Furthermore, scavenger studies[3–5] have shown the existence of a second reactive precursor, identified as the hydrogen atom.

It is our purpose to extend these results to higher alcohols in an attempt to correlate differences in precursor yields with the polarity of the medium. In the first of these studies we have investigated the formation of hydrogen in irradiated *n*-propanol in the presence of scavenger.

Propanol was purified by refluxing over 2,4-dinitrophenyl-hydrazine for 24 h to remove aldehydes and ketones followed by fractional distillation. Solutions of acetone (Merck, *pro analysi*) in this material were then degassed by repeated pumping and shaking and transferred to 10 ml. 'Pyrex' ampoules. These ampoules were irradiated for periods varying between 2 and 12 min after which the hydrogen formed was extracted in a modified Van Slyke gas pipette, injected into the carrier gas stream of a gas chromatograph and determined by conventional methods. The acetone concentration of the solutions after degassing was also determined by gas chromatography.

Irradiations were carried out in a nominal 400-c. cobalt-60 source giving a dose rate of $1{\cdot}1 \times 10^{17}$ eV/ml./min as determined by a Fricke dosimeter, taking $G(Fe^{3+})$ as 15·6 ions per 100 eV. The dose rate in propanol was found by correcting this value for the difference in electron density between the alcohol and the dosimeter solution.

Dose-yield curves for pure deaerated propanol were linear over the region investigated, and from the slope $G(H_2)$ was determined as 4·2 molecules/100 eV. In the presence of acetone the characteristic dependence of $G(H_2)$ on scavenger concentration found in the case of ethanol[4,5] was observed as is shown in Fig. 1.

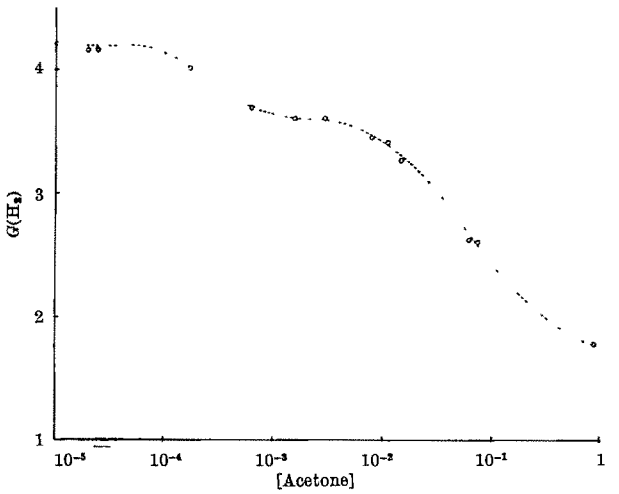

Fig. 1. $G(H_2)$ as a function of added [acetone]

As for ethanol, the initial decrease in $G(H_2)$ is attributed to electron scavenging by acetone. Thus the difference between the initial value, $G(H_2)_0$, and the plateau, $G(H_2)_p$, is equal to $G_{e^-solv.}$: the values determined from Fig. 1 are:

$$G(H_2)_0 = 4{\cdot}2 \text{ and } G(H_2)_p = 3{\cdot}6$$

thus $G_{e^-solv.} = 0{\cdot}6$ molecules/100 eV.

From the foregoing data it is also possible to estimate the rate constant of the reaction of the electron with acetone relative to reaction with propanol. This ratio was found to be:

$$\frac{k(e^- + (CH_3)_2CO)}{k(e^- + C_3H_7OH)} = \frac{k_1}{k_2} = 7 \times 10^4$$

Using the recently determined[6] absolute rate constant of the electron with acetone of $5{\cdot}9 \times 10^1$ l.mole^{-1} sec^{-1} we find:

$$k\,(e^- + C_3H_7OH) = 8{\cdot}5 \times 10^4 \text{ l.mole}^{-1} \text{ sec}^{-1}.$$

This estimation is based on the assumption that the rate constant k_1 is the same in propanol as in water. This is justified by the fact that a recent determination[7] of k_1 in ethanol is in good agreement with k_1 in water; similar observations[1,2] have been made in pulse radiolysis investigations of reactions in water, methanol and ethanol.

The further decrease in $G(H_2)$ can likewise be ascribed to competition between acetone and propanol for hydrogen atoms:

$$H + C_3H_7OH \xrightarrow{k_3} H_2$$

$$H + (CH_3)_2CO \xrightarrow{k_4} \text{products other than } H_2$$

Application of simple competition kinetics leads to the expression:

$$\frac{1}{\Delta G(H_2)} = \frac{1}{G(H_2)_p - G(H_2)} = \frac{1}{G_H} + \frac{k_3[C_3H_7OH]}{k_4[(CH_3)_2CO]G_H} \quad (1)$$

Thus a plot of $\frac{1}{\Delta G(H_2)}$ against $\frac{[C_3H_7OH]}{[(CH_3)_2CO]}$ should be linear with the intercept equal to $\frac{1}{G_H}$. From the slope $\frac{k_3}{k_4}$ may also be estimated. This was applied to the experimental data and the results obtained are shown in Fig. 2.

From Fig. 2 we find $G_H = 1{\cdot}90$ molecules/100 eV and $\frac{k_3}{k_4} = 6{\cdot}63 \times 10^{-3}$.

The remaining non-scavengeable or molecular yield can now be determined as:

$$G^M_{H_2} = G(H_2)_0 - (G_H + G_{e^-solv.})$$
$$= 1{\cdot}7 \text{ molecules/100 eV.}$$

The radical and molecular yields are summarized in Table 1; included are the corresponding yields from methanol and ethanol.

Table 1

Alcohol	$G(H_2)$	G_{e^-solv}	G_H	$G^M_{H_2}$
	Yield in molecules/100 eV			
Methanol (ref. 3)	5·4	1·4	2·4	1·6
Ethanol (ref. 4)	4·8	0·9	2·3	1·65
Propanol	4·2	0·6	1·9	1·70

Two interesting observations may be made from a comparison of these yields with those from methanol and ethanol. First, a systematic decrease in $G(H_2)$ from methanol to propanol, suggesting greater de-activation of excited states in the case of the larger molecules. Secondly, a decrease in the yield of solvated electrons is seen as

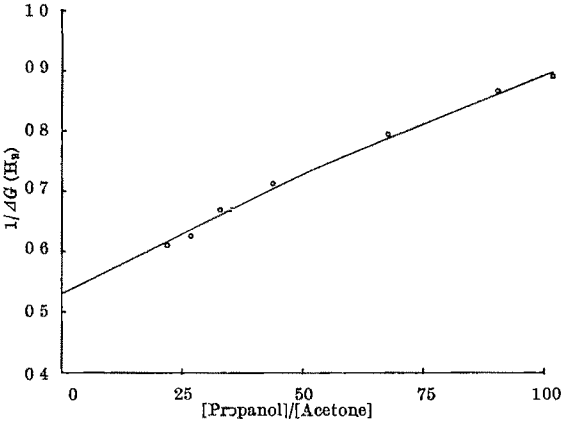

Fig. 2. Plot of equation 1 for hydrogen yields from propanol containing acetone

might be expected from the decreasing polarity of the solvents.

In view of the lack of information on the other products of the radiolysis a discussion of possible reaction mechanisms is not considered appropriate at the present time. A more detailed study of the system is at present being made, the results of which will be communicated at a later date.

Unusual Co-ordination of α-Phenylbutylamine with Nickel Thiocyanate as a Result of Clathration

NUMEROUS α-arylalkylamines co-ordinate with nickel (II) thiocyanate to form complexes of the type $[Ni(NCS)_2(amine)_n]$, where n is 2 or 4 (ref. 1). The complexes for which n is 2 are light green and are insoluble in most solvents. These properties and their infra-red spectra[2] suggest that they have a polymeric octahedral structure with nickel atoms bridged through the thiocyanato groups. The complexes for which n is 4 are blue and are readily soluble in many solvents, such as methanol or chloroform. However, they are not soluble in water, in which they undergo hydrolysis with formation of nickel hydroxide. Our X-ray diffraction investigations[3], which are still in progress, have shown that these complexes are trans-octahedral with the thiocyanato groups linked through their nitrogen atom.

When nickel thiocyanate is allowed to react with an excess of some α-arylalkylamines, a new complex is obtained in which the nickel atom is apparently co-ordinated with five molecules of amine. The same compound may also be obtained by recrystallization of the tetramine complex in a methanol solution of the amine. With α-phenylbutylamine, a complex of the following composition was thus obtained: nickel, 6·4; thiocyanate, 12·6; α-phenylbutylamine, 80·9 weight per cent. Calculated for $Ni(NCS)_2(amine)_5$: nickel, 6·4; thiocyanate, 12·6; α-phenylbutylamine, 81·0.

Considering the aforementioned composition, this compound may be taken as five-, six- or seven-co-ordinate, according to the following formulations: $[Ni(Am)_5](NCS)_2$, $[Ni(NCS)(Am)_5](NCS)$ and $[Ni(NCS)_2(Am)_5]$. The first two structures can be rejected for several reasons. On one hand, the solubilities of the complex do not account for ionic character. On the other hand, the N—C stretching frequency of the thiocyanate group appears to be the same in the infra-red spectra of both the pentamine and the tetramine complex (2,096 cm^{-1}). It is known that the stretching frequency of the N—C bond is different for ionic and co-ordinated thiocyanate[4]. However, the seven-co-ordinate formula is also improbable as the spatial configuration of the molecule of α-phenylbutylamine should preclude such an arrangement.

Numerous complexes of the type $[Ni(NCS)_2(\alpha\text{-arylalkylamine})_4]$ are able to form clathrates with many aromatic compounds[5]. Those formed by the complex of α-phenylbutylamine are particularly stable and contain exactly one molecule of 'guest' per molecule of complex so that they may be considered as true stoichiometric compounds[6]. However, the association between both components does not involve covalent bonding but more probably charge-transfer interactions through the aromatic nuclei of both the guest and the amine co-ordinated to nickel[7]. In view of the aromatic character of α-phenylbutylamine, it is plausible that it should be clathrated as well as other aromatic compounds of similar shape. This interpretation is strongly supported by X-ray diffraction data. Fig. 1 shows the powder diagrams of (I) the tetramine complex, (II) the pentamine complex, and (III) the clathrate formed by the former with *sec*-butylbenzene. The three diagrams each have many diffraction maxima in common, but the similarity between (II) and (III) is particularly marked and shows that the pentamine complex is clearly a clathrate formed by the octahedral tetramine complex with one additional molecule of amine.

Previous investigations have shown the crystal structure of the clathrates formed by the complex $[Ni(NCS)_2(\alpha\text{-phenylbutylamine})_4]$ to be largely governed by the shape of the enclosed molecules. Thus, for example, the clathrates of *p*-xylene and *p*-dichlorobenzene have a similar structure which differs markedly from that of the original complex[6]. This conclusion is supported by the preceding data but, apparently, the clathration of *sec*-butylbenzene or of α-phenylbutylamine itself does not involve such a radical change in crystalline structure. Moreover, the tetramine complex of α-phenylbutylamine may be obtained as two distinct forms characterized by slightly different diffraction patterns, one of which is diagram (I) of the figure, whereas the second is quite similar to diagram (II). Similarly, the infra-red spectra of both forms are different but the spectrum of the second form is practically identical with that of the pseudo-pentamine complex. Obviously, one form of the tetramine complex has a structure which is not significantly modified

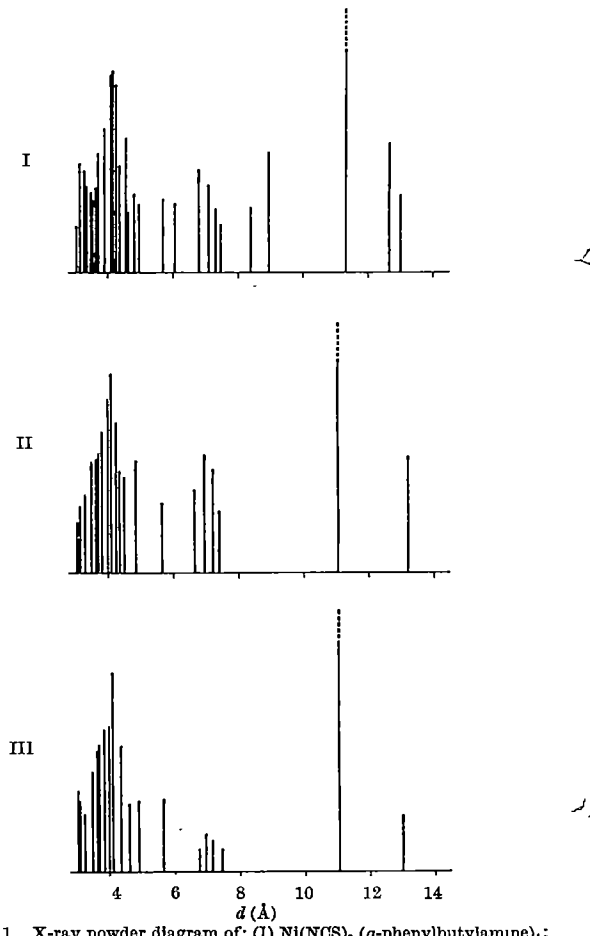

Fig. 1. X-ray powder diagram of: (I) $Ni(NCS)_2(\alpha\text{-phenylbutylamine})_4$; (II) $Ni(NCS)_2(\alpha\text{-phenylbutylamine})_5$; (III) clathrate formed by (I) with *sec*-butylbenzene

by the clathration of a fifth molecule of amine. In this case, clathration appears to be merely the result of filling spaces present in the crystal lattice of the complex.

The preparation of other co-ordination complexes in which nickel (II) is apparently seven-co-ordinate was recently reported[8]. These complexes belong to the type $[NiX_2(\text{methylpyrazine})_5]$, where X is a halogen atom or thiocyanate. Taking into account that complexes of methylpyridines with nickel (II) thiocyanate readily form clathrates with a great variety of aromatic compounds[9], there is little doubt that the abnormal stoichiometry of these methylpyrazine complexes has also to be explained by clathration.

This work was partly supported by the Institut Belge pour l'Encouragement de la Recherche Scientifique dans l'Industrie et l'Agriculture. We thank Prof. J. J. Fripiat, University of Louvain, and Dr. G. De Clippeleir of this laboratory for the X-ray diffraction.

The Fujiwara Reaction : Some Observations on the Mechanism

WHEN certain 1 : 1 : 1-trichloro-compounds are heated in the presence of pyridine and aqueous caustic alkali, a red colour is imparted to the pyridine layer[1,2]. The reaction is extremely sensitive. The nature of the red material has not been fully elucidated, but the following mechanism has been proposed[3]:

The reaction is used extensively in both toxicological screening[4] and for quantitative work[5–9], and because of this it is surprising to find that little work has been undertaken to elucidate the mechanism.

In this investigation the reaction was conducted by heating for 1 min in a boiling water bath a test-tube containing about 3 ml. aqueous caustic and 3 ml. pyridine, and (if colourless) adding the substance under test. Heating was continued for several minutes, and a positive reaction indicated by a red colour in the pyridine layer.

As a result of the following experiments, we concluded that the red reaction product from all 1 : 1 : 1-trichloro compounds tested (that is, chlorbutol, chloral hydrate, trichloroacetic acid, and chloroform) was identical and independent of the starting material: (1) The pyridine absorbed at 365 and 530 mμ in all cases. (2) The red pyridine, chromatographed by thin-layer chromatography (Merck 'Kieselgel *GF* 254'—solvent ethyl acetate, saturated with water), yielded red spots, after it had been sprayed with aqueous caustic of identical R_F (0·54). (3) In all cases the ethanol eluate of the red spots absorbed at 314 and 410 mμ, which shifted after adding aqueous caustic to 362 and 525 mμ and was reversed by the addition of concentrated hydrochloric acid. Spontaneous decomposition of the material absorbing at 410/525 mμ slowly occurred, leaving the 314/362 mμ material, which persisted.

It appeared likely that chloroform (or dichlorocarbene) was implicated, since hot caustic treatment of chloral hydrate and trichloroacetic acid is known to yield chloroform under these conditions[10] as does chlorbutol, which we have shown to produce acetone (2 : 4-dinitrophenyl hydrazone derivative, m.p. 122°–124° C, mixed m.p. 123°–124° C). By contrast, trichloroethanol does not produce chloroform or formaldehyde (except in trace amounts) but yields mainly glycollic acid (benzoyl derivative; m.p. 118°–121° C, mixed m.p. 118°–121° C) and this does not produce a red colour in the Fujiwara reaction.

Trichloroethylene ($CCl_2=CHCl$) also reacts to give a red colour with different spectrophotometric properties from the 1 : 1 : 1-trichloro derivative, with a different R_F value (0·75), and does not therefore conflict with this theory.

We found that a reaction would also occur in ice-cold conditions, and absorption curves in these cases varied according to the reactant. These are summarized in Table 1. Peaks in cold solution slowly drifted on warming or prolonged standing in most cases.

We propose on the basis of our findings the following mechanism for the Fujiwara reaction. The compound I absorbing at 390–400 mμ is formed initially by the attachment of the trichloro compound to the pyridine ring. This is the 'cold reactor' and has spectrophotometric properties and stability which differ according to the reactants. We are unable to demonstrate this complex under the normal 'hot' conditions except, transitorily, in the case of chlorbutol, and indeed it is possible that under hot conditions it does not form in all cases. It is possible that chloral hydrate and trichloroacetic acid do not directly couple but decompose to chloroform first, which then couples. Such a complex would never reach a measurable level with trichloroacetic acid since the reaction proceeds too slowly. All these 'closed ring' complexes are clearly unstable, and have not been reported hitherto. Ring breakage occurs giving compound II, which absorbs at 530 mμ. Feigl[3] has implied that these open chain compounds differ according to the starting material, but our experiments do not indicate this in the case of the 1 : 1 : 1-trichloro red reactors, since they are indistinguishable one from another. Further heating causes decomposition to glutaconic aldehyde (III). This absorbs at 365 mμ, an observation in agreement with Schwarzenbach *et al.*[11].

As further evidence of this theory, the eluted red spots exhibit a property consistent with a keto-enol structure, in that absorption bands vary with changes in *p*H. We suggest that the 410/525 mμ material is II and the 314/362 mμ material is I–II, both of which co-exist in the normal Fujiwara reaction. We have shown that prolonged standing or heating causes the disappearance of II, which is changed to III. This has been demonstrated both in the alcohol eluate and in the pyridine.

Table 1

Reactant	Absorption peaks under cold conditions (mμ)	Absorption peaks under normal hot conditions (mμ)
Chloroform	365 400 530	365 530
Chloral hydrate	400 530	365 530
Trichloroacetic acid	365 530	365 530
Chlorbutol	390	365 530
Trichloroethylene	365 530→540	365 540
Trichloroethanol	390	365 430

The strikingly different properties of the trichloroethanol reaction lead us to suggest that the whole molecule remains attached after ring breakage: first, because we were unable to obtain chloroform on heating trichloroethanol with aqueous potassium hydroxide; secondly, by analogy with the chlorbutol complex I, which we have shown to be relatively stable.

It is apparent that the reaction as normally conducted leads to a mixture of II and III, and that prolonged heating or standing converts II to III. Friedman and Cooper[8] use the peak at 365 mμ for quantitative measurements, as they find it more stable than the 530 mμ peak, which agrees with our observations. Furthermore, we find a decrease in optical density at 530 mμ produces a relatively small increase at 365 mμ, a fact previously observed[12]. It seems possible, therefore, that optimum conditions for quantitative work are more likely if the reaction is carried to completion, and all measurements of optical density are made on the glutaconic aldehyde. Whatever method is used, however, it is clearly vital in quantitative work to standardize conditions and time of heating, and length of delay before reading.

Although we did not pursue in detail the reaction with trichloroethylene, we did observe a somewhat similar phenomenon under ice-cold conditions, which is shown in Table 1.

The 'cold' reaction, although capable of distinguishing reacting compounds, has little micro-analytical value since 50–100 mg are necessary to demonstrate the phenomenon.

We thank Mrs. Marian Horner and Mrs. Aileen Burford-Mason for technical assistance. The work was financed by the Horserace Betting Levy Board, to whom we are grateful.

Some Observations on Ions of Low Mass Number in Hydrocarbon Flames

An A.E.I. *MS2* mass spectrometer has been modified to sample ions from flames burning at atmospheric pressure. The spectrometer is of the 90° sector magnet type. The flame ions after traversing the magnetic field are collected on an electrode plate subsequent to passing through a twelve-stage Allen type electron multiplier. The system enables ion currents at the collector as small as 10^{-15} amp. to be measured.

In essence, the system bears close resemblance to that used by Knewstubb and Sugden[1] and Green and Sugden[2]. The burner used consists of a 6 in. length of capillary 'Pyrex' or silica tube of about 1 mm bore. The flame produced by this system is a fast burning pre-mixed flame of the Bunsen type. The ions are introduced into the mass spectrometer through a small orifice, 0·001–0·002 in. diameter, pierced in 0·002 in. thick platinum foil mounted in a massive water-cooled brass plate. The ions entering the apparatus are focused through a series of differentially pumped chambers, each at a successively reduced pressure, by a system of electrostatic lenses (Fig. 1).

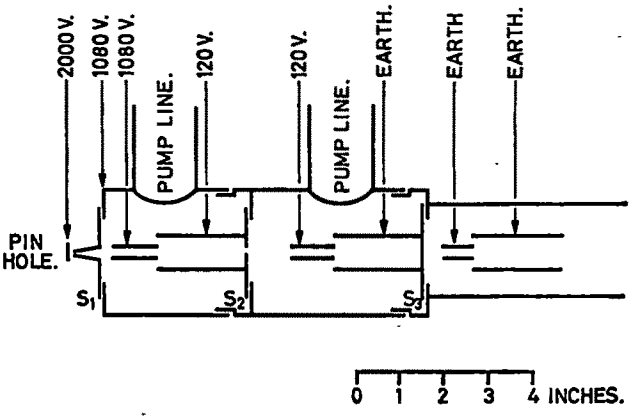

Fig. 1. Schematic diagram of ion collimating systems

The ion collimating system used in this work differs from that used by Knewstubb and Sugden in that the ions enter the pinhole at a potential of 2,000 V and are focused by a series of reducing potentials, finally arriving at the analyser tube at earth potential. Also with this system the ions arrive more quickly in the low-pressure region of the spectrometer, effecting a rapid quenching effect on the ions and reducing the chance of collisions in the ion beam.

Ion spectra can be scanned, either manually, or automatically in conjunction with a chart recorder system, by varying the magnetic field.

A hydrogen/air flame was chosen as the basic flame for the experimental work, small amounts of hydrocarbon additive being added either from a direct supply of commercially bottled gas or in the case of liquid additives by the use of a concentric jet atomizer. A wide range of hydrocarbon additives have been studied including methane, ethylene, acetylene, benzene, kerosene and petroleum.

A direct study of the flame by Schlieren photography has revealed that the flames are quite laminar within the sampling zone, which was between the reaction zone and about 1 in. downstream. The Schlieren work has also clearly shown the presence of the boundary layer on the sampling surface reported by Green and Sugden[2], and has given some indication of its size.

Several interesting features have been observed which have not been reported previously[1–4]. Experiments have shown the presence of H^+, H_2^+ and H_3^+ ions in hydrogen/air/hydrocarbon flames. The identity of these ions has been confirmed using deuterium in place of hydrogen. The H_2^+ and H_3^+ ions are present in about equal concentrations, producing ion currents of around 10^{-15} amp. These ions reach a maximum concentration in the reaction zone and persist downstream into the burnt gas region.

Results show that the concentration of the H_2^+ ion relative to the total ionization was dependent to a considerable extent on the size of the input orifice in the platinum foil. However, the concentration of the H_3^+ ion was not so dependent suggesting that this is a 'true' flame ion and that the H_2^+ ion is most probably formed within the sampling system.

The proton is present to the extent of 1/500th of the concentration of the most abundant ion, H_3O^+, the latter producing an ion current on the collector plate of about 10^{-11} amp. The *MS2* in standard form is capable of detecting ions at mass 2, but not at mass 1. Thus in order to establish whether or not an ion of mass 1 existed in the flame, the spectrometer had to be modified. For this purpose there are two alternatives—namely, reducing the current to the magnet coil or increasing the accelerating voltage. In our case the former modification was the

simpler. Unfortunately, the instability of the magnetic field at low magnet coil currents prevented an accurate profile of the H^+ ion along the flame from being obtained.

However, using deuterium instead of hydrogen it was possible to obtain an axial profile of the D^+ ion in a deuterium/air/acetylene flame. This is shown in Fig. 2, which also shows a similar profile for the D_3O^+ ion taken at the same positions in the same flame. The similarity between the two profiles suggests the possibility of an equilibrium between the proton and the hydroxonium ion, and accounts for the presence of the protons.

$$H^+ + H_2O \rightleftharpoons H_3O^+$$

A further interesting feature of this work has been the observation of the presence of detectable ion currents in the mass number region 7–11 in hydrocarbon flames. A well-defined peak occurring at about mass number 10 has not so far been clearly assigned. Using deuterium it was observed that the peak shift is about 2 mass numbers.

Addition of lithium chloride to the flame does not enhance the ion currents observed in this region due to the formation of ions of lithium hydride. It is therefore concluded that the ions are not due to the presence of lithium impurities either in the flame or from the 'Pyrex' burner.

The shape of the peak at mass number 10 does not suggest the presence of a meta-stable ion—a possibility which is unlikely due to the apparent absence of higher molecular weight hydrocarbon peaks, these usually being associated with the formation of meta-stable ions.

The presence of the doubly charged ions H_3O^{++} and H_4O^{++} at mass numbers $9\frac{1}{2}$ and 10 respectively cannot be ruled out and this possibility is receiving further consideration.

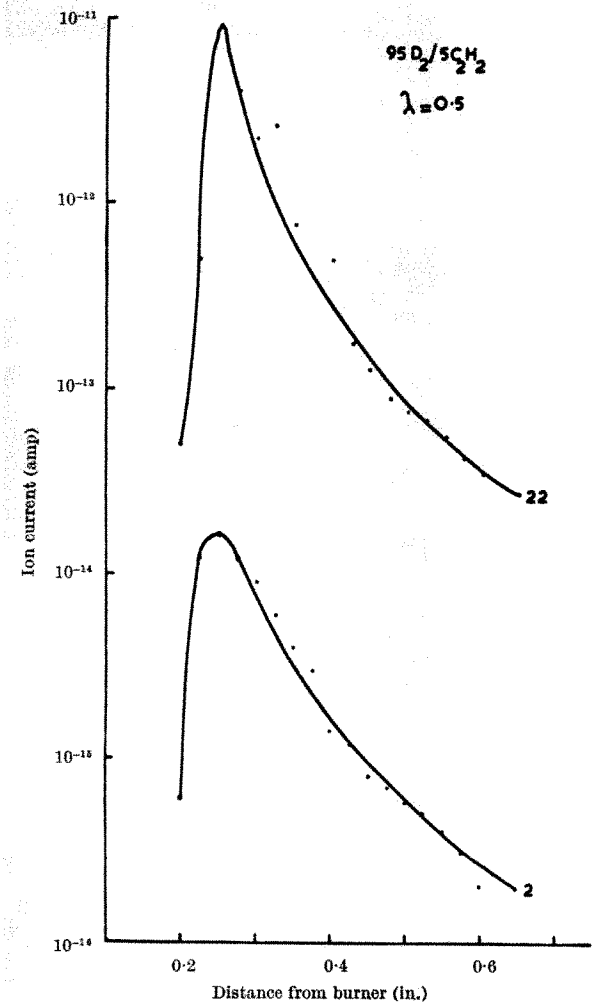

Fig. 2. Profiles of ions of mass numbers 2 and 22 in a deuterium/acetylene/air flame

BIOCHEMISTRY

Enzymatic Synthesis of Labelled Cytidine-5′-Diphosphate Ethanolamine

The chemical methods available for preparing cytidine diphosphate ethanolamine (CDP-ethanolamine) either give a poor yield of the product[1] or require rather elaborate procedures[2,3]. In the method described here, use has been made of the enzyme CTP : ethanolamine-phosphate cytidylyltransferase (*EC*. 2.7.7.14) from rat liver, to prepare cytidine-5′-diphosphate-(2-^{14}C)-ethanolamine and cytidine-5′-(β-^{32}P)-diphosphate ethanolamine in high yield. This enzyme, which was originally described by Kennedy and Weiss[4], is present exclusively in the particle-free supernatant from a tissue homogenate[5,6].

A 20 per cent homogenate of adult rat liver (4 g) in 0·3 M sucrose was centrifuged at 100,000*g* for 1 h. The supernatant (10 ml.) was applied to a column (2 × 20 cm) of 'Sephadex *G*-25' (or *G*-50), particle size 20–80μ and eluted with 0·01 M phosphate buffer, *p*H 7·6. Collection was commenced when the effluent became reddish in colour, and was stopped when the effluent became colourless. The red effluent (10 ml.), containing the bulk of the cytoplasmic protein, could be stored at 0° C, or in a frozen state, for 3–4 days with little loss of cytidylyltransferase activity.

Phosphorylethanolamine, labelled with phosphorus-32 or carbon-14, was prepared using a method similar to that of Riley[7], by heating equimolar amounts of ethanolamine and orthophosphoric acid at 155°–160° C for 4 h at a pressure of 10 mm of mercury. Phosphorylethanolamine was isolated from the reaction mixture using column chromatography on 'Dowex 1 × 2 (formate)[8]. The fraction containing phosphorylethanolamine was evaporated to dryness, dissolved in water and the *p*H adjusted to about 7 with N sodium hydroxide.

To the cytidylyltransferase preparation (5 ml., containing 15 mg protein per ml.) was added 0·1 M potassium *ortho*phosphate–sodium hydroxide buffer, *p*H 7·6 (4·5 ml.), M magnesium chloride (0·5 ml.), 0·001 M phosphorylethanolamine (10 ml.), and 0·04 M cytidine triphosphate disodium salt (Schwarz BioResearch, Inc.) (2·0 ml.). After incubating at 37° C for 2 h, the reaction mixture was heated at 100° C for 2 min to precipitate the protein, cooled to 0° C, diluted to 50 ml. with water and the *p*H adjusted to 8–9 using N sodium hydroxide (1·0 ml.).

The cloudy fluid was centrifuged, and the supernatant and subsequent washings (80 ml.) passed through a 'Dowex 1 × 2' (formate) column (1 × 15 cm), which was then washed with 50 ml. of water. Elution of the column was carried out in a manner similar to that of Kennedy[1], by linearly increasing the concentration of formic acid. The linear gradient was obtained by running 0·04 M formic acid into the mixing chamber, which originally contained water (500 ml.). When collecting fractions of 10 ml., CDP-ethanolamine appeared in fractions 21–24; it was preceded by a peak of unreacted phosphorylethanolamine

(fractions 10–14) and succeeded by a small peak of cytidine-5′-monophosphate (fractions 27–31). The CDP-ethanolamine was evaporated to dryness at about 40° C in a rotary evaporator.

On analysis, the product gave the correct ratio for cytidine : phosphorus and was homogeneous when examined by paper chromatography in isopropanol : water : trichloroacetic acid : 18 N ammonium hydroxide (75 : 25 : 5 : 0·3, v/v/w/v)[8]. Hydrolysis with N hydrochloric acid at 100° C for 1 h yielded only cytidine monophosphate and phosphorylethanolamine. The product was as effective as the chemically synthesized nucleotide in transferring phosphorylethanolamine to phospholipid precursors in brain and liver homogenates.

Using a molar ratio of phosphorylethanolamine to cytidine triphosphate of 1 : 8 in the reaction mixture, yields of CDP-ethanolamine, based on phosphorylethanolamine, were 40–60 per cent. A yield of about 30 per cent was obtained with a molar ratio of 1 : 2. The original liver homogenate cannot be used efficiently for the biosynthesis, since the yield of CDP-ethanolamine is reduced both by hydrolytic enzymes and by the presence of CDP-ethanolamine : 1,2-diglyceride ethanolamine phosphotransferase. Though liver supernatant alone was as active in the reaction as the effluent from 'Sephadex', this step removed compounds of low molecular weight, including endogenous nucleotides, which would otherwise have been difficult to remove from the final product.

This procedure can be recommended for a rapid, efficient and inexpensive synthesis of labelled CDP-ethanolamine.

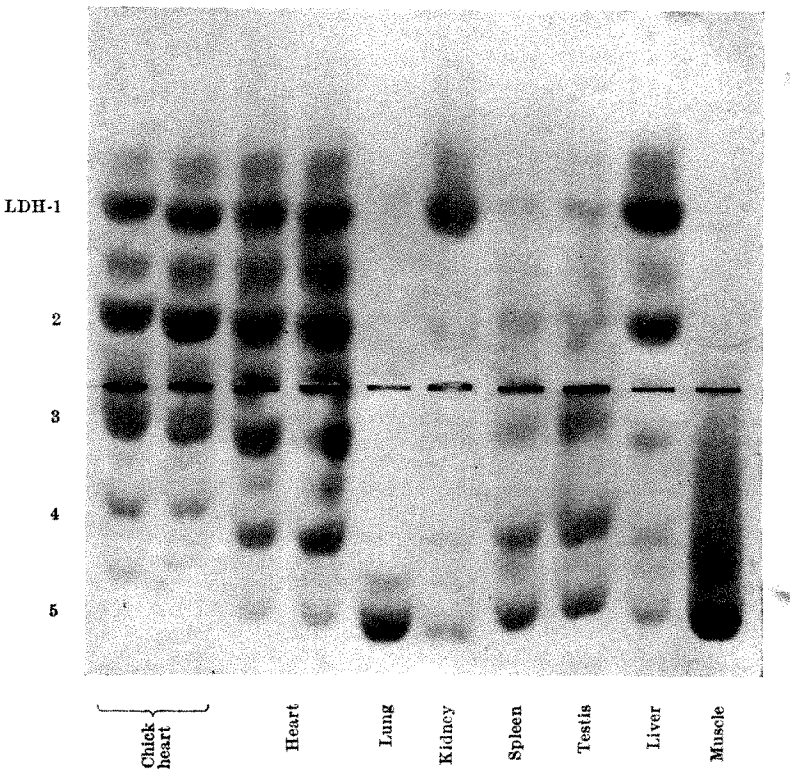

Fig. 1. Photograph of a starch-gel zymogram of penguin isozyme patterns. Note that each organ shows a characteristic pattern. The chick heart patterns are slightly different from the adults, though nearing completion of their ontogeny. The five major isozymes are numbered; the intercalated bands probably represent permutations of the major five though still showing some specificity in tissue distribution. The muscle tissue was from the pectoralis major

Stability of Lactate Dehydrogenase Isozyme Patterns in Penguins

PENGUINS were chosen for this investigation because of their highly specialized adaptation to an aquatic life and because of the extreme physiological conditions they are subjected to during the breeding season. One of the most abundant species is the Adelie penguin, *Pygoscelis adeliae*, which has a circumpolar distribution south of the Antarctic pack-ice. Unlike other birds this species endures a prolonged fast averaging 6 weeks during incubation[1] and another fast of shorter duration when it moults. At both times they may lose more than 40 per cent of their body-weight. Though flightless, their pectoralis muscles are well developed for extensive swimming and diving at sea.

Material from sixteen Adelie penguins and one African penguin, *Spheniscus demersus*, was examined. The African penguin was a captive bird which had died from aspergillosis. The Adelies were collected at the Cape Crozier rookery on Ross Island (77° S., 169° E.) at the end of the season in February 1964, when most of the adults and the chicks were leaving for their winter sojourn in the pack-ice. Four physiological conditions were represented in the specimens:

(i) *Parents* (six males and two females). Birds that were either arriving with full stomachs or about to depart to sea having regurgitated semidigested food to their offspring. The weight of these birds varied from 3·2 kg to 4·7 kg and their blubber (also an indication of their state of nourishment) from 2 mm to 4 mm thick. It is believed that a small amount of food would be digested, but most of it remains in the stomach for feeding the chicks.

(ii) *Pre-moult adults* (three males) could have been non-breeders, unsuccessful breeders, or parents after chick-rearing[2]. Before the moult Adelies gorge with food at sea and rapidly gain weight, accumulating large deposits of fat. Our three birds weighed 6·0, 6·3 and 6·5 kg, respectively, and their blubber thickness was 10–12 mm.

(iii) *Post-moult adults* (two males). These Adelies had fasted on land for no less than 2 weeks during the moult. Most of their fat reserve would have been metabolized. Our two specimens weighed 2·9 kg and 3·4 kg and their blubber was 2 mm or less in thickness.

(iv) *The chicks* (two males and one female) had been deserted by their parents and were ready for their first swim at sea. Two of our samples were dying from starvation, though fully developed. The other was strong and capable of survival at sea. Their weights were 1·5, 1·8, and 2·1 kg.

Thus, these four physiological states represented extreme emaciation and inactivity (starving chicks and post-moult adults) for comparison with parents which had been swimming and living at sea, and with pre-moult birds which had accumulated a great store of fat before the prolonged fast and inactivity away from sea during the forthcoming moult.

Seven of the Adelie penguins were dissected soon after being killed, the tissues frozen within 2 h and kept in this state until analysed. The rest of the birds were frozen whole in the Antarctic, thawed for dissection in the United States and the material refrozen immediately.

The penguin tissues were assayed for their content of lactate dehydrogenase (LDH) isozymes by the usual procedures of starch-gel electrophoresis[3]. Tissues were homogenized in phosphate buffer *p*H 7·2 and electrophoresed about 24 h at 4° C. A photograph of a starch-gel zymogram is shown in Fig. 1. Like all other vertebrates studied, each tissue of the penguin shows a specific pattern in terms of the relative abundance of the different isozymes. The patterns in penguins are unusual in that the net charge on the isozymes is more positive than is true for mammals or other birds that have been investigated. These observations were also true for the African penguin, although it is distinguishable from the Adelie in its isozyme pattern. Moreover, the pattern in the Adelie heart tissue is remarkable in showing large amounts of all the isozymes, not just those at the LDH-1 end of the spectrum as is true for other warm-blooded animals. At least nine bands of LDH activity are evident in heart homogenates. By analogy with mammalian systems five major isozymes can be identified. These are presumably the five tetramers of *A* and *B* sub-units. The four additional minor isozymes, conspicuous in heart tissues, but not so evident in other tissues, constitute an unexplained deviation from the simple patterns seen in avian and mammalian tissues[4]. A similar type of pattern in heart tissues has, however, been found in a fish (*Merluccius bilinearis*[3]) and analysis of this pattern in the fish heart indicates that the extra four bands intercalated among the major five are probably permutations or modified versions of them. The specific molecular responsibility for their electrophoretic behaviour has not been determined.

The characteristic tissue specific patterns of isozymes strongly imply that each enzyme plays a specific physiological part, and because we now know that at least two genes are involved in the synthesis of LDH isozymes the different patterns pose a problem in differential gene function—or gene regulation. Much experimentation has been directed towards changing isozyme patterns by altering the cellular environment of cells in tissue culture[5] or attempting to correlate the dramatic changes evident during ontogeny with physiological conditions. These efforts have so far failed.

Since the penguin is probably subjected to greater extremes of physiological stress than any other bird, its tissues might be expected to reflect these conditions in changed isozyme patterns. However, our results show that in the adult the isozyme content of tissues is highly constant. Some slight indication of terminal ontogenetic changes in heart patterns was evident in the penguin chicks (Fig. 1), but they were already fully developed and ready for departure to sea. Only the liver zymograms showed some differences among individuals, but the differences could not be correlated with any particular physiological state or method of collection. The conclusion from our analyses must therefore be that tissue content of isozymes is highly characteristic of a state of cellular differentiation but is quite refractory to change in the face of the most extreme forms of environmental or physiological stress. It is difficult to reconcile this stability in the adult, subject to extreme physiological changes, with the extensive changes that occur during embryonic life. It would seem that the molecular events related to the functioning of LDH are divorced from the mechanisms regulating the genes which control the patterns of isozyme synthesis.

The laboratory work was supported by a grant from the U.S. Atomic Energy Commission and from the National Science Foundation, and the field work by a grant from the Office of Antarctic Programs, National Science Foundation.

Distribution of Selenium in the Tissues of the Eye

FOR the past few years we have been investigating the presence and distribution of selenium in the normal and dystrophic state[1,2]. The biological role of selenium is as yet unknown; however, the physical and chemical properties of the element are well established. One of the outstanding characteristics of selenium is that it behaves differently in the light and in the dark. This fact is used to advantage in a number of modern instrumentations, such as the photoelectric colorimeter, the xerographic process, and the so-called 'electric eye'. Consequently, we were interested in determining whether selenium is a constituent of the eye in various animal species as well as in man.

Eyes of the lamb, calf and pig were collected directly from Charles Miller's slaughter house in North Bergen, New Jersey. They were kept in dry containers surrounded by wet ice and were processed immediately on arrival at the laboratory. Each whole eye was weighed, freeze-dried, and selenium was determined by the method of Taussky *et al.*[3,4].

The data in Table 1 represent the arithmetical mean of six animals of each species ranging from six months to one year. The age of this group is significant, because it has previously been observed[2] that selenium shows a tendency to increase in the tissues of chickens as they grow older. The Manhattan Eye Bank provided the human eyes. This group ranged in age from sixty to eighty years, which may explain the high value of their selenium content.

Our next step was to investigate the distribution of selenium in the different tissues of the eye, because we expected to find the greatest concentration in those parts

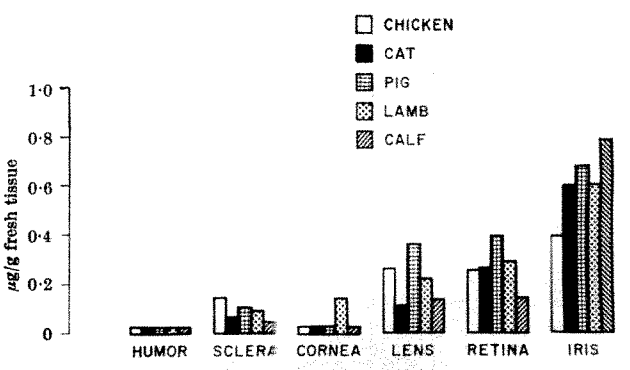

Fig. 1. Distribution of selenium in the tissues of the eye of five species ♀♂

Table 1. SELENIUM CONTENT OF THE WHOLE EYE

Species	Wet weight (g)	Selenium (μg)
Baby chicks	0·4–0·6	0·04
Chicken	1·5–2·5	0·19
Cat	3·0–4·0	0·20
Pig	6·0–7·0	0·39
Lamb	11·0–12·0	0·85
Calf	18·0–19·0	0·73
Human	6·0–8·0	5·98

Table 2. SELENIUM CONTENT OF THE TISSUES OF THE EYE

Tissue	Chicken		Cat		Pig	
	Wet wt. (g)	Selenium (μg)	Wet wt. (g)	Selenium (μg)	Wet wt. (g)	Selenium (μg)
Humour	1·30	0·01	1·72	0·01	3·86	0·02
Sclera	0·14	0·03	0·38	0·04	1·24	0·12

Retina	0·76	0·22	1·15	0·16	0·38	1·29
Iris	0·41	0·25	0·42	0·32	0·16	0·14

concerned with the regulation of light. We investigated six tissues: the humour, sclera, cornea, lens, retina, and iris (Fig. 1). Whereas the aqueous and vitreous humour, the sclera, and the cornea show only traces of selenium, the lens and retina have larger amounts, and the iris has the greatest accumulation. These results are expressed as concentrations of selenium; the actual amount of selenium per tissue is shown in Tables 2 and 3.

Investigations of selenium in the eye of additional species, as well as of man in younger age groups, are in progress.

We thank Messrs. Albert and Gordon Miller for contributing the eyes to our investigations. We also thank Mrs. Cornelius E. Rhoads, director of the Manhattan Eye Bank, for her collaboration. The work was supported in part by a grant from Muscular Dystrophy Associations of America, Inc.

Lysozyme and Serum Bactericidal Action

NORMAL human serum kills Gram-negative bacteria by the antibody-complement system[1–4]. Killed bacteria are converted to spheroplasts by lysozyme[5–8]. Subsequent loss of intracellular contents by spheroplasts leaves the empty cytoplasmic membranes or ghosts[5,8]. Serum action proceeds as follows[8], using R for viable bacterial rod, R^* for killed rod, S for spheroplast, and G for ghost:

$$R \xrightarrow[\text{Complement}]{\text{Antibody}} R^* \xrightarrow{\text{Lysozyme}} S \longrightarrow G$$

However, Inoue *et al.*[6] also reported that a high concentration of lysozyme enhanced the killing or bactericidal action of serum. This is at variance with the generally accepted concept that cell wall damage by the antibody-complement system makes these bacteria susceptible to lysozyme[5,7,8].

The influence of a high concentration of lysozyme on serum action was therefore studied by kinetic analysis which allows a correlation of the bactericidal action of serum with morphological changes in bacteria[8]. Smooth *Escherichia coli* 0:127 in rapid growth phase from brain-heart infusion broth culture were collected by centrifugation and suspended in 0·15 sodium chloride at an optical density of 0·40. Optical density was measured spectrophotometrically at 650 mμ with the suspension in 16 × 150 mm tubes. Numbers of viable bacteria were determined by growth assay[9]. Differential counts of bacterial rods, spheroplasts, and ghosts were made on samples fixed in 2 per cent formalin using a phase-contrast microscope. Two experiments were done at the same time on bacteria from one broth culture. One tube contained 0·25 ml. normal human serum, 2·0 ml. bacteria, and sufficient saline to make 3·0 ml. The second tube contained similar volumes of serum and bacterial suspension with egg white lysozyme added to a concentration of 100 μg/ml. in a total volume of 2 ml. The bacterial suspensions were chilled rapidly in an ice bath, the other reagents added, and both tubes were then incubated in a water bath at 37° C. Samples were taken frequently for the growth assay and microscopic counts.

The results of these experiments are illustrated in Figs. 1 and 2. Normal serum killed the bacteria and transformed the bacterial rods to spheroplasts and ghosts. Added

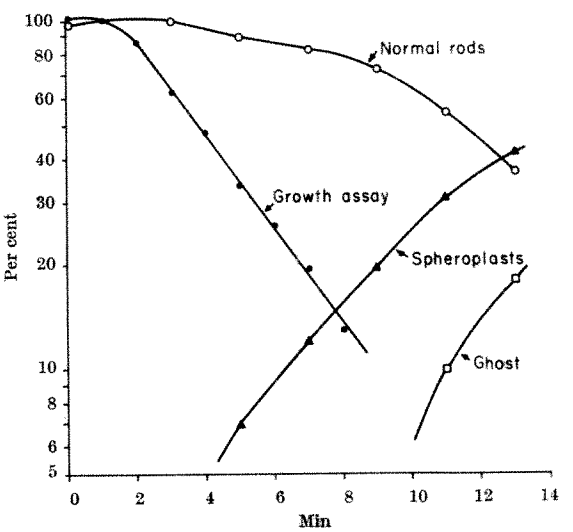

Fig. 1. Killing of *E. coli* and formation of spheroplasts and ghosts by normal human serum

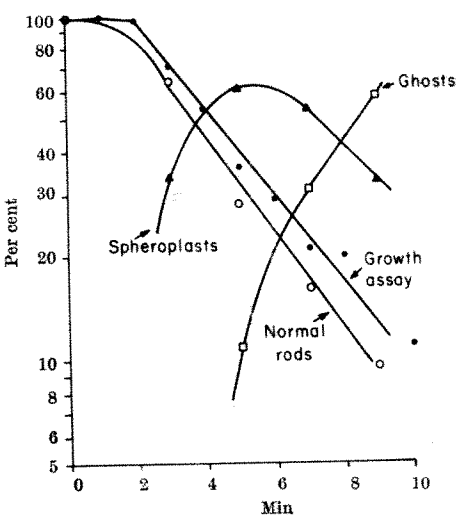

Fig. 2. Killing of *E. coli* and formation of spheroplasts and ghosts by serum with added 100 μg/ml. lysozyme

egg white lysozyme had no demonstrable effect on the rate of serum killing as determined by growth assay, but did increase the rate of transformation of killed rods to spheroplasts. Similar experiments, using colony counts instead of the growth assay, also failed to detect any influence of the added lysozyme on serum killing.

Egg white lysozyme at 100 μg/ml. had no effect on this *E. coli* in the absence of serum. Killed bacterial rods, prepared by exposing the *E. coli* to bentonite-absorbed serum[6], were promptly converted to spheroplasts by lysozyme. Spheroplasts, prepared with serum[8] and stabilized by 0·006 M calcium chloride, were not affected by lysozyme.

These investigations support the concept that the role of lysozyme in serum action is limited to the conversion of killed bacteria to spheroplasts.

This investigation was carried out under the auspices of the Commission on Immunization of the Armed Forces Epidemiology Board and was supported in part by the Office of the Surgeon General, Department of the Army, by the U.S. Public Health Service, and by the State of Washington Initiative 171 Funds for Research in Biology and Medicine.

Actomyosin of Human Vascular Smooth Muscle

Actomyosin of vascular smooth muscle appears to be similar in certain properties to actomyosin of uterine smooth muscle[1]. These properties include solubility, viscosity (ATP sensitivity), and ATPase activity. Needham[2] first observed that uterine actomyosin showed an elevated ATPase activity when the potassium chloride concentration was raised from 0·1 M to 0·5 M. Filo *et al.*[3] also observed this to be true for hog carotid artery actomyosin, and we have observed the potassium chloride-induced elevation of ATPase activity of actomyosin of cow carotid artery[1]. In extending our investigations of contractile proteins of vascular smooth muscle to human blood vessels, we find that in the properties of solubility and viscosity behaviour (ATP sensitivity) the actomyosin of human umbilical artery is similar to the contractile proteins of other vascular smooth muscles. However, with respect to the potassium chloride induced elevation of the ATPase activity, the actomyosin of the human umbilical artery differs from the contractile proteins of other vascular smooth muscles. This report presents data to show that, unlike the actomyosin ATPase enzymes of those smooth muscles studied to date, that of the human umbilical artery is not stimulated by high concentrations of potassium chloride (0·5–0·6 M).

Umbilical cords, obtained from the hospital delivery room, were collected over a 24 h period and maintained in Ringer's solution at 4° C. The arteries were separated from the cords, rinsed in saline, minced, and homogenized using three volumes of the Weber–Edsall medium consisting of 0·6 M potassium chloride, 0·01 M sodium carbonate, 0·04 M sodium bicarbonate, and fortified with 5×10^{-4} M ATP (final concentration). The whole homogenate was stirred overnight at 4° C and the actomyosin was extracted as previously described[1]. The final yield of human umbilical artery actomyosin was 4 mg/g of wet weight. ATPase assays and viscosity runs for ATP sensitivity were carried out as previously described[1].

Table 1 demonstrates that artery actomyosin, either from the cow or the human, shows essentially the same degree of viscosity change in response to added ATP. This parameter, the ATP sensitivity, is a useful property in comparing various contractile proteins. For example, skeletal muscle actomyosin and cardiac actomyosin show ATP sensitivities in the neighbourhood of 150. Uterine and artery actomyosins are usually well below this, generally in the range of 30–60 (refs. 2 and 4).

It can be seen by the data in Table 2 that the actomyosin of the human umbilical artery has ATPase activity which is not stimulated by elevated concentrations of potassium chloride. In this respect the actomyosin of human umbilical artery differs from the actomyosins of cow artery, hog artery, and uterine smooth muscle[1–3]. Control studies with actomyosin of skeletal muscle showed that enhanced enzyme activity induced by high concentrations of potassium chloride was specific for the smooth muscle proteins. The ATPase activity of human artery actomyosin, like those of all actomyosins studied so far, is activated by either calcium or magnesium provided that the potassium chloride concentration is of a low ionic strength (final concentration 0·05–0·1 M). In the presence of a high ionic strength concentration of potassium chloride (0·5–0·6 M) magnesium depresses the ATPase activity.

Table 1. ATP Sensitivity of Artery Actomyosin (Human Umbilical)

Preparation No.	ATP sensitivity*
1	66
2	51
3	59
4	51
5	53

Conducted at 25° C using an Ostwald viscometer (3·0 ml.). Preparation 5 is actomyosin derived from cow carotid artery. All protein concentrations were between 4 and 5 mg/ml. in 0·5 M potassium chloride, 0·1 M *tris* pH 7·2, and 0·002 M ATP (final concentration).

* ATP sensitivity in per cent $= \frac{\log \eta_{rel} \log \eta_{rel\ ATP}}{\log \eta_{rel\ ATP}} \times 100$

Log η_{rel} = logarithm relative viscosity.

Table 2. The Effect of High and Low Concentration of Potassium Chloride on ATPase Activity of Actomyosin of Human Artery

Preparation No.	Specific activity* High KCl	Low KCl
11	0·8	0·9
13	1·2	1·5
14	1·3	2·0
15	0·7	0·9
16	0·6	0·6
17	0·6	1·1
18	1·3	1·3

Conditions: actomyosin of different preparations of human umbilical artery, 1–2 mg protein/ml. in 0·02 M imidazole buffer, *p*H 7·2, 0·005 M calcium chloride and either 0·05 M potassium (low KCl) or 0·5 M potassium chloride (high KCl), ATP (final conc. 0·0025 M) was added to start the reaction. The reaction was run at room temperature for 10 min.

* Specific activity equals micromoles inorganic phosphorus liberated per mg protein per min.

Another difference between the protein of the umbilical artery and the other smooth muscle proteins was observed: whereas the alkali earth metal cations of barium chloride, calcium chloride, and strontium chloride stimulated the ATPase activity of contractile proteins of cow aorta and cow carotid artery, barium chloride and strontium chloride had no such effect on the ATPase activity of the umbilical artery protein. (The effect of these ions on the contractile protein of the uterus was not investigated.)

These results indicate that the stimulation of actomyosin ATPase activity by high concentrations of potassium chloride is not a general effect observed in all smooth muscle contractile proteins, and that umbilical artery is distinct in this respect from uterine smooth muscle and from vascular smooth muscles such as hog and bovine carotid artery and bovine aorta. Whether this is a species difference or a reflexion of the anomalous nature of the smooth muscle of the umbilical artery remains to be investigated.

Cystine Content of Silk Fibroin (*Bombyx mori*)

UNTIL recent years silk fibroin was thought to be free from the sulphur-containing amino-acids, and in a critical assessment of many amino-acid analyses in 1958 (ref. 1) it was concluded that there was insufficient evidence to support the theory that cystine was present in fibroin. Since that time there have been several reports of the presence of cystine in this protein.

Schroeder and Kay[2] had already estimated cystine in 1954 during their amino-acid analysis of fibroin, though they did not regard its presence as proved. They used the method of Schram, Moore and Bigwood[3], in which the protein was oxidized with performic acid and hydrolysed; the cysteic acid formed was estimated on a column of 'Dowex 2' and indicated 0·18 per cent of cystine in fibroin. Zuber, Ziegler and Zahn[4] found a content of 0·12 per cent by estimating the cysteic acid in hydrolysates of performic acid-oxidized fibroin by high-voltage electrophoresis and reaction with ninhydrin.

Earland and Raven[5] converted the amino-acids in a fibroin hydrolysate into their 2 : 4-dinitrophenyl derivatives, oxidized these with performic acid, and separated the strongly acidic DNP-cysteic acid from the other DNP-amino-acids by high voltage electrophoresis in 33 per cent acetic acid. They were able to obtain 35 mg of the compound and thus add elementary analyses to the chromatographic evidence of its identity. The amount of DNP-cysteic acid isolated corresponded to a cystine content of 0·13 per cent.

More recent evidence for the presence of cystine was given by Gustus[6], who showed that treatment of fibroin with liquid ammonia gave the blue colour characteristic of proteins containing fully combined cystine residues. Thus the presence of cystine in fibroin now seems to be well established.

In view of the importance of this amino-acid in relation to the structure of the fibroin molecule, it is desirable to have an accurate assessment of the cystine content. To this end determinations have been made by two independent methods, due to Goa[7] and Moore[8]. The first method involves heating with hydrazine to convert cystine to hydrogen sulphide, which is measured colorimetrically after absorption in a bismuth nitrate reagent. In the second method the protein is oxidized by performic acid, to convert cystine residues to cysteic acid, and afterwards hydrolysed; the cysteic acid is then determined on an amino-acid analyser.

These methods were applied to two types of fibroin, namely, that taken directly from the glands of silkworms and that prepared from raw silk after removal of sericin by degumming. Gland fibroin was prepared from glands removed from silkworms as they were about to spin. After a brief rinse in water, the glands were coagulated in 25 per cent (v/v) alcohol : water for about an hour. The outer layers of cells and sericin were then removed and the core of fibroin was cut into small pieces, washed in turn with water, alcohol and ether, and then dried *in vacuo*. Raw Japanese silk was degummed in soap solution and washed as described by Lucas, Shaw and Smith[9]. A sample of raw silk was also degummed by the method of Dunn *et al.*[10], which involves the treatment with water under pressure at 120° C for 10 h.

The analyses were made on samples that had been dried to constant weight over phosphorus pentoxide *in vacuo*. The procedures of the original authors were followed, except for a few modifications that were made because the small cystine content necessitated the use of relatively large samples of protein. In Goa's method, 25–100 mg samples of fibroin were heated with 1 ml. hydrazine hydrate at 140° C in sealed tubes for 18 h; even with this prolonged treatment traces of insoluble material remained in the digests. The contents of the tubes were transferred to an all-glass apparatus similar to that of Goa, and acidified with 3 ml. of 18 N sulphuric acid. The hydrogen sulphide liberated was carried by nitrogen into 4 ml. of the bismuth nitrate reagent and the optical density of the brown colour produced was measured at 400 mμ in a 1-cm cuvette on a 'Unicam *SP* 600' spectrophotometer against the reagent as blank. Standard solutions of cystine containing 20–150 μg, subjected to the same procedure, gave the relationship: $C = 20{\cdot}2\,E + 1{\cdot}89$ between the amount of cystine (C, μg) and optical density (E) and from this the quantity of cystine in each sample of fibroin was calculated.

Moore's method was used unchanged on 30–90 mg samples of fibroin. Portions of the hydrolysates, corresponding to two-fifths of each sample, were analysed for cysteic acid on the 150-cm columns of a Phoenix model 8000 amino-acid analyser by the method of Spackman, Stein and Moore[11]. The amounts of cysteic acid were calculated from the constant for aspartic acid assuming a recovery of 94 per cent.

Table 1. DETERMINATION OF CYSTINE IN VARIOUS PREPARATIONS OF SILK FIBROIN

	Cystine content			
	Goa's method		Moore's method	
Type of fibroin	Per cent	N/N per cent*	Per cent	N/N per cent*
Gland	0·23	0·15	0·24	0·15
Soap-degummed	0·21	0·13	0·19	0·12
Water-degummed at 120° C†	0·16	0·10	—	—

* Cystine nitrogen per 100 g fibroin nitrogen.
† Dunn *et al.* (ref. 10).

The results in Table 1 show good agreement between the two methods and, as these are based on quite different reactions, this gives confidence in them. While both procedures would determine cystine and cysteine, the experiments of Gustus[6] suggest that most of the amino-acid is present in the oxidized form.

We may conclude, therefore, that intact fibroin has a cystine content of 0·23 per cent, and that about 13 per cent of this cystine is destroyed during soap-degumming and about 30 per cent during degumming with superheated water.

The importance of the cystine content in our knowledge of the fibroin molecule can only be conjectured until more is known about the intact molecule. Most determinations of molecular weight[12] and *N*-terminal residues[13] have been made on fibroin prepared by degumming and re-dissolution and, in view of the possibilities of degradation involved in these processes, it is not surprising that a wide range of values has been found. A preliminary study of gland fibroin in the ultracentrifuge in these laboratories[14] indicates that the molecular weight is of the order of 4×10^5 and the cystine content now found therefore corresponds to about four cystine residues per molecule. Preliminary determination of the N-terminal residues of gland fibroin[14] by Sanger's method have shown that glycine, serine and aspartic acid are present in about equimolecular amounts, with a small amount of alanine. It is likely, therefore, that there are at least four chains in the fibroin molecule, and the cystine present could provide inter-chain disulphide links for such a molecule of a molecular weight about 4×10^5. However, the possibility of intra-chain disulphide links cannot as yet be excluded.

Further progress in our knowledge of the structure of fibroin will depend on attempts to establish unequivocally the existence of inter-chain bonds and to break these and isolate the component chains of the molecule.

BIOPHYSICS

Dry Thermal Inactivation of Trypsin and Ribonuclease

IN the course of some recent work, it became necessary to obtain information on the dry thermal inactivation of trypsin and ribonuclease. A search of the literature indicated that very little work had been done on the dry inactivation of enzymes. In the present experiments, dry samples of these two enzymes were heated *in vacuo* at temperatures ranging from 160° to 200° C. The inactivation process was found to be irreversible. The values of the thermodynamic parameters ΔH and ΔS were also calculated from the survival data.

The vacuum heating chambers used in these experiments consisted of six small brass cups with thin (0·6-mm) copper bottoms. The cups were connected to a mechanical forepump through a vacuum manifold. With this arrangement, the pressure could be maintained at 40μ of mercury during the course of an experiment.

The enzyme samples were prepared by pipetting 0·02 ml. of a stock solution (1 mg/ml.) of the enzyme in distilled water on to a stainless steel disk. These disks were then placed in a desiccator and dried by fast vacuum pumping. After this operation, the disks were placed in the vacuum chambers and the chambers were evacuated.

The heating procedure consisted of immersing the cups in a constant-temperature bath for a known length of time. After the heating period, the cups were cooled by placing them in a cold-water bath (20° C). The temperature was measured by means of a thermocouple placed in the bath. A number of runs were made with a second thermocouple placed on the inside bottom of the cups. The purpose of these runs was to determine the time necessary for the temperature in the cup to rise to the bath temperature. This rise time was found to be short (the maximum observed was 200 sec at 210° C) and all heating times were corrected for it.

The activity of heated trypsin samples, with respect to a non-heated control, was determined by the usual casein digestion assay[1]. The protein from two disks was dissolved in 2 ml. of acetate buffer at *p*H 5·5. 1 ml. of this solution (20 μg/ml.) was added to the casein solution (10 mg/ml.) and incubated for 24 min at 37° C. The assay was standard in all other respects.

In the case of ribonuclease, only one disk was added to 2 ml. of acetate buffer, also at *p*H 5·5. 1 ml. of this solution (10 μg/ml.) was incubated with 3 ml. of a 1-mg/ml. solution of ribonucleic acid (RNA), in the same buffer, for 10 min at 25° C. The reaction was stopped by adding 1 ml. of a 25 per cent perchloric acid–uranyl acetate solution. The assay of Anfinsen was carried out on the supernatant liquid[2]. The enzymes and the RNA were commercial products obtained from General Biochemicals, Inc. The distilled water, used in making all solutions, was injection-grade water supplied by Baxter Laboratories, Inc.

Within the limits of experimental error, the survival ratio at any fixed temperature was found to be an exponential function of the heating time. This function had the form $A = A_0 \exp -kt$. The value of k, the rate of thermal inactivation, was obtained from the slope of the inactivation plots (on a semi-logarithmic scale) and the value of ΔF was calculated according to the theory of absolute reaction rates[3]. These data are summarized in Table 1.

Table 1

Enzyme	Temperature (° C)	k (sec^{-1})	ΔF (cal/mole)
Ribonuclease	161	$1{\cdot}04 \times 10^{-4}$	33,700
	170	$1{\cdot}94 \times 10^{-4}$	34,200
	192	$6{\cdot}00 \times 10^{-4}$	34,500
	204	$1{\cdot}04 \times 10^{-3}$	34,900
Trypsin	160	$1{\cdot}58 \times 10^{-4}$	33,300
	175	$2{\cdot}98 \times 10^{-4}$	33,800
	184	$5{\cdot}20 \times 10^{-4}$	34,100
	195	$8{\cdot}75 \times 10^{-4}$	34,300
	205	$1{\cdot}50 \times 10^{-3}$	34,500

As can be seen from Table 1, ΔF is a slowly increasing function of temperature. ΔF also satisfies the relation $\Delta F = \Delta H - T\Delta S$. Thus for trypsin, $\Delta H = 22{,}500$ cal/mole; $\Delta S = -25$ cal/mole degree and, for ribonuclease, $\Delta H = 22{,}400$ cal/mole and $\Delta S = -24$ cal/mole degree. Zero or negative values of ΔS have been observed in the past for the dry heating of biological materials[4]. Since the meaning of this behaviour is obscure, no physical significance has been attached to the values of ΔH and ΔS found in this work. They are considered as constants which characterize a given reaction.

Influence of Electric Field on the Capacity of Phospholipid Membranes

VARIOUS bimolecular models of the cell membrane have already been made[1–3]. Such bimolecular films separating two aqueous solutions are formed by applying a solution of phospholipids to the hole in a 'Teflon' cup.

In the present investigation, we have attempted, using artificial phospholipid membranes, to investigate the electromechanical properties which apparently play an essential part in the activity of the cell membrane. Indeed, there is a potential difference of the order of 0·1 V across the resting excitable cell membrane. This produces substantial mechanical forces which compress the membrane. In the course of excitation, the electric field across the membrane decreases and the mechanical compression also falls. This, in turn, could lead to enlargement of the radii of the pores and an increase in the permeability of the cell membrane. In fact, the pores in cell membranes do enlarge in the course of excitation[4]. With the use of a phospholipid model, it became possible

to investigate whether the electric field can change the essential configuration of the membrane.

If the electric field is capable of compressing the cell membranes it might be expected that the application of voltages to bimolecular phospholipid models would increase their capacity, which would decrease with the removal of the voltage. An effect of this kind has, in fact, been observed. The capacity of the membrane was measured by the bridge method (5,000 c.p.s.), using platinum electrodes, and was found to be $0{\cdot}37 \pm 0{\cdot}01$ F/cm². The constant polarizing voltage was measured with separate non-polarizing electrodes. The change in the capacity of an artificial bimolecular membrane under the influence of direct and alternating voltages is shown in Fig. 1. Fig. 1 also shows that the capacity increases on the application of either direct or alternating voltages. After removal of the voltage, the capacity reverts to its previous value. The potential difference (of the order of 0·1 V) which normally exists across the excitable cell membrane substantially changes the capacity of bimolecular membranes. This effect does not depend on the direction of the applied electric field. ΔC increases approximately in proportion to the square of the applied voltage.

If the change of capacity is connected with the mechanical compression of the membrane, it might be expected that the effect of alternating field would be proportional to the value of the effective voltage. This effect has been shown to occur. In all cases the value ΔC was a constant function of the sum of the effective alternating and constant voltages applied.

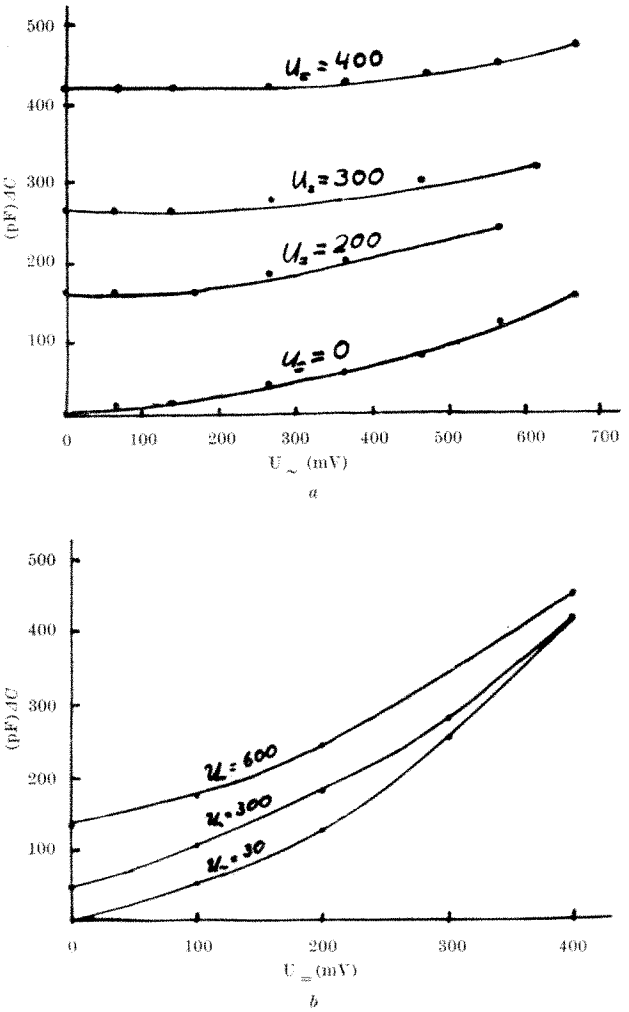

Fig. 1. The dependence of capacity change on voltage: (*a*) alternating, (*b*) constant. Membrane capacity at $U_{=} = 0$ and $U_{\sim} = 30$ mV is equal to 6,200 pF

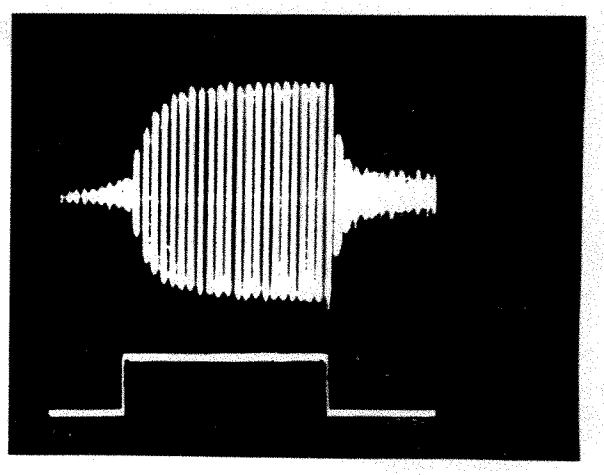

Fig. 2. A bridge imbalance due to the increase of capacity after the application of constant voltage. The amplitude of the rectangular impulse is 200 mV. Time marks at 50 msec intervals

When the electric field is applied, the capacity does not instantly assume a value appropriate to the voltage: the time constant of the delay is approximately 0·3 sec. A bridge imbalancement due to an increase of capacity after the application of constant voltage is shown in Fig. 2.

This rise of capacity as a result of the application of voltage may be associated either with a decrease in the thickness of the bimolecular film or with the extension of its surface as a result of the transformation of the edge of the phospholipid ring into a bimolecular film. In order to find out which of the two effects is present, the thickness of the bimolecular layer was found by measuring the intensity of the light reflected from the membrane. A narrow ray of monochromatic light was used, which was focused on the bimolecular part of the membrane, so that the intensity of the reflected light was not influenced by any changes in the thickness of the lipid at the edges. The refractive index was obtained by measuring Brewster's angle[2]. The intensity of the reflected light was registered on a photo-electronic multiplier. The thickness of the bimolecular membrane was found to equal 74 ± 15 Å, and the error is determined mainly by an error in the measurement of the refractive index. The method of measurement of the change in thickness was accurate to within 1 per cent. Experiments showed that the intensity of the reflected light did not vary with the applied alternating voltage up to amplitudes of 1 V. This means that the change in thickness does not exceed 1 per cent, although the capacity undergoes a change of up to 3 per cent. It might be expected that the thickness variation would be compensated by the simultaneous change of the refractive index of the film, but the intensity of the reflected light measured at different polarizations of the incident light showed that this effect is absent.

The change of capacity is evidently connected with the reversible transformation of the edge of the membrane ring into a bimolecular layer. In fact, optical measurements have shown such effects at the border of the bimolecular membrane after the application of the voltage. In some cases the bimolecular film is not continuous, as a result of impurities in phospholipid solution, and small light spots corresponding to thicker sites in the membrane can be observed on the film. A distinct optical effect is seen in this case: light-spots darken with the application of the field and become visible again when the field is removed. The effect of changes in capacity is far greater in this case. It may be mentioned that constant and alternating voltages of amplitude greater than 0·1 V can be seen to accelerate the formation of a bimolecular film from coloured membrane.

It might be asked whether an effect of this kind has significance for the activity of cell membranes *in vivo*.

Such membranes are not homogeneous; the phospholipid layer in the region of the pores is unlikely to be a simple bimolecular film. It is in just this area that it is logical to expect the electric field to have substantial mechanical influence.

The transformation of the non-bimolecular part of the membrane into a bimolecular one on the border and in other regions of non-homogeneity under the influence of electric fields apparently takes place as the result of the work of the electric field against surface tension. We therefore investigated the correlation between the value of the surface tension coefficient and the effect of applied voltage.

The surface tension coefficient was found from the analysis of membrane surface variations as a function of the differences in hydrostatic pressure at its sides. The coefficient of surface tension was calculated by extrapolation of the function to zero difference of pressure and was equal to $2{\cdot}3 \pm 0{\cdot}1$ dyne/cm.

The dependence of capacity change on the voltage and the coefficient of surface tension calculated for a non-compressible bimolecular membrane surrounded by a non-bimolecular ring, gives the following relation:

$$\frac{\Delta C}{C_0} = K \frac{(\Delta V)^2}{\sigma}$$

where C_0 is the capacity of the membrane in the absence of applied voltage; ΔC, the change in capacity as a result of an applied voltage; σ, the coefficient of surface tension; and K is a constant depending on the geometric parameters of the membrane and the ring.

The value of σ calculated from this relation is consistent in order of magnitude with that found experimentally. Preliminary results also showed a correlation between the value of the coefficient of surface tension and the change in capacity under the influence of the applied voltage.

PHYSIOLOGY

Uptake of Norepinephrine in Periglomerular Cells of the Olfactory Bulb of the Mouse

A HISTOCHEMICAL investigation, using the fluorescence method of Falck[2], has shown that the uptake of exogenous catecholamines in reserpine-depleted, normally catecholamine-containing neurones is limited within the mouse brain to a rather small number of nerve cell groups[4]. The majority of these nerve cells are situated in regions which also show catecholamine-containing nerve cells in untreated animals. In this communication evidence is presented that norepinephrine can be taken up in numerous periglomerular cells in the olfactory bulb. No catecholamine-containing cells have so far been observed in the olfactory bulb in normal animals.

The experiments reported here were performed on twenty male albino mice (20–25 g). The amine stores were first depleted by reserpine (15 mg/kg subcutaneously). 3 h later, nialamide (100 mg/kg) was injected intraperitoneally in order to inhibit rapid metabolism of the administered catecholamine. 15 min later, azapetine phosphate (10 mg/kg) was given intraperitoneally, followed after another 15 min by the intraperitoneal administration of either L-norepinephrine (16–24 mg/kg, ten animals), L-epinephrine (10 mg/kg, two animals) or L-3,4-dihydroxyphenylalanine (DOPA; 50 mg/kg without azapetine, two animals). Doses are given for the free base. Five animals served as controls, receiving reserpine, nialamide and azapetine. One animal was given 500 mg/kg nialamide only and was killed 6 h later. The other mice were decapitated about 5 h after reserpine, that is, 1–2 h after administration of the catecholamine. The brain was rapidly excised and thin brain slices were frozen in *iso*pentane cooled by liquid nitrogen, 2 min after decapitation of the animal. The tissue pieces were then freeze-dried for 6 days and subsequently exposed to formaldehyde gas using the method of Falck[2,3]. During this treatment, catecholamines, DOPA and 5-hydroxytryptamine condense with formaldehyde to form products which exhibit a green fluorescence in the case of the catecholamines and DOPA. The fluorescence colour of the condensation product formed by 5-hydroxytryptamine is yellow, with the combination of filters used[2,4]. After infiltration of the tissue pieces with paraffin *in vacuo*, 10μ serial sections were cut in a frontal or sagittal plane and mounted in 'Entellan' (or in liquid paraffin in the case of epinephrine). Some sections were stained with toluidine blue after fluorescence microscopy. The frontal sections comprised olfactory bulb, olfactory peduncle and olfactory tubercle, whereas the sagittal sections reached from the olfactory bulb to the medulla oblongata. The same regions were also investigated in untreated animals.

In the olfactory bulb of normal mice, no green fluorescent cells were observed. The same is true for the animal which received 500 mg/kg nialamide. No green fluorescence at all (neither cell bodies nor nerve endings) could be detected in the brain of the control animals. After 16–24 mg/kg norepinephrine a varying number of green fluorescent cells showed up in the layer of periglomerular nerve cells (or lamina granularis externa)[1,6] of the olfactory bulb (Fig. 1). The cells were small, round to oval, and exhibited a weak to moderate, seldom strong, fluorescence. The fluorescence intensity varied greatly from one cell to the other. Only in rare cases could the proximal parts of processes be seen fluorescing for a short distance, mostly directed towards a glomerulus. In sections stained with toluidine blue the green fluorescent cells were iden-

Fig. 1. Frontal section through the olfactory bulb of a mouse. After 24 mg/kg norepinephrine administered under the conditions described in the text, a green fluorescence of varying intensity shows up in the small periglomerular cells situated around two glomeruli. The ventromedial surface of the bulb is seen at left; the outer plexiform layer appears at right (×300)

tified after fluorescence microscopy as periglomerular cells. Fluorescence was only found in part of the periglomerular cells. They were distributed regularly about the glomeruli. They were most numerous and their fluorescence was most intense in the posterior portion of the olfactory bulb, especially in its ventral half. Close to the posterior end of the bulb, a few fluorescent cells were always present within the ventromedial sector of the superficial fibre layer, medial to the pars medialis of the anterior olfactory nucleus. They may belong to caudally situated glomeruli. Towards the anterior part of the bulb, the periglomerular cells generally showed a weaker fluorescence and the fluorescent cells became less numerous, being mostly confined to the ventromedial edge of the bulb. The number of fluorescent periglomerular cells changed somewhat from one experiment to the other, and in three of the ten cases very few fluorescent cells were observed. No other green fluorescent structures were found within the bulb, nor was green fluorescence seen in the anterior olfactory nucleus. After 50 mg/kg DOPA a weak green fluorescence developed in a number of periglomerular cells, whereas after administration of 10 mg/kg epinephrine no green fluorescence was found in this brain region.

As no green fluorescence was seen in the controls, the appearance of green fluorescence in the periglomerular cells after administration of norepinephrine and—less intense—after DOPA indicates an uptake of norepinephrine and DOPA by these cells. This DOPA is probably transformed in part to the related amines. Hence the question arises whether the periglomerular cells of normal animals contain a catecholamine. In experiments carried out under the aforementioned conditions, green fluorescence was found in nerve cell bodies in the arcuate and periventricular nuclei of the hypothalamus, in the area retrochiasmatica, area postrema and in the olfactory bulb, as well as in nerve endings in the external layer of the median eminence. Green fluorescence was also observed in the endothelial cells after administration of DOPA and, sometimes, in the choroid plexuses after norepinephrine[4]. With the exception of the retrochiasmatic area and the olfactory bulb, all these nuclei also show catecholamine-containing nerve cells under normal conditions. However, the fluorescence intensity was greatly increased in these cells after administration of norepinephrine as compared to that in normal animals, and more green fluorescent nerve cells became visible. It therefore seems possible that the periglomerular cells normally contain a catecholamine, but in such small quantities that no fluorescence can be observed. No conclusion can be drawn from the uptake of norepinephrine as to the type of catecholamine present in the cells.

The olfactory bulb is not known to belong to the regions situated outside the blood-brain barrier[5]. As the other groups of nerve cells showing uptake of catecholamines are all localized in such regions or are—at least possibly—connected with them, the uptake of norepinephrine by periglomerular cells is a somewhat surprising finding. Since the dendrites and axons of periglomerular cells end in glomeruli[1], it must be assumed that norepinephrine was taken up from the circulation within the bulb.

The function of the periglomerular cells is as yet poorly understood. It is therefore difficult to understand the significance of the possible catecholamine content of such cells.

Effect of Vasopressor Substances on the Thoracic Duct Lymph Flow

PREVIOUS observations on the effect of vasopressor substances on the thoracic duct lymph flow have been summarized by Haynes[1] and Ruscynyák *et al.*[2]. However, there is still a certain amount of disagreement in the literature and previous investigations have only shown changes in lymph flow rate without recording blood pressure. Recently adrenaline[3,4] and noradrenaline[3] were observed to stimulate the thoracic duct lymph flow in dogs. An increase in lymph flow rate following administration of angiotensin was also demonstrated in our laboratory[5]. The mechanism underlying the lymph production due to vasopressor substances, however, is not completely understood. The present communication reports experiments carried out on rats in which the effects of various vasopressor substances on thoracic duct lymph flow were studied and compared.

Experiments were performed on heparinized (1,000 U./kg) male Wistar rats weighing 150–250 g, which had been anaesthetized by intraperitoneal administration of 25 per cent urethane solution (5 ml./kg). The subdiaphragmatic thoracic duct cannulation[6] and measurements of lymph flow were identical with those previously described[5]. The lymph flow rate was determined by measuring the volume for 5-min periods. Arterial blood pressure was recorded with a mercury manometer from the common carotid artery. After a steady flow rate had been established for 20 min as a control period, vasopressor substances in 0·2 ml. saline solution were injected intravenously for 90 sec. A total of thirty-nine tests were performed on thirty-two rats.

The thoracic duct lymph flow rate and its response to vasopressor substances showed considerable individual variation. Initial blood pressure ranged from 80 to 120 mm mercury and initial lymph flow rate ranged from 0·015 ml./5 min to 0·040 ml./5 min. In each test the mean value obtained in the control period was taken to be the 100 per cent value and all measurements concerning either blood pressure or lymph flow rate were expressed as a percentage of the control. Mean responses of blood pressure and lymph flow rate to various pressor substances are shown in Fig. 1.

Various grades of response in lymph flow rate were accompanied by variable pressor responses to the vasopressor substances, that is, 0·02 U. and 0·1 U. vasopressin (lysin-8-vasopressin, Sandoz), 0·5 μg noradrenaline, 0·5 μg α-angiotensin (α-L-asp[1]-angiotensin II-amide, 'Hypertensin', Ciba) and 0·5 μg β-angiotensin (β-L-asp[1]-angiotensin II). The increase in lymph flow rate lasted 25 min or more, while the rise in blood pressure passed more temporarily, especially within 5 min after noradrenaline and angiotensin administration. Magnitude and length of time of the increase in lymph flow rate were different among the substances. The mean percentage value and standard error for the total increase in lymph flow within 25 min after the injection was 44·0 ± 43·2 with 0·02 U. vasopressin, 58·2 ± 36·0 with 0·1 U. vasopressin, 173·0 ± 55·5 with 5 μg noradrenaline, 102·1 ± 64·8 with 0·5 μg α-angiotensin and 182·0 ± 101·0 with 0·5 μg β-angiotensin. Although vasopressin caused the greatest rise in blood pressure, the total increase in lymph flow following 0·1 U. vasopressin was significantly smaller ($P > 0·05$) than that after 5 μg noradrenaline or 0·5 μg α-angiotensin. Noradrenaline, which showed the same pressor effect on arterial blood pressure as α-angiotensin, caused a significantly greater increase in total lymph flow than angiotensin ($P > 0·05$). 0·5 μg β-angiotensin seemed to induce a greater increase in lymph flow than 0·5 μg α-angiotensin. However, the difference is statistically not significant because of large individual variations in the former group.

According to Bollman *et al.*[6], about 80 per cent of the thoracic duct lymph is contributed by intestinal lymph

and about 20 per cent of it is derived from the liver in resting rats. The most probable factor responsible for the overproduction of lymph in intestine and liver following the administration of vasopressor substances is considered to be a temporary increase in capillary blood pressure in these organs, which is also accompanied by other haemodynamic changes. Intestinal motility has been observed to have no definite effect on lymph flow rate[7]. It has long been known[8,9] that elevated venous pressure increases capillary pressure and lymph formation more than similar changes of arterial blood pressure[10,11]. However, attention should be paid to the fact that the draining vein is the portal vein for the intestine while for the liver it is the hepatic vein. Noradrenaline is known to increase either caval or portal venous pressure[12,13], while angiotensin has been observed to induce a slight increase in caval venous pressure but no change[14] or a decrease[15] in portal venous pressure. Our explorative experiments, however, showed an elevation of portal venous pressure of about 50 mm water for 5 min following the intravenous administration of 0·5 μg angiotensin to 12 rats (unpublished data). The equipressor dose of noradrenaline has been shown to cause a greater increase in caval venous pressure than angiotensin[13]. None of these findings contradict the fact that the equipressor dose of noradrenaline causes a greater increase in total lymph flow than does angiotensin. As Fig. 1 shows, lymph flow responses following the administration of vasopressor substances lasted much longer than did the changes in blood pressure. It could not be ascertained, however, whether or not any other factor (such as an increased capillary permeability) plays a part in the sustained lymph flow rate. An initial decrease following administration of vasopressin is considered to be due to a sudden fall in portal blood pressure after vasopressin[16–18].

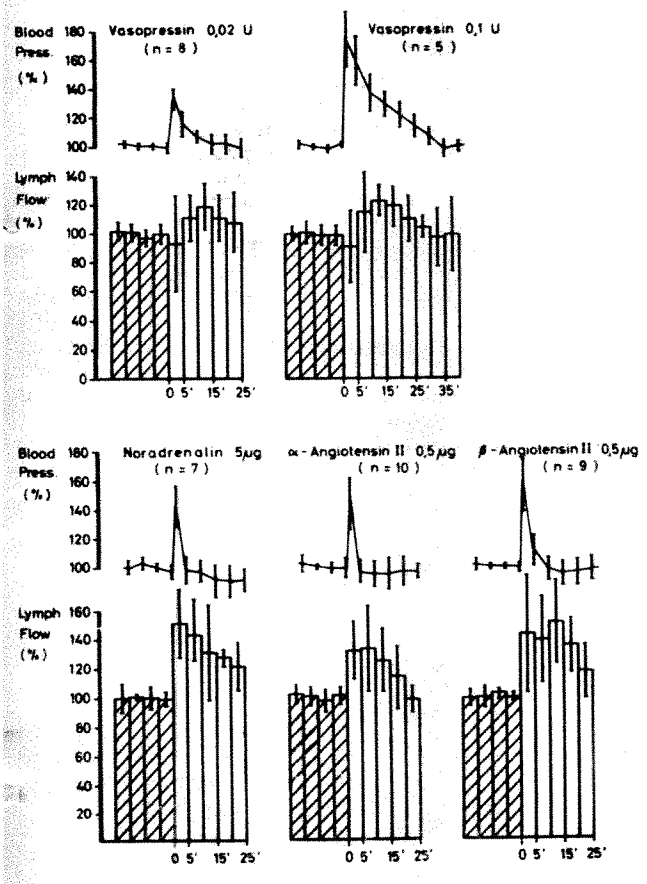

Fig. 1. Blood pressure and lymph flow before (shaded column) and after (white column) the administration of various vasopressor substances. For details see text

Vasopressin was recently observed to cause an accentuated and sustained constriction of venous blood vessels, but only a moderate constriction of arterial blood vessels using hind leg preparation of cats[19]. If the abdominal blood vessels were to respond similarly to vasopressin, the latter increase in lymph flow rate following vasopressin could also be explained by a rise in capillary blood pressure.

We thank Ciba, Ltd., Basle, for supplying the hypertensin analogue β-L-asp[1]-angiotensin II (substance 33,902–*Ba*).

α-Methyldihydroxyphenylalanine and Release of Noradrenaline

IT is now generally accepted that α-methyldihydroxyphenylalanine (α-methyldopa) is an effective means of lowering the blood pressure in cases of hypertension. The mechanism of its action, however, is by no means clear. One of the known actions of α-methyldopa is the inhibition of the enzyme dopadecarboxylase, and, as this enzyme is involved in the synthesis of noradrenaline, it was thought that its inhibition could explain the lowering of the blood pressure. It was found[1,2] that α-methyldopa caused depletion of noradrenaline in the brain and heart, and at first this seemed to support the ideas about its hypotensive action. The duration of tissue noradrenaline depletion was, however, far greater than the duration of the dopadecarboxylase inhibition and the lowering of blood pressure. Furthermore, stronger decarboxylase inhibitors than α-methyldopa do not cause a lowering of blood pressure in hypertensive patients[3]. Animal experiment has shown[4] that, despite noradrenaline depletion of tissues, α-methyldopa does not interfere with the effects of sympathetic nerve stimulation.

In view of the uncertainty about the action of α-methyldopa, experiments were designed to see if this substance affected the release of the chemical transmitter of the sympathetic nervous system.

Cats were anaesthetized with chloralose (80 mg/kg) given intravenously after induction with ethyl chloride and ether. The release of noradrenaline by the postganglionic sympathetic nerve fibres was measured in the spleen, by the method of Brown and Gillespie[5]. They found a relationship between the output of noradrenaline from the spleen and the frequency of stimulation of the splenic nerves. At a frequency of 30/sec the mean output is 980 pg/stimulus and at 10/sec it is 160 pg/stimulus.

In the present work, the output of noradrenaline has been measured after both chronic and acute treatment with α-methyldopa. In chronic experiments, the cats were given intraperitoneal injections of α-methyldopa (100 mg/kg) between 5 and 16 h before the experiment. In some experiments, in which treatment was started up to 30 h before the acute experiment, a second injection of α-methyldopa was given. In the acute experiments, the α-methyldopa was given intravenously (100 mg/kg) or by close arterial injection (10–15 mg) into the spleen by way of the hepatic artery. In all experiments, the output of noradrenaline from the spleen in response to splenic nerve stimulation at frequencies of 30 and 10/sec was normal, regardless of the method or duration of the treatment with α-methyldopa.

It was shown, further, that in normal anaesthetized cats the output of noradrenaline at a stimulus frequency of 10/sec is raised by giving the adrenergic blocking agent phenoxybenzamine, while that at 30/sec shows little alteration. It is thought that in the presence of phenoxybenzamine the output of noradrenaline as a result of nerve stimulation is a good indication of the actual release by the nerve endings. Treatment with α-methyldopa did not cause any alteration in the action of phenoxybenzamine. It is concluded, therefore, that α-methyldopa has no effect on the release of noradrenaline by the postganglionic sympathetic splenic nerves.

In some experiments the blood pressure responses of cats treated with α-methyldopa were investigated. The pressor responses to clipping the common carotid arteries and to splanchnic nerve stimulation were the same before and after intravenous α-methyldopa. In cats which had been pretreated with α-methyldopa, the pressor responses were no different from those in control animals. These findings are consistent with observations on the effect of α-methyldopa on the cardiac contractility response to stellate ganglion stimulation[6] and on the cardiovascular responses to central vagal stimulation[7].

PHARMACOLOGY

'Thalidomide' Syndrome in Baboons

NUMEROUS attempts to reproduce the malformations which occurred in human babies from 'Thalidomide'-treated mothers have met with only limited success[1–3]. Although many representatives of aves and mammalian experimental species have been investigated for this purpose, the results fall short of paralleling the effect of the drug on the human foetus[4]. Sub-human primates have been utilized on two occasions[5,6]. Lucey and Behrmann[5] showed that treating rhesus monkeys with 'Thalidomide' before implantation resulted in the inhibition of implantation. Delahunt and Lassen[6] induced typically malformed foetuses in four of seven pregnant *Cynomolgus* monkeys which were treated after implantation had already occurred (days 32–42). Although the embryology of the baboon has not been investigated as extensively as that of some other sub-human primates, developmental processes paralleling those in the human have been found[7]. Further investigation of the embryology is in progress.

Fig. 1. A normal foetus (9 weeks)

Our experiments reveal that 'Thalidomide', given in relatively low dosage (5 mg/kg) *per os*[8] at the time of conception, does not prevent nidation in the baboon (in contrast to rhesus) and that distinct deformities are induced in the baboon embryo and foetus which are associated with the 'Thalidomide' syndrome as observed in man[9].

Ten female baboons were used in the present investigation. They were placed with a male for a 2-day period except in two cases (*A*-331 and *A*-336) in which mating occurred for 5 days. The time of mating was based on perineal turgescence, vaginal smears and the interpretation of previous cycles[10]. Mating for a 2–12 h period was successful in at least ten cases in which embryos were delivered in early stages of development. Mating over long periods of time has not been found necessary when these criteria were used and a history of the menstrual cycle was known.

Four female baboons were given 'Thalidomide' (5 mg/kg) orally from the time of ovulation (day 0) until the animals recycled (no conception) or until day 30. Pregnancy was confirmed in one of the four females (*A*-336) on the twentieth day by digital palpation and is currently in the sixth week of gestation.

Five female baboons (*A*-74, *A*-303, *A*-331, *A*-466 and *N*-20) received 'Thalidomide' (5 mg/kg) starting between days 18 and 20 of gestation, except for female *N*-20, which received the first dosage on the twenty-second day. The duration of the treatment was varied but ranged between 12 and 22 days. Table 1 summarizes the results of the experiment.

Female *A*-466 aborted during the ninth week of gestation and only the placenta was recovered. Caesarean

Table 1

Animal No.	Start of treatment (days gestation)	Duration of treatment (days)	Gross observation
A-336	0	30	Pregnant, sixth week
A-74	18	14	Amelia, spina bifida cystica. Slight malformation of ear
A-303	18	12	Amelia, posterior limb. Phocomelia, anterior limb. Bilateral cleft lip. Agnathia. Retarded growth
A-331	18	18	Resorbing
A-466	18	18	Spontaneous abortion, foetus not recovered
N-20	22	22	Oedema, single umbilical artery
A-167	30	10	Normal

Fig. 2. A malformed baboon foetus (9 weeks). Arrows indicate the deformity of the limbs, spina bifida and slight malformation of the ear

sections were performed during the ninth week of gestation on females *A*-74, *A*-303, *A*-331 and *N*-20. The foetus of *A*-74 was grossly malformed (Fig. 2). All four limbs were severely retarded in growth (amelia) (verification of this malformation is being sought histologically); spina bifida cystica and shortening of the tail were also apparent. The ears showed a slight malformation, having rotated slightly more posteriorly than normal. The foetus of *A*-303 showed a marked retardation in development, being equivalent to a normal 40-day baboon embryo in overall size. The foetus was probably dead but the overall composition appeared quite normal; the diameters of the chorion and amnion were equivalent to other 9-week foetuses, but the extra-embryonic fluid had a very definite yellow tinge as did the fluid of the other animals in the experiment. The gross malformations were amelia of the posterior limbs, phocomelia of the anterior limbs, bilateral cleft lip and agnathia.

Female *A*-331 showed blood on the external genitalia, just before surgery, and was in the process of aborting judging by coloration and foetal–maternal tissue relationships. The foetus was almost entirely resorbed and appeared as a white stringy mucous mass within the normal-appearing amnion and chorion. The overall dimensions of the entire embryonic sac were considerably smaller than normal.

The foetus of *N*-20 was characterized by extreme oedema and a single umbilical artery. Since oedema is often associated with venous complications, additional cardiovascular anomalies are strongly suggestive and will be studied histologically.

To test the effects of 'Thalidomide' during the second month of pregnancy, female *A*-167 received 100 mg/kg for 10 days starting with day 30. A normal foetus, as observed by gross examination, was delivered by Caesarean section at three and one-half months.

Based on the present findings, the hypothesis advanced by Lucey and Behrmann[5] that 'Thalidomide' kills the embryo prior to implantation cannot be supported. In the baboon, at least, it is suggested that a close relationship in the early reproductive physiological processes exists between man and the baboon. Experimental work on armadillo[11,12] and rabbit[13] embryos suggests that 'Thalidomide' damages only the embryoblastic cells, leaving the trophoblastic cells uninjured and capable of implantation. This is also borne out by our experiments, as exemplified by the foetuses of *A*-303 (retardation of development, gross anomaly and apparent foetal death) and *A*-331 (remnant of a resorbing embryo), and yet both these embryos were supported by normal membranes.

The foetal malformations described for the baboon are identical in type to most of those described in the newborn infants of women receiving 'Thalidomide'[8]. The deformities are distinct and occurred in all animals treated at minimum dosages. The effect of this drug on developmental processes in the baboon and the parallelism to the human is striking.

Lysosomes and Gout

IN recent years there has been much interest in the role of crystals in causing acute attacks of gout. Faires and his colleagues at Philadelphia[1] and Seegmiller *et al.* at Bethesda[2] were able to produce such attacks by injecting microcrystalline sodium monourate into gouty and non-gouty volunteers. With this experiment in mind, investigations were undertaken, at cellular and sub-cellular level, of events that may be important in initiating the inflammatory phenomenon in acute gout.

Microcrystals of sodium monourate were prepared by the method of Seegmiller *et al.*[2]. Fresh human polymorphs were obtained by sedimenting fresh blood in heparin with 1/10th volume of 6 per cent dextran in saline. Most of the white cells were in the upper plasma layer which was sampled for cell counts; 0·1 ml. of the cell suspension in the patients' own plasma was then placed on an ordinary 3 in. × 1 in. glass slide and covered with a 19 mm × 38 mm cover-slip, three sides of which were sealed with 'Vaseline'. Crystals ranging in length from 0·5μ to 8μ were suspended in normal saline and a drop of the suspension was introduced into the preparation through the unsealed side.

The slide, resting on a pad of wet cotton wool, was enclosed in a Petri dish and incubated at 37° C in a sealed incubator periodically flushed with 5 per cent carbon dioxide in air.

The polymorphs readily ingested the smaller crystals and rapidly became degranulated, the process being completed within a few minutes (Fig. 1). The dissolution of the granules was readily observed in living cells vitally stained with acridine orange and examined by phase contrast. The cells showed a different type of response to crystals longer than 8μ or to clumps of small crystals; they were unable to engulf such large bodies, and instead clustered around them to form rosettes (Fig. 2), which were also rapidly degranulated.

The effect of colchicine on polymorphs exposed to crystals of sodium monourate was investigated; the cultures were observed at 5-min intervals up to 60 min. In the presence of the drug, some cells failed to phagocytose crystals, while others ingested crystals but were not degranulated (Fig. 3). It was thought that these phenomena indicated a stabilizing action of colchicine on the

membrane systems of the cell and particularly on the membranes of the cytoplasmic granules.

Recent work (by Novikoff)[3] has shown that the characteristic granules of polymorphs are lysosomal in nature and contain acid hydrolases in a bound form. Preliminary experiments were carried out to see whether colchicine would have a direct stabilizing action on the isolated granules *in vitro* and inhibit the release of their enzymes. Granules were isolated from polymorphs by the technique of Cohn and Hirsch[4], treated *in vitro* with the drug at concentrations of 5–50 μg/ml., and incubated for 60 min at 37° C. After incubation the suspension was spun at 10,000*g* for 20 min and the proteolytic activity of the supernatant was measured by the method of Anson[5] with 4 per cent (weight/volume) haemoglobin in 0·1 M acetate buffer at *p*H 4 as the substrate. Activity was expressed either as μg of acid-soluble tyrosine released by 1 ml. of suspension after 20 min incubation at 37° C or as the percentage of the total activity of the sample measured after the release of the protease by the non-ionic detergent 0·1 per cent *BRIJ* 35. Preliminary results showed that 75 per cent of the total proteolytic activity of the normal 'granular-mitochondrial' fraction was recovered from the supernatant. When the granule fraction was pretreated with colchicine, however, only 50 per cent of the activity was released. Thus it would appear that colchicine reduced the titration of bound enzyme.

The results of this investigation suggest that in acute gout, the polymorphonuclear leucocytes either ingest or adhere to microcrystals of sodium monourate, become degranulated and release lysosomal enzymes into the tissue; this reaction may be partly responsible for the subsequent inflammatory changes. If so, then colchicine may produce its therapeutic effects by stabilizing the lysosomal membranes and thus preventing degranulation

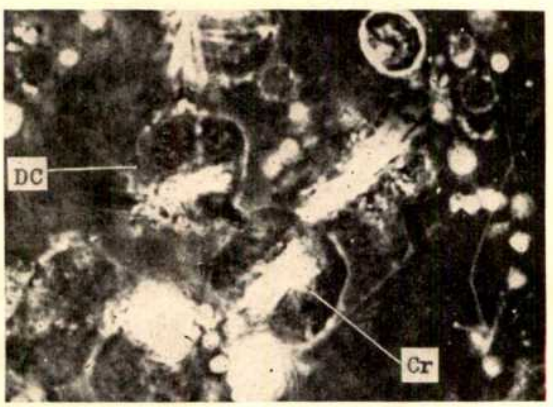

Fig. 1. *DC*, Degranulated cell; *Cr*, crystals. Stained with acridine orange: phase contrast (× 750)

with consequent liberation of hydrolases; in this way, by limiting degranulation following phagocytosis, the drug may break the vicious circle of inflammation.

IMMUNOLOGY

Species Distribution of Gastrointestinal Antigens

IMMUNOFLUORESCENCE provides a simple means of studying the species distribution of antigenic components of animal tissues[1]. The availability of gastrointestinal-specific antisera as immunohistological reagents prompted us to explore the distribution of gastrointestinal antigens in mammalian and other vertebrate fauna of Australia. Two types of sera were used. One, prepared in rabbits by immunization with microsomal material from fresh surgical specimens of human colonic mucosa, had been previously shown to react with an acid mucopolysaccharide component of human and some other mammalian gastrointestinal mucosal cells and with no other tissue in the body[2]. The other, obtained from patients with pernicious anaemia, contains naturally occurring autoantibody to human gastric parietal cells; this antibody has also been shown not to be species-specific[3].

The investigation was conducted on separate tissue blocks from stomach, small intestine and large intestine taken usually within 1 h of death from a large variety of mammals, as listed in Table 1, and other vertebrate species. Blocks, snap frozen in liquid nitrogen–isopentane freezing mixture at about −160° C or, less satisfactorily, in containers cooled to −76° C in a dry ice–alcohol mixture, were stored at −70° C until they were sectioned at 6μ in a cryotome at −20° C; sections were air-dried at 0°–2° C. In the case of the gastrointestinal-specific rabbit serum, staining was normally carried out on sections fixed for 2 min in 95 per cent ethanol at 0°–2° C by direct immunofluorescence using a conjugate with lissamine rhodamine *B* (*RB* 200); sandwich staining with conjugated anti-rabbit

globulin was also used in some confirmatory experiments. With the pernicious anaemia sera, unfixed sections of gastric fundus were stained by the sandwich method using *RB* 200-conjugated anti-human globulin. Stained slides were examined by brightground ultra-violet-blue fluorescence microscopy. Details of the technical methods are described elsewhere[4].

Specificity of the immunofluorescence reactions of the two antisera was demonstrated by failure to stain tissues other than gastrointestinal mucosa or gastric parietal cells, respectively; these were themselves not stained by labelled normal pre-immunization rabbit serum or by normal human serum. Confirmatory information was obtained by cross-absorptions of the antisera with homogenates of colon, stomach fundus or liver of various animals.

The results are summarized in Table 1. With the rabbit antiserum, staining was obtained in all the mammalian colons, but, except for a positive reaction with the human foetus, staining of small intestine was seen only in the adult placentals and two marsupials (koala and marsupial mouse); gastric staining was confined to man, monkey and pig. The reaction was strongest in colon, less intense in small intestine and least in stomach, where it was patchily distributed with the mucous cells. The most intense staining was given with the homologous (human) mucosa, while a strong but less-intense reaction was obtained with all other placentals examined except the rodents, in which it was least and, moreover, not regularly obtained. Marsupial gastrointestinal tract either gave similar staining intensity to the rodents or a little better, and gastric staining was not seen. In the monotremes, colonic staining only was found, but this was as intense (Fig. 1) as that of any of the placentals other than man.

With the pernicious anaemia serum, staining was limited to gastric parietal cells. It was most intense in the placentals among which no conspicuous difference in brightness was seen, and was uniformly of lesser degree in the marsupials (Fig. 2); no reaction was seen with the monotreme stomachs. Positive staining was invariably obtained where there were gastric parietal cells as recognized by conventional histological methods; these cells were never detected in specimens giving negative immunofluorescence reactions.

No staining was observed in animals from any other vertebrate class. These included seven bird species (domestic fowl (2), hawk, kingfisher, kookaburra (3), magpie, seagull (2) and swamp hen), three reptile species (blue-tongued lizard (2), red-bellied black snake and tortoise), two amphibians (frog and toad), and thirteen fish species (including dogfish, shark, flathead, snapper, trevally, whiting, goldfish, tench, brown trout and rainbow trout). One invertebrate alimentary organ, from the squid, also gave negative results.

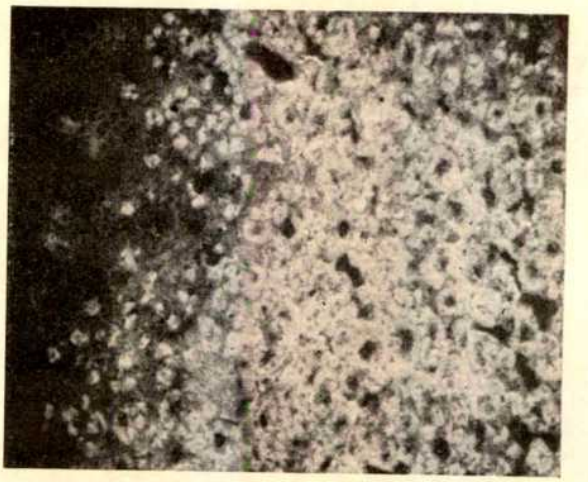

Fig. 2. Fresh frozen section of koala stomach fundus treated first with human pernicious anaemia serum and then with *RB* 200-conjugated goat anti-human-globulin. Staining limited to the parietal cells. (×90)

The cross-antigenicity in the gastrointestinal tracts of the mammals was confirmed by the serum absorption studies. Neither serum showed any inhibition of staining from absorption by non-mammalian gastrointestinal homogenates or by liver homogenate of any species. With rabbit-serum reactions, complete inhibition of staining was achieved only by absorption with human colon homogenate. Colon homogenates from other species were effective in inhibiting staining of that species, but only partially so in inhibiting staining of human colon; in this respect species which gave the least staining had the least inhibitory power.

With the pernicious anaemia serum, less exhaustive absorption studies were carried out, but they suggest greater antigenic identity between the mammalian gastric parietal cells. Just as staining intensity did not vary materially among the placentals or among the marsupials, absorption inhibition of staining appeared to depend only on the concentration of parietal cells in the stomach from which the absorbing homogenate was derived; when these

were abundant, complete inhibition was achieved. Rat gastric fundus was, for example, completely effective as an absorbing agent in inhibiting staining of human gastric parietal cells by the pernicious anaemia serum.

The relatively poor and somewhat inconstant staining of rodent gastrointestinal mucosa by the rabbit antiserum is worthy of comment. As the serum had been prepared in a rabbit, its lesser reaction with this and other rodents can perhaps be attributed to a partial failure to develop gastrointestinal autoimmunity or immunity against too closely related gastrointestinal antigens of the other rodents. In earlier investigations of the properties of the antiserum[2], staining of rodent gastrointestinal mucosa was not observed in the few animals examined. The present positive results are presumably the outcome of working with different animal strains in larger numbers and perhaps of the introduction of liquid nitrogen snap-freezing as a technical improvement in preserving tissue antigens for immunohistology. The last-mentioned point may also explain the present failure to confirm our previous tentative suggestion that there might be systematic differences in the anatomical distribution of gastrointestinal staining by the rabbit serum between ruminants and carnivores. The negative findings in some young animals (pup and kitten) reflect some species variation when compared with the positive results in human foetuses and in the lamb.

Perhaps the most interesting observation from the present investigation is the demonstration of closer antigenic similarity between placental and monotreme colonic mucosa than the marsupial, in contrast with the total absence of gastric parietal cell antigen in the monotremes, though abundant in placentals and marsupials. The limitation of the gastrointestinal antigens to the mammals also differs from the distributional behaviour of a kidney-specific material demonstrated in various vertebrates including mammals, birds and fish[1].

We thank the Department of Fisheries and Wildlife for help in gathering the specimens, and Miss R. M. Stevens, Mr. A. Maxwell and Mr. D. Quinn for technical assistance. The work was supported by grants from the Anti-Cancer Council of Victoria and the National Health and Medical Research Council.

Growth of *L1210* Leukaemia Cells

THERE is evidence that the number or size of the cell inoculum, the site of inoculation, the host of origin or the conditioning of the host[1] can alter the strain specificity of neoplasms and that some neoplasms can be transplanted from strain of origin and grow progressively in homologous strains with the animals dying of the neoplastic disease. Greene[2] reported the successful transplantation of heterologous neoplasms into the brains of rats and mice and suggested that the brain might be exempt from any immunological response.

The present communication concerns investigations of the progressive growth of leukaemia *L1210* implanted intracerebrally at various log-dose inocula into homologous strains of mice which grew (*BDF1*, *CDBA*) or regressed (*C3H*, *C57BL/6*) when an intraperitoneal inoculation of 5×10^6 cells was used.

Leukaemia *L1210* cells were collected from a *DBA/2* host which had been inoculated intraperitoneally 6 days previously. A cell count was carried out and the stock was diluted with cold Earle's balanced salt solution (EBSS) so that the cell inoculum was injected intracerebrally in 0·025 ml. using a microlitre syringe (Hamilton Co.) by penetrating the skull with a 27-gauge needle. Ten mice of each strain (*BDF1*, *CDBA*, *C3H* and *C57BL/6*) were used at each dose-level. The animals were observed daily for survival and subsequent death due to tumour growth.

The results (Table 1) indicate that the intracerebrally implanted *L1210* was lethal to compatible hosts (BDF_1 and *CDBA*) with an inoculation of ten cells, whereas the number of cells necessary to kill more than 50 per cent of the mice was greater than ten cells for *C3H* mice and greater than 1,000 cells for *C57BL/6* mice.

The data reveal that, at the higher cell inocula, *L1210* grows progressively in the brain probably because of its ability to overcome an immunological response, whereas at lower cell inocula the immune mechanism exists but is not as effective as the response elicited by the intraperitoneal inoculation of the leukaemia cells.

It would appear that each mouse strain may have its own threshold level for growth of incompatible neoplasms when brain is used as the site of inoculation. This may, in turn, be an expression of the antigenicity of each tumour or the natural resistance of the host.

This investigation was supported by a contract with the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health.

PATHOLOGY

Carcinogenic Action of *N*-Methyl-*N'*-nitro-*N*-nitrosoguanidine

N-Methyl-*N'*-nitro-*N*-nitrosoguanidine (NG) is known to be a potent mutagenic substance for *Escherichia coli*[1], *Salmonella typhimurium*[2], and *Chlamydomonas reinhardi*[3]. Induction of chromosomal aberrations in the cells of root meristems of *Vicia faba* by NG has been reported[4]. It is claimed that NG is the most potent mutagen yet discovered, since NG induced at least one mutation per cell of *Escherichia coli* treated at the optimal condition permitting 50 per cent survival[5]. The production of a number of multi-site mutants resulting from the accumulation of single-site mutations has been noticed[2,5].

This report deals with the carcinogenic activity of NG. NG was purchased from K and K Laboratories, Inc., New York, and was dissolved in warmed sterile saline at a concentration of 5 mg per ml. Wistar strain male rats,

Initially 6 weeks old, were maintained on commercial CE-2 animal diet and water *ad libitum*. Either 0·2 ml. or 0·5 ml. of the NG solution was subcutaneously injected into the backs of these animals once a week as near as possible in the same site; the total doses of NG per animal were 10 or 25 mg. Any tumours which formed were removed when an animal died or when they reached an area of 2 × 3 cm. Tumours were histologically examined and subcutaneously transplanted into young normal rats by the trocar method. During the period of application of NG, ulcerations occurred in some of the animals, but they gradually subsided after the last injection.

Twenty-four rats survived for a period of 5 months after the first injection and the observations were continued for a further 7 months. The results are summarized in Table 1. The tumour incidences were 33 and 50 per cent in animal groups which received total doses of 10 and 25 mg, respectively. Most of the tumours were typical fibrosarcoma, but there were single cases of myxomatous fibrosarcoma, medullary-type fibrosarcoma, fibrosarcoma with giant cell, and rhabdomyosarcoma. The tumour transplantability is also recorded in Table 1. The rate of takes of transplants ranged from 20 per cent to 66 per cent in the first generation.

The mechanism of this carcinogenicity is obscure, but the alkylation of nucleic acids and/or proteins may be involved in the process as in the case of dimethylnitrosoamine, revealed by Magee *et al.*[6]. Although it was reported that NG yields neither nitrous acid nor diazomethane in neutral condition[5], enzymes may exist which catalyse this reaction *in vivo*.

We are now exploring various ways of applying NG with the hope of producing different types of tumour in different organs.

This work was supported in part by a grant from the Japanese Ministry of Education. We thank Dr. T. Baba of the Pathology Division of this Institute for making the histopathological diagnoses.

MICROBIOLOGY

Methaemoglobin Formation by *Mycoplasma gallisepticum*: the Role of Hydrogen Peroxide

Mycoplasma gallisepticum, the agent responsible for common respiratory disease of turkeys, has been shown to agglutinate turkey erythrocytes[1]. During the course of investigations of a neurotropic strain of this organism (*S6*) which produces encephalitis associated with cerebral arteritis[2], it was observed that incubation of a suspension of *M. gallisepticum* with washed turkey erythrocytes at 37° C caused the cells to become dark brown. Washed mycoplasmas enclosed in dialysis tubing also caused browning of erythrocyte suspensions and converted turkey and human haemoglobin to a brown solution which exhibited the spectral characteristics of methaemoglobin.

Methaemoglobin formation was studied in a system consisting of 5×10^9 mycoplasmas, washed three times, suspended in 0·5 ml. of buffered Ringer's solution and enclosed in dialysis tubing which was submerged in 5 ml. of a 0·16 per cent haemoglobin solution. The addition of galactose, mannose or glucose, in concentrations of 25 mg/ml., resulted in the appearance of methaemoglobin after 15 min of incubation at 37° C. In the absence of a sugar the same process required 1–2 h. Mycoplasmas incubated at 4° C, with or without added sugar, and organisms killed by heating at 50° C for 30 min, or disrupted by ten cycles of rapid freezing and thawing, failed to produce methaemoglobin.

The browning of intact turkey erythrocytes by mycoplasmas was also temperature-dependent, accelerated by the addition of simple sugars, and not produced by heat-killed or disrupted mycoplasmas. The addition of 10^9 mycoplasmas to 2 ml. of a 2 per cent suspension of erythrocytes containing galactose or mannose resulted in methaemoglobin formation after incubation for 15 min at 37° C. Although methaemoglobin was not formed by mycoplasmas at 4° C, the organisms rapidly became attached to the surface of erythrocytes at this temperature, and Giemsa-stained films showed individual erythrocytes to be coated with numerous mycoplasmas. When such cells were washed three times in cold Ringer's solution, using low-speed centrifugation to eliminate unattached mycoplasmas, the majority of erythrocytes were still coated with ten or more organisms. The washed, coated cells were resuspended in buffered Ringer's solution to a 2 per cent concentration, and incubated at 37° C. In the presence of mannose or galactose, the cells became dark brown within 15 min; without added sugar the reaction required 2 h or longer. It thus appeared that the presence of actively metabolizing mycoplasmas on the surface of erythrocytes facilitated methaemoglobin formation. It was estimated that the number of cell-attached mycoplasmas required for browning of erythrocytes was less than 0·25 per cent of the number needed when the organisms were separated from the erythrocytes by dialysis membranes.

In view of the known capacity of hydrogen peroxide to form methaemoglobin, and the reported absence of detectable catalase in several strains of mycoplasma[3], it seemed possible that the dialysable factor produced by *M. gallisepticum* might be hydrogen peroxide. No catalase activity could be detected in sonically disrupted *M. gallisepticum* in this laboratory. Accordingly, catalase and peroxidase were tested for their ability to prevent methaemoglobin formation by mycoplasmas.

Horseradish peroxidase in combination with ascorbic acid, protected turkey haemoglobin against the action of mycoplasmas contained in dialysis sacs (Table 1). As little as 40 μg of enzyme per ml. prevented the appearance of methaemoglobin.

Catalase had a similar protective effect. With mycoplasmas contained in dialysis sacs surrounded by hae-

moglobin, the presence of 40 μg of the enzyme per ml. prevented the formation of methaemoglobin (Table 2). Bovine serum albumin, at a protein concentration 2·5 times that of catalase, afforded no protection. When a 'moat' was created between the mycoplasmas and haemoglobin, by a system comprised of a dialysis sac of mycoplasmas and one of haemoglobin, both suspended freely in a solution of buffer containing catalase, as little as 1 μg per ml. of enzyme prevented the formation of methaemoglobin (Table 3). In this system, the lowest molar concentration of catalase haem groups which afforded protection was less than 0·1 per cent of the protected haemoglobin haem groups, indicating that the catalase protection was enzymatic rather than competitive.

By using an excess of horseradish peroxidase in combination with 4-methoxy-α-naphthol[4], it was possible to detect and measure peroxide in high speed supernatants prepared from mycoplasma suspensions (Table 4). No peroxide was detectable in washed suspensions of mycoplasmas held at 4° C. In contrast, portions of 5×10^9 organisms incubated in the presence of mannose elaborated hydrogen peroxide in amounts of $6{\cdot}3 \times 10^{-5}$ M during 10 min at 37° C. The kinetics of peroxide production and its stimulation by sugars closely paralleled the kinetics of methaemoglobin formation by *M. gallisepticum*.

Colonies of *M. gallisepticum*, growing at the surface of PPLO-agar[5], produce sharply delineated areas of α-haemolysis when the agar is covered with a new layer of agar containing 4 per cent turkey or human blood. The incorporation of catalase in the blood agar overlay prevented the development of haemolysis (Table 5). The appearance of plates in the presence and absence of catalase is illustrated in Fig. 1.

It is not known whether the observations reported here apply in general to other mycoplasma species. We have also observed methaemoglobin formation by a dialysable factor elaborated by suspensions of *M. pneumoniae* and *M. neurolyticum*. In both instances the reaction was inhibited by the presence of catalase.

Table 1. EFFECT OF PEROXIDASE ON MYCOPLASMA-INDUCED METHAEMOGLOBIN FORMATION

Time (min)	Mycoplasma peroxidase	Mycoplasma no peroxidase	No mycoplasma peroxidase
0	−	−	−
30	−	+	−

Reaction mixtures were incubated at 37° C and contained 8×10^9 mycoplasmas (*M. gallisepticum*) in 0·8 ml. of Ringer's solution in dialysis tubing, turkey haemoglobin (0·157 per cent), potassium phosphate buffer, *p*H 7·2 (0·05 M), ascorbate (5×10^{-3} M) and horseradish peroxidase (Sigma) 40 γ/ml. The presence of methaemoglobin is indicated by '+'.

Table 2. EFFECT OF CATALASE ON MYCOPLASMA-INDUCED METHAEMOGLOBIN FORMATION

Time	Catalase	Albumin	No additive
0	−	−	−
30	−	+	+

Reaction mixtures were incubated at 37° C and contained mycoplasmas, haemoglobin and buffer as in Table 1, mannose (25 mg/ml.), beef liver catalase (Sigma) 40 γ/ml. or bovine serum albumin (0·1 mg/ml.) as indicated.

Table 3. EFFECT OF VARYING CATALASE CONCENTRATIONS ON MYCOPLASMA-INDUCED METHAEMOGLOBIN FORMATION

Incubation time	Catalase concentration (γ/ml.) 8	4	2	1	0
0	−	−	−	−	−
1·5 h	−	−	−	−	+

Reaction mixtures resembled those in Table 2 except that 1 ml. of turkey haemoglobin (0·167 per cent) in Ringer's solution was contained in a dialysis sac which was separated from the similarly enclosed mycoplasma suspension by buffer, mannose and catalase at the concentrations shown.

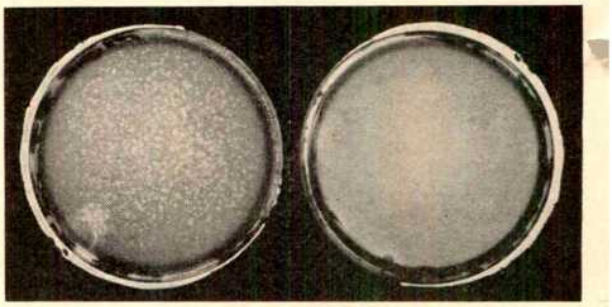

Table 4. PEROXIDE PRODUCTION BY *M. gallisepticum*

Conditions of incubation	0° C 1 h	Heat inactivated* mycoplasmas	37° C 5 sec	37° C 10 min
Peroxide detected	None	None	None	$6{\cdot}3 \times 10^{-5}$ molar

Reaction mixtures contained a suspension of 5×10^9 mycoplasmas in mannose (25 mg/ml.) and phosphate buffer *p*H 7·2 (0·05 M) in a 1 ml. volume. Following incubation the mycoplasmas were sedimented at 18,000*g* for 15 min and the supernatant was treated with peroxidase (4 u./ml.) and 4-methoxy-α-naphthol (2×10^{-4} M). The *O.D.* at 620 mμ was recorded on the Gilford spectrophotometer.
* 70° C for 15 min.

This work was supported by a contract from the U.S. Army Medical Research and Development Command Department of the Army.

Note added in proof. Following the submission of this paper, Somerson *et al.*[6] reported that the haemolysis produced by *M. pneumoniae* on blood agar plates is inhibited by catalase and peroxidase, and suggested that hydrogen peroxide was responsible.

Selective Uptake of an Antibilharzial Nitrothiazole Compound by *Schistosoma mansoni*

REPORTS on the uptake of schistomicidal drugs in the parasite are few and so far have been limited to ^{124}Sb-labelled antimonials[1,2]. Following the description of a potent nitrothiazole schistosomicide, 1-(5-nitro-2-thiazolyl)-2-imidazolidinone (Ciba 32,644-*Ba*)[3,4], the distribution of this compound was studied in mice infected with *Schistosoma mansoni*. The ^{14}C-labelled nitrothiazole was found to be highly concentrated in both adult worms and embryonated eggs.

Ciba 32,644-*Ba*, labelled with ^{14}C in position 4 of the imidazolidinone ring (I) (specific activity 2·3 μc./mg) (ref. 5), was administered orally to two female mice in a dose of 1 g/kg.

I

The animals, which had been infected with cercariae 7 weeks before treatment, were bled 6 h and 24 h after receiving the drug. Various tissues were fixed in phosphate-buffered 10 per cent formalin and embedded in paraffin. Adult worms were removed from the mesenteric veins and were carefully washed in saline before histological processing; segments of the intestine were treated in the same way. Microautoradiographs were prepared by covering 5μ sections with '*AR* 10' stripping

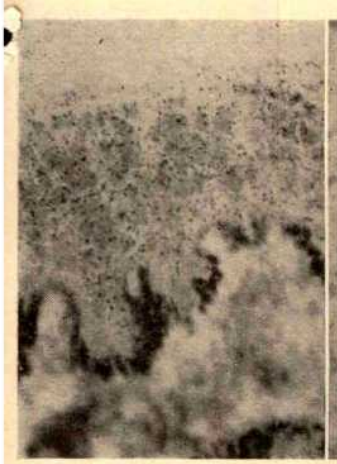

Fig. 1

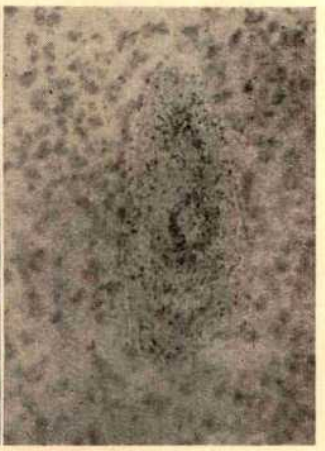

Fig. 2

Fig. 1. Autoradiograph of female *S. mansoni* shows high concentration of activity in vitellogenous cells, 24 h after treatment of the host with ^{14}C-labelled 32,644-*Ba*. Intestinal cells are covered with pigment deposits (×540)

Fig. 2. Heavy labelling of embryonated ovum in the liver tissue of an infected mouse, 24 h after treatment with ^{14}C-labelled nitrothiazole. Cells composing the granuloma contain little activity (×540)

film and exposing for 8 weeks at 4° C. Grain counts were made over 20 random areas of 10^{-4} mm^3 in each tissue examined.

The distribution of ^{14}C in the autoradiographs is given in Table 1. Female worms (Fig. 1) were found to incorporate the label to a larger extent than the males and the concentration in the deposited ova (Fig. 2) was greater than that in any other tissue except gastric mucosa. Eggs within the liver showed the same level of radioactivity as eggs deposited in the intestinal wall, despite the fact that the former were more densely surrounded by fibrous granulomata.

Table 1. AUTORADIOGRAPHIC DISTRIBUTION* OF ^{14}C IN *Schistosoma* AND IN TISSUES OF INFECTED MICE TREATED WITH A SINGLE ORAL DOSE OF 1 G/KG CIBA 32,644-*Ba* LABELLED WITH ^{14}C

* Grain number per unit area ($n = 20$), mean ± standard deviation.
† P ascertained with t-test.
N.S., not significant.

In the majority of the host tissues, radioactivity levels were fairly uniform and there was little or no increase with time. The high concentration found in the intestinal mucosa appears to be consistent with prolonged absorption of the orally administered compound.

Studies in species other than the mouse[5] have indicated that the absorption of ^{14}C-labelled 32,644-*Ba* proceeds slowly over several hours following a single oral dose. During absorption, the plasma concentration of the unchanged product is maintained at a low level (about 0·5 μg/ml.) since rapid metabolic conversion of the compound occurs in the tissues. This leads to an increase in the plasma level of the metabolites. The latter are excreted slowly in the urine, as well in the bile and faeces.

In order to exclude the possibility that the accumulation of ^{14}C in the parasite was due to the uptake of metabolites, an *in vitro* incubation technique[4] was used.

Pairs of adult worms were incubated for 24 h at 37° C either in rabbit plasma to which was added ^{14}C-labelled 32,644-*Ba* or in metabolite-containing plasma obtained from rabbits pretreated 48 h previously with 100 mg/kg of the compound. The parasites (about twenty pairs of approximately 15 mg wet weight) were then ashed and their activity was determined by liquid scintillation spectrometry. The results (calculated with the aid of a ^{14}C–32,644-*Ba* standard) are given in Table 2. The data indicate that only the non-metabolized nitrothiazole was incorporated by the parasite. The rate of incorporation was independent of the concentration of 32,644-*Ba* in the medium at low levels. The small amount of label which was taken up by parasites from metabolite-containing rabbit plasma was due presumably to the presence of traces of unchanged nitrothiazole. By means of thin-layer chromatography of lyophilized homogenate of worms on silicic acid (solvent system: chloroform-dimethylformamide, 9 : 1) it was shown further that treated parasites contained only metabolites of 32,644-*Ba*.

Table 2. *In vitro* UPTAKE OF ^{14}C-LABELLED CIBA 32,644-*Ba* AND ITS METABOLITES BY *S. mansoni*

Addition to incubation medium	Concentration in Plasma (μg/ml.)	Parasites (μg/g)	Incorporation index
32,644-*Ba*	0·58	34	59
32,644-*Ba*	1·65	98	59
32,644-*Ba*	12·9	121	9
Metabolites*	9·1	1·4	0·15

For conditions of experiment see text. The lowest plasma concentration used (0·58 μg/ml.) corresponds to the level of Ciba 32,644-*Ba* attained *in vivo*.
* Containing traces of non-metabolized nitrothiazole (approx. 0·005 μg/ml.).

The present results allow the conclusion that unchanged Ciba 32,644-*Ba* is taken up from body fluids both by adult *Schistosoma mansoni* parasites and by embryonated eggs over a prolonged period of time and that metabolites accumulate in organs of the parasite. Rapid metabolic conversion of the nitrothiazole by the parasite appears to be responsible for the ensuing tissue damage, possibly by causing overloading of a particular enzyme system which, in the light of preliminary data, might be a nitro-reductase. The concentration of radioactivity was highest in tissues which can be shown to suffer early morphological changes (that is vitellogenous cells of females and gonads of both sexes)[6].

BIOLOGY

Observations on the Opah, *Lampris regius* (Bonnaterre)

AN opah, *Lampris regius* (Bonnaterre), was captured on February 11, 1964, by the Japanese research vessel *Shoyo Maru* at approximately 3° 15·8′ S. and 128° 18·0′ W. in the South Pacific ocean. This individual, weighing 64 kg and measuring 119 cm (fork length), was caught at a depth of approximately 100 m on long-line gear used for fishing for tunas and billfishes[1].

The body of the fish was covered with scars, as is usual for this species. Bell and Kask[2] have shown that some of the scars are caused by lampreys, *Lampetra tridentata*, but that others are of unknown origin. My experience with *L. regius* in the waters of the South

Pacific leads me to conclude that many of the scars result from bites by squid. The outline of the scars, which is often oval rather than round, or were like two overlapping circles or ovals, is very similar to some of the wounds and scars observed by Guitart[3] on *Xiphias gladius*. Such shapes could be expected as a result of a wound inflicted by the beak of a squid. It is unlikely that such scars could be a result of such parasites as *Pennella*. I have examined twenty-seven specimens of *L. regius* from the South Pacific, caught by the R.V. *Shoyo Maru* during her twelfth voyage[4], and none of these has had any external parasites, with the exception of one individual which was infested around the eye with a few minute copepods *Clavellistes shoyoae*[6]. *L. regius* is caught on long-line gear in many parts of the Pacific Ocean[1,4,5]. Persons engaged in long-lining for tunas have informed me that *Pennella* is not found on opah.

This 64 kg individual was a running-ripe female. The eggs, which oozed out when pressure was applied to the sides of the body, were spherical, colourless, and transparent, with a diameter of 2·30 mm. When placed in sea-water the eggs sank. Neither oil globules nor any pattern on the surface of the eggs were visible with the naked eye. The eggs were kept in sea-water for about half an hour prior to preservation in 5 per cent formalin, at which time they became whitish and opaque although their diameter did not change. The membrane of the preserved eggs appears to be transparent, but under the magnification of a dissecting microscope the presence of very minute, linearly arranged rugosites can be detected. There is a well-delimited perivitelline-like space in the preserved eggs.

The fish was dissected and its ovaries examined. The two ovaries together weighed 980 g; a considerable portion of the eggs was, however, lost while bringing the fish aboard the vessel. The ovarian eggs were in various stages of maturation, the immature eggs being opaque. Two squid beaks were the only material found in the stomach.

I thank the Nankai Regional Fisheries Research Laboratory for permission to participate in a portion of Voyage 13 of the *Shoyo Maru*.

Nest-structure of a Social Wasp varying with Siting of Leaves

THE nest-building habits of a social wasp, *Ropalidia variegata* (Smith) were closely observed at the Indian Statistical Institute, Calcutta, from November 1963 to July 1965. Each nest is constructed largely on the lower side of a leaf, to which it is attached by a stiff and rather brittle pedicel, which is continuous with the first cell. The remaining cells of the nest, arranged in vertical rows[1,2], hang almost vertically from the first cell, the second cell being placed about 45° to the right or left of the line of gravity of the first cell (Fig. 1).

Forty-seven nests, comprising eleven colonies, were built on leaves of the cultivated banana (*Musa sapientum*), and fifty-three nests (five colonies) on leaves of the dicotyledon, *Diospyros discolor*. It was found that the number of vertical rows of cells differed in the nests on the two types of leaves, and this is thought to have been due to the pronounced differences in the morphology of the leaves. That the shape of the nest of some species of *Ropalidia*, notably *R. fasciata*, depends to some extent on that of the object to which it is attached has been reported[1]. This means that nests suspended from an elongate object, such as a stalk or a palm leaflet, tend to be more elongate than those hanging from a leaf with a broad surface.

A banana leaf is very large, its lamina measuring about 180 × 60 cm. Its petiole is very stout and grooved, extending into the lamina region as the prominent mid-rib. The lower part of the petiole always remains vertical as it partially wraps the erect pseudo-stem. The long and broad lamina is thus adapted for upward or downward movement. Even when the lamina is blown horizontally, its mid-rib generally maintains the usual angle of inclination. The wasp nests only on the lower surface of the lamina and invariably along the raised mid-rib (Fig. 1*a*). On account of this position and since the banana leaf generally moves in a vertical plane, the hanging nests seldom lose their balance.

A leaf of *Diospyros discolor* measures about 20 × 6 cm and the plane and position of its lamina often change, since it easily responds to wind. The smaller size of the leaf (compared to that of the banana), the weaker petiole and the flexible nature of the shoots on which the leaves are borne are factors that tend to produce frequent changes in the position of the lamina.

59·6 per cent of nests of the eleven colonies on the banana plants possessed only two rows of cells each, and this figure differs significantly even at the 1 per cent level (χ^2 test with one degree of freedom) from the corresponding one for the nests on *Diospyros* (34 per cent).

In order to test how far the structure of the nests on the two plant species differed, tests for homogeneity of parallel samples[3] were performed after condensing the data as shown in Table 2, where group *A* represents nests on *Diospyros* and *B* on *Musa*.

The χ^2 test showed that this difference is significant at the 5 per cent level. The difference between the mean number of rows of cells per nest on banana and *Diospyros* (Table 1) was significant at the 5 per cent level ('*t*'-test).

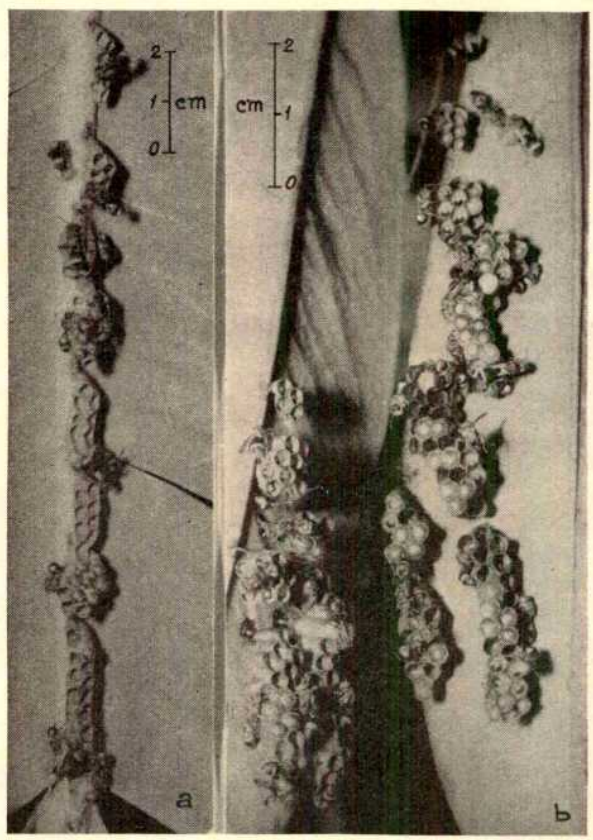

Fig. 1. Colonies of *Ropalidia variegata* (Smith) on the leaves of *Musa sapientum* (*a*) and *Diospyros discolor* (*b*)

Table 1. NUMBER OF ROWS OF CELLS PER NEST OF *Ropalidia variegata*

No. of colonies	No. of nests	Plant	No. of vertical rows per nest 1	2	3	4	5	6	7	Mean
5	53	*Diospyros*	1	18	20	9	4	0	1	3·0189
11	47	*Musa*	1	28	11	7	0	0	0	2·5106

Table 2

Group	Rows of cells per nest <3	3	>3	Total
A	19	20	14	53
B	29	11	7	47
A+*B*	48	31	21	100

As the nests always hang from their first cells, they are unable to withstand permanent deviations from their initial vertical postures that may be caused by wind. When the position of a leaf bearing these nests is slightly altered, the stability of the tilted nest is restored by adding new cells or rows of cells along the side nearer to the line of gravity. A colony on a leaf lasts for a few months, and during this period the leaf may be subjected to further deflections in different directions. Thus, the number of cell-rows in a nest increases in course of time, and the nests show vast variations. In many nests, the early formed cells follow a two-row pattern. But, with time, more and more cells are added at various positions of the nest to combat the disturbances caused by the wind.

One of the nests of a colony, which had two rows of cells, slipped from its attachment and was refixed by a paper clip. Obviously the repair was not approved by the wasps, for they forthwith added new cells, forming a further five vertical rows of two cells each, thereby restoring the equilibrium of the nest[4]. The biological significance of this phenomenon is important. In changing the structure of the nest to suit different sites and trees, the wasp demonstrates adaptability to ensure survival under varying conditions.

I thank Prof. van der Vecht, Rijksmuseum van Natuurlijke Historie, Leiden, for identifying the wasp.

Infection of *Culex fatigans* with a Microsporidian

BIOLOGICAL control is assuming an ever-increasing importance as a means of augmentation of, or substitution for, the use of pesticides in the control of both medically and economically important arthropods. This applies in particular to *Culex fatigans*, the main vector of *Wuchereria bancrofti* throughout most of the tropics and subtropics. Control of this mosquito is complicated by the widespread occurrence of resistance to most insecticides, together with the complexities of larval control by sanitation or other non-insecticidal methods.

In the course of attempts to infect *C. fatigans* with various pathogens and parasites, infections with a microsporidian provisionally identified as *Plistophora culicis* Weiser[1,2] were established in both adult and larval stages of this mosquito. The spores of this microsporidian were obtained from Prof. Meir Yoeli, of New York, who found it to be the cause of high mortality in his colonies of *Anopheles stephensi*. The infection originated in wild-caught *Anopheles dureni* from the Congo[3].

The infections were obtained in the adults by suspending a cotton-wool swab moistened with a fresh suspension of spores in a cage containing newly emerged mosquitoes. The swab was moistened morning and evening with distilled water. No alternative food supply was provided for the first week, then sugar water was made available.

Larvae were infected by hatching *C. fatigans* eggs in a bowl to which fresh spores had been added. Once again no food was added for the first week during which time

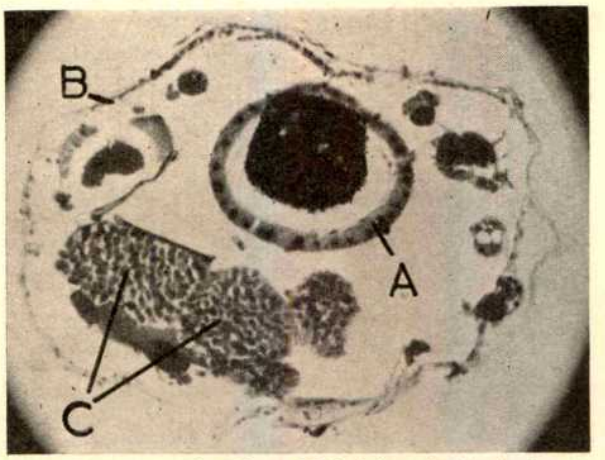

Fig. 1. Transverse section of larva of *Culex fatigans* showing developmental stages of *Plistophora culicis* in fat body. *A*, Gut wall; *B*, body wall; *C*, infected fat body

mortality was high. Thirty-three larvae remained alive at this stage. From these a total of three adults, two pupae and two larvae were found to be infected.

No external signs of infection were noted in the parasitized larvae, pupae, or adults, all infections being found on microscopic examination. Larvae, on sectioning, showed considerable involvement of the fat bodies (Fig. 1). The infection did not prevent larvae pupating or adults emerging from these pupae; larval life was prolonged, however, up to 56 days in one case.

Further experiments are being carried out using spores stored in distilled water at 0° C for 2–4 months and spores stored in liquid nitrogen, either dry or in glycerol, for 3–12 months. Infections have been established in *Anopheles stephensi* using spores stored dry in liquid nitrogen for 3 months.

Air Movement and Termite Behaviour

TERMITES show great activity around even a small breach in their nest and soon begin to build to repair the damage. In laboratory vessels, termites seal off any gaps to the outside air, even around the edge of an apparently close-fitting stopper. The stimulus inducing this behaviour has most often been considered to be a fall or gradient of humidity (see, for example, Grassé and Noirot[1], Stuart[2]).

I have investigated the nest-building behaviour of the damp-wood termites *Zootermopsis angusticollis* and *Z. nevadensis* (Hagen). In addition to the behaviour already described, these insects build crusts or ledges of material over their living quarters when they are kept in laboratory vessels. This material usually consists of faecal or wood particles cemented together with a watery secretion exuded from the anus. In large specimen tubes that contain a central partition made of wood or cardboard and sawdust for building material at the bottom of the tube, the termites tend to build on upward-facing edges and ultimately build a ledge from the top of the partition across to the walls of the tube. Any gaps in the partition above a certain level are filled in. It was found, however, that whereas building continued at a rapid and fairly constant rate at a relative humidity of 92 per cent, at lower relative humidities (56 per cent and 35 per cent) the rate of building was initially lower and building ceased almost totally after the first 24 h of the experiment, when the overall activity of the insects was greatly

reduced. It seems unlikely, then, that a fall in humidity is a stimulus to nest-building activity. In fact, Ernst[3] showed that *Z. nevadensis* takes 5–6 h to react in a humidity gradient; some other species took several days.

In further tests, termites were put into an open 100 × 30 mm glass tube with a centre partition 15 cm high coming out of the tube. The termites immediately began to climb the partition, but at certain levels showed an 'avoidance reaction' and turned back. The avoidance reaction began 2–3 cm above the bottom of the tube and occurred with gradually increasing frequency towards the open end. It must be assumed that this is a response to air movement, since within the relatively few seconds taken to set up the experiment there was no time for gradients of, for example, humidity or carbon dioxide to be established. After a brief phase of apparent exploratory behaviour the insects began to cement building particles on to the partition. From the combined results of a number of experiments with *Z. nevadensis* a direct correlation was found between the distribution of building particles and the 'distribution' of avoidance reactions ($r = 0{\cdot}87$, $P < 0{\cdot}01$). The air movement in an open tube was measured by recording the movement of a very fine cotton hair under a microscope, and the amplitude of movement was found to increase logarithmically towards the open end of the tube. The amplitude of air movement and the number of avoidance reactions at different levels were also found to be closely correlated ($r = 0{\cdot}97$, $P < 0{\cdot}0001$ for *Z. augusticollis*; $r = 0{\cdot}93$, $P < 0{\cdot}001$ for *Z. nevadensis*).

These results show that termites have an extremely high sensitivity to air movement. This sensitivity varies continuously, and the absence of a clear threshold is in accordance with the general theory of sensory discrimination of Duncan and Sheppard[4]. The evidence obtained here shows that a very small proportion of termites can detect air movements of the order of one thousandth of those in a closed room. The sense organs concerned are believed to be located on the antennae, since (*a*) termites with the distal two thirds of their antennae amputated do not show an avoidance reaction in a gradient of moving air, and (*b*) responses to light puffs of air on the antennae have been recorded from electrophysiological preparations with electrodes in the antennal nerve.

This very high sensitivity to air movement clearly helps to explain how termites are attracted to even minute openings of their nest to the exterior, and could explain how some dry-wood termites are able to leave a paper-thin shell of wood between themselves and the outside air. It also suggests that great caution is necessary in the design of experiments with termites. Lüscher[5] has shown that there is a continuous circulation of air in the large mound nests of *Macrotermes natalensis* (Haviland). In Ivory Coast nests hot air rises from the fungus gardens and nursery area and is cooled in large descending ducts below the surface of the mound. In Uganda nests the hot air diffuses outwards from chambers at the top of the mound and cool air enters below. It is very difficult to suggest how such complex nests come to be built, but it may well be worth considering that termites ensure a circulation by building around air currents that are set up in the developing nest.

Most of the work described here was done during the tenure of a North Atlantic Treaty Organization research fellowship of the Department of Scientific and Industrial Research, held in the department of Prof. M. Lüscher (Berne), to whom I am indebted for his hospitality and assistance.

Interference Microscopy of the Pattern of Leaf Surfaces

INTERFERENCE microscopy with reflected light is generally used for surface control of ball-bearings, but the technique can be adapted for investigations on the nature of plant surfaces.

As plant surfaces are generally dull and reflect little light, it is necessary to prepare several replicas. Plastic film (0·07 mm thick) is softened with acetone and pressed on to the leaf surface. After 3–5 min the replica is sufficiently hard and is stripped off and placed in the so-called 'Zehender chamber' (a mirrored surface with a cover slip); it is then viewed under the microscope.

Depending on the nature of the surface, one obtains interference pictures with lines of constant distance on the embedding medium. In air the line distance is 0·54μ, in water 1·5μ, and in certain oil mixtures 3μ and 5μ, respectively. In Fig. 1*a*, *b* and *c*, replicas with contour lines enable one to draw profile lines along any direction. In this way a picture of the actual relief of the surface can be gained.

This technique can be used to check changes in the pattern of the surface of a leaf as it develops and the influence of various physiological conditions on the

A Second Gibberellin-like Substance in Immature Barley Seed

IN an earlier paper it was shown that gibberellic acid occurs in the immature seed of barley, and it was mentioned that a second gibberellin-like substance was found in the extracts[1]. This second substance was eluted from a charcoal : celite column with 90 per cent aqueous acetone. When chromatogrammed on paper using *n*-butanol–1·5 N ammonia (3 : 1) or benzene–glacial acetic acid–water (4 : 2 : 1) it had the same R_F as gibberellins A_4 and A_7.

These preliminary experiments were carried out with samples gathered one week and four weeks after anthesis. There appeared to be more activity in the younger sample, so the following year a large batch was gathered about ten days after anthesis. Extraction of the bulk of this yielded only gibberellic acid, but a small part of the sample was extracted separately by a slightly different procedure, and both substances were found on this occasion. Bioassay of the second substance by dwarf pea seedlings[2] indicated an activity of 0·5 μg gibberellic acid equivalent per kg fresh weight of seed, whereas the activity shown by the cucumber hypocotyl assay[3] was 24 μg gibberellin A_9 equivalent per kg. Part of the sample was further purified by elution from a silica : celite column (1 : 2 w/w) with varying proportions of ethyl acetate and chloroform. Most of the activity was found in those fractions in which gibberellins A_4 and A_7 would be expected. Part of this repurified sample was tested by the lettuce seedling assay[4], in which only a trace of activity was found, and part was tested on dwarf maize seedling[5] (cultivar d_1), no significant activity being found.

The high activity in the cucumber assay, the low activity in the pea seedling test, and the R_F evidence all suggested that the substance could be gibberellin A_4 or A_7, but the lettuce assay result appeared to eliminate gibberellin A_7, which is highly active in this assay, while the activity seemed too low even for gibberellin A_4. Both gibberellins A_4 and A_7 are as active as gibberellic acid in the d_1 maize assay, so this assay also failed to confirm the identity of the unknown substance.

Thin-layer chromatography of the sample was carried out by the method previously described, but no fluorescent spot could be detected after spraying with sulphuric acid. It is possible that some fluorescence may have been masked by impurities, but the extracts appeared to be fairly highly purified at this stage. Most and Vlitos[6] have reported the extraction from sugar cane of a group of substances with similar properties, that is, they are biologically active especially in the cucumber assay but do not fluoresce on thin-layer chromatograms. This lack of ability to fluoresce after reacting with sulphuric acid may imply that these substances do not have a gibbane skeleton, but it is not yet known whether all gibbanes fluoresce, and these substances may be gibberellins in structure as well as activity.

I thank Dr. D. F. Jones for the thin-layer chromatography.

RADIOBIOLOGY

Previous Reproductive History and the Susceptibility to X-ray-induced Congenital Anomalies

THE suspicion that primiparous mice are more apt to produce anomalous offspring, following foetal X-irradiation, than are multiparous mice, has led to the necessity of determining the normal incidence of such anomalies among large numbers of control mice of both categories. This investigation deals with the normal primiparous and multiparous *CF*1 mice of exactly the same age (7–9 months) and the analysis of the condition of their offspring. In direct contrast with this is presented a parallel study of pregnant primiparous and multiparous *CF*1 mice X-irradiated at a specific time and to a specific dose to determine whether a single variable (primiparity or multiparity) might alter the incidence of anomalies induced by X-rays. This paper reports data from 225 litters (2,700 implantations).

The strain of mouse used was the *CF*1 which we have found to be satisfactory for many years. All mice for this experiment were received at one time from the source, and were kept under identical conditions of temperature, humidity, food and water for the duration of the experiment. All females used were from 7 to 9 months of age (the range being due to the fact that pregnancies for the multiparous mice could not always be immediately achieved). The multiparous females were kept pregnant from 2 months of age, and every one had been pregnant four times followed by a 2-week period of rest before the experimental pregnancy.

Pregnancies were achieved by exposing the females to males of the same strain for a period of 2 h (8–10 a.m.) and females found to have vaginal plugs were segregated and labelled as to the time of conception. At 18 days gestation each pregnant mouse (controls or irradiated) was dissected and the contents of the uterus exposed and analysed, and the sex of each foetus determined.

For X-irradiation, paired tubes were used in a cross-fire of rays, with the pregnant mice placed equidistant between the tubes so as to be exposed uniformly to the rays. The dose was calculated as the dose delivered to the foetuses within the gravid uterus. (The physical factors of irradiation were 184 kVp. and 30 m.amp; half value layer, 0·6 mm copper, filtration 0·28 copper and 0·50 aluminium, distance from the tubes to the uterus 72 cm; and dose rate 50 r./min). A single exposure-level of 150 r. was chosen and delivered at exactly 8 days gestation because previous experience had shown that this stage and dose would definitely provide a wide gamut of congenital anomalies[1–3].

The anomalies observed besides resorption and death were: exencephaly, cephalic blisters, microcephaly, brain haemorrhage, eye and jaw defects, persistent exteriorized intestines, and stunting. There was no attempt to determine inner histological alterations.

The experimental data involve 125 control and 100 experimental pregnancies, giving 1,484 control implantations and 1,216 irradiated implantations. There appeared to be little difference in the condition of the foetuses among the controls except that there was a higher (3·3 per cent) incidence of anomalies among the primiparous than among the multiparous females (1·5 per cent). There were a few more dead foetuses among the multiparous controls (1·8 per cent) than among the primiparous controls (0·6 per cent), but the percentage of apparently normal foetuses was quite similar.

The mouse embryo at 8 days gestation is just beginning massive differentiation of almost all its tissues so that it is quite susceptible to the insult of X-rays[4]. An exposure of 150 r. at this time will invariably produce anomalies, so that similar treatment of the primiparous and the multiparous females should indicate whether previous

reproductive experience altered in any way the reaction of the embryos and foetuses to ionizing radiations.

The primiparous females, even though of the same age as the multiparous females, produced more anomalies (34·7 per cent) than did the multiparous females (29·5 per cent). While these percentage differences do not seem great, they involve a total of more than 1,200 foetuses examined and are indeed significant.

With regard to sex ratios, it was found that among unirradiated foetuses there were 52 per cent males to 48 per cent females, but among both X-irradiated groups the percentage of males was significantly higher (57·1 per cent and 58·3 per cent). This seems to suggest a differential mortality among the presumptive females. This is supported by a recent investigation[5] in which radiotherapy increased the frequency of human male births.

The anomalies are reported in Table 2. It should be noted that stunting occurs even among the controls (primiparous females 2·8 per cent and multipara 1·4 per cent). It has not been determined whether this is due to nutritional deficiency which could be rectified after birth, or to a congenital anomaly. Exencephaly rarely occurred among the controls, and is very greatly increased among both the irradiated groups—somewhat more so among the primiparous females. In addition there were other anomalies which occurred among those X-rayed, particularly eye defects which were found more frequently among the foetuses of our primiparous females. The overall incidence of anomalies appears to be slightly higher among those females which had never before been pregnant than among the multiparous females. Among the multiparous pregnancies, the males showed a lower incidence of anomalies than did the females. The explanation of this is not available, since there did not appear a commensurate depression in the implantation frequencies.

This work was performed under contract for the U.S. Atomic Energy Commission and aided in part by a grant from the Division of Radiological Health, Bureau of State Services, U.S. Public Health Service.

Liberation of 5-Hydroxytryptamine in the Brain Stem of Adrenalectomized Rats after X-irradiation

EXPERIMENTAL results reported in previous papers have suggested that rat brain liberates 5-hydroxytryptamine (5-HT) after X-irradiation[1,2]. The biochemical and physiological investigation of irradiated experimental animals is complicated by non-specific neuroendocrine reactions which play a part in the adaptation syndrome. In order to exclude this factor, we carried out experiments on adrenalectomized rats, which are also more sensitive to X-irradiation. The main changes in the content of 5-hydroxyindoles after X-irradiation were observed in the brain stem[1], which contains the centres which regulate and co-ordinate the endocrine system.

In this paper we examined total, basic and acidic 5-O*R* indoles (where *R* is a hydrogen atom or an aryl or alkyl group) in the brain stem of adrenalectomized rats after X-irradiation (900 r.). The basic 5-O*R* indoles are mainly similar to the 5-HT and the acidic ones to 5-hydroxyindoleacetic acid (5-HIAA), the main metabolite of 5-HT. By the simultaneous determination of all these compounds it is possible to investigate the rate of biosynthesis, release and metabolism of 5-HT. The content of 5-HIAA can be used to measure 5-HT release because the main part of the 5-HT liberated is metabolized to 5-HIAA.

Albino rats of both sexes weighing 150–180 g were used. Bilateral adrenalectomy was performed under ether anaesthesia. The adrenalectomized rats were maintained on 1 per cent saline throughout the experiment. The dose (900 r.) was measured in an ionizing chamber over the period of exposure. The dose rate was 83 r./min. The radiation factors were 220 kV and 15 m.amp. A 0·5-mm copper and a 1·0-mm aluminium filter were used, and the distance of the target from the skin was 40 cm. Immediately after irradiation the animals were killed and the brains were isolated. Four brain stems were pooled for each determination.

Total and acidic 5-O*R* indoles were estimated according to the method of Ashcroft and Sharman[3] and basic compounds by the method described by Bogdanski *et al.*[4], which was slightly modified. Fluorimetric measurements were carried out using a 'Locarte' semifluorescence spectrofluorimeter in concentrated hydrochloric acid at 550 mμ and with an activating wave-length of 295 mμ.

Data showing the influence of X-irradiation on the content of total, basic and acidic 5-O*R* indoles in the rat brain stem are given in Tables 1 and 2.

Irradiation of controls produces a significant increase of total 5-O*R* indoles, as we have already reported[1]. Sham-operated animals behave in the same way as the controls.

In adrenalectomized rats there was an increase of total and basic 5-O*R* indoles on the first day after operation. After irradiation (900 r.) such animals showed a statistically significant increase of total and acidic 5-O*R* indoles in comparison with adrenalectomized and non-irradiated ones (Table 1).

On the seventh day after operation, an increase of total 5-O*R* indoles only was observed in the brain stem of adrenalectomized rats. Irradiation of these animals has a similar effect on 5-O*R* indoles as in rats which were irradiated on the first day after operation (Table 2).

West *et al.* have postulated that glucocorticoids regulate the level of 5-HT and histamine in tissue stores[5,6]. In adrenalectomized rats the content of 5-HT is increased in many tissues[7]. De Maio[8] observed an increase of 5-HT in the brain of adrenalectomized and hypophysectomized rats 24 h after operation. This increase was greatest in the basal part of the brain. Other workers have not obtained the same results[9,10]. From the aforementioned results it seems that the content of 5-HT in the brain of adrenalectomized rats depends on different intervals after operation. Adrenalectomy does not affect brain monoamine oxidase activity[10]. Therefore, increase of the 5-HT content of the brain of adrenalectomized rats is probably a consequence of increased 5-HT biosynthesis.

Ionizing radiation stimulates the hypothalamic centres[11] and activates many of the neuroendocrine reactions. One of the first reactions is the release of adrenocorticotrophic hormone (ACTH)[12]. Moussatché and Pereira[13] have suggested that 5-HT is a chemical mediator of ACTH release. It is possible that the liberation of 5-HT by the brain stem after irradiation is involved in this process.

Many of the early phenomena of radiation damage are caused by the freeing of neurohormones (including 5-HT) (ref. 14). Our results suggest that there is an intensive liberation of 5-HT in the brain stem after X-irradiation in adrenalectomized rats. This explains the increase of 5-HIAA. The increase of total 5-O*R* indoles after irradiation is much greater than the increases of 5-HT and 5-HIAA put together. This is probably due to the presence of other metabolites of liberated 5-HT in the brain stem not at present identified[1]. The liberation seems to be in dynamic equilibrium with biosynthesis, that is, greater liberation causes greater biosynthesis. Therefore, the content of 5-HT does not change in adrenalectomized rats after irradiation.

The next stage of our work will be the investigation of the mechanism by which 5-HT is liberated.

Effects of Gamma Radiation on Freeze-dehydrated Apples (*Pyrus malus*)

BIOCHEMICAL and physiological effects of gamma-irradiated fresh fruits and vegetables have been reported from our laboratories[1–9] in an attempt to extend the storage life and maintain wholesomeness. Because they are almost weightless, and because of their high nutritive value, freeze-dehydrated food are convenient for consumption by astronauts during space flights. High-frequency short-wave rays may be encountered in space flights and/or subsequent landing on the Moon or other planets. The experiment reported here was to elucidate some chemical and histological effects of gamma-radiation doses on freeze-dehydrated apple slices.

Fresh 'Golden Delicious' apples were peeled, cored, sliced and freeze dehydrated as discussed in a previous paper[10]. The freeze-dehydrated apples were irradiated with caesium-137 gamma-rays at 0 (control), 1×10^5, 3×10^5, 6×10^5 and $1{\cdot}8 \times 10^6$ rads doses at a rate of $2{\cdot}5 \times 10^4$ rads/h. The irradiation temperature was 25° C and nitrogen gas was flushed over the samples during the process of irradiation.

Irradiated and non-irradiated products were analysed for volatile substances responsible for flavour and aroma and for nutritional aspects as reducing sugars and ascorbic acid. Methanol extracts of the products were used for colour determination. Rehydration rates were measured at 40° C. Histological studies were also conducted (Figs. 1–3).

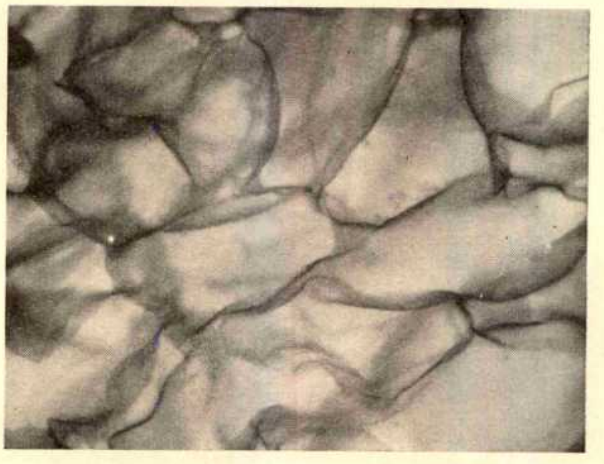

Fig. 1. Photomicrograph of parenchyma cells in freeze-dehydrated apple (control)

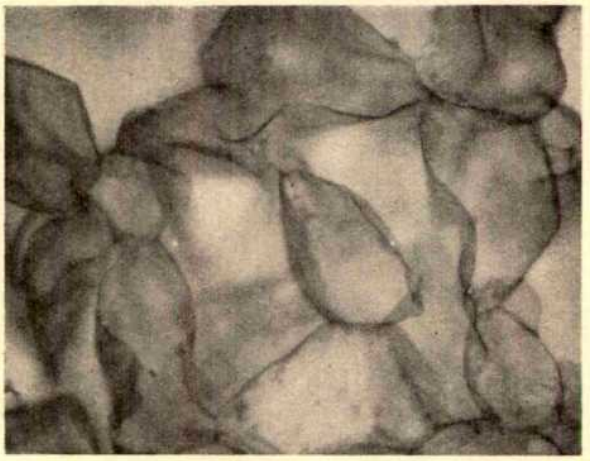

Fig. 2. Photomicrograph of parenchyma cells in freeze-dehydrated and irradiated apple at 3×10^5 rads doses

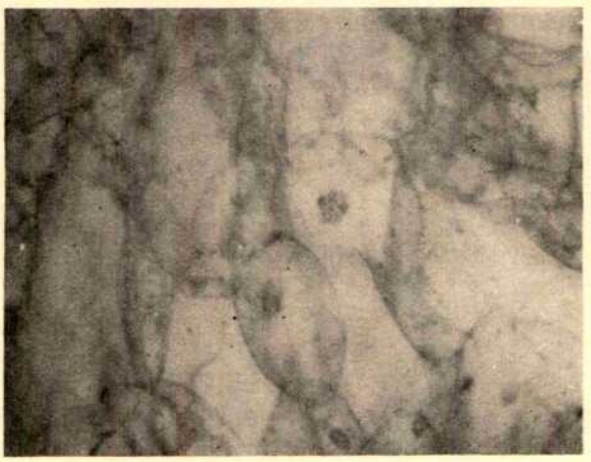

Fig. 3. Photomicrograph of parenchyma cells in freeze-dehydrated and irradiated apple at $1{\cdot}8 \times 10^6$ rads doses

Progressive browning and softening of the products were observed during irradiation as the doses increased beyond 1×10^5 rads. Chemical analyses showed (Table 1) that volatile compounds were reduced by low doses of radiation, but increased by doses of more than 3×10^5 rads. This may be due to the original volatile compounds being destroyed during exposure to 1×10^5 rads, while depolymerization of non-volatiles produced at high doses causes an increase in total volatiles. Free reducing sugars were increased almost imperceptibly as doses increased, while ascorbic acid was decreased. Optical densities at 420 μm and rehydration rates were also increased at high doses. Microscopic examination of the cell structure showed that some parenchyma cells were separated with radiation doses of 3×10^5 rads (Fig. 2). Some ruptured and thin cell walls were observed at doses of $1{\cdot}8 \times 10^6$ rads and coagulation of certain cellular materials was also obvious (Fig. 3). It is believed that freeze-dehydrated fruits are more stable than fresh fruits when both are similarly irradiated. The difference may be due to the active enzyme systems in fresh products.

Table 1. Effects of γ Radiation on Freeze-dehydrated Apples

Doses (rads)	Volatile reducing substances (μequiv./100 g)*	Reducing sugars (%)	Ascorbic acids (loss %)	Optical density at 420 μm	Rehydration ratio†
0×10^5 (control)	2,464	53·56	0	0·158	4·25
1×10^5	770	54·08	6	0·208	4·28
3×10^5	1,078	54·60	16	0·212	4·46
6×10^5	1,232	58·24	27	0·218	4·58
$1{\cdot}8 \times 10^6$	2,433	59·80	38	0·220	4·91

ANATOMY

Intestinal Villi in Rhesus Monkeys

Literature on villus pattern in the rhesus monkey is scarce. Lineback[1] noted, using ordinary histological methods, that villi were flange-shaped in the duodenum and that towards the lower end of the ileum they attained a more typical finger-like form. It is, however, difficult to decide firmly about the shape of villi without dissection microscopy. Booth *et al.*[2] pointed out that leaf-like villi may appear finger-like in a histological section depending on its plane. This communication reports on the configuration of intestinal villi in apparently normal rhesus monkeys utilizing the technique of dissection microscopy.

In this investigation, twenty-two animals, which had been trapped 10–20 days previously, were autopsied after sodium pentothal anaesthesia. Their body weight varied from 1·50 to 8·50 kg with an average of 2·80 kg. The animals were fed on a mixed diet of bananas, soaked gram and wheat bread for 1–5 days before they were killed. In a concurrent investigation of 101 animals, including ten used in the present experiments, the faecal fat content varied from 1 to 4 g per cent with an average of 1·8 per cent[3]. The small intestine had a normal gross appearance in these animals.

Eighteen small pieces from the duodenum, forty-six from the proximal 4 in. of the jejunum and twenty-four from the terminal ileum were investigated under the dissection microscope in a fresh state. These blocks were subsequently embedded in paraffin and sections were studied histologically after staining with haematoxylin–eosin.

Three types of villi were commonly encountered on dissection microscopy. Classical finger-like and tongue- or leaf-like villi constituted the first two categories (Figs. 1

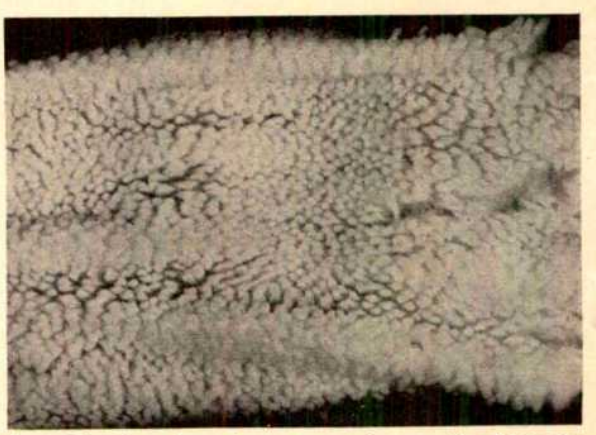

Fig. 1. Dissection microscopic appearance of mucosa of small intestine of rhesus monkey. The entire area is studded with slender finger-like villi which appear as small knobs. These were found in jejunum and ileum

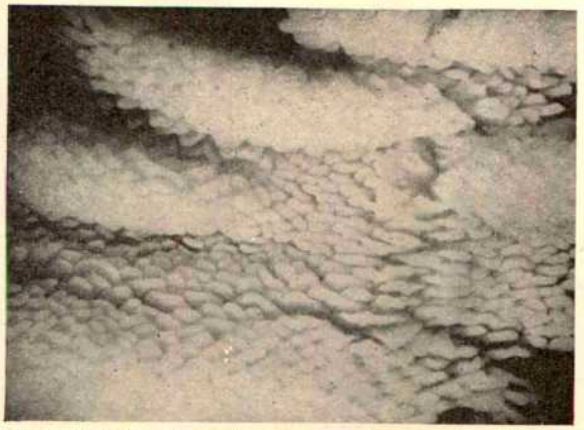

Fig. 2. Dissection microscopic appearance of mucosa of small intestine of rhesus monkey. The entire area shows broad leaf-like or tongue-shaped villi which were found mostly in jejunum and ileum

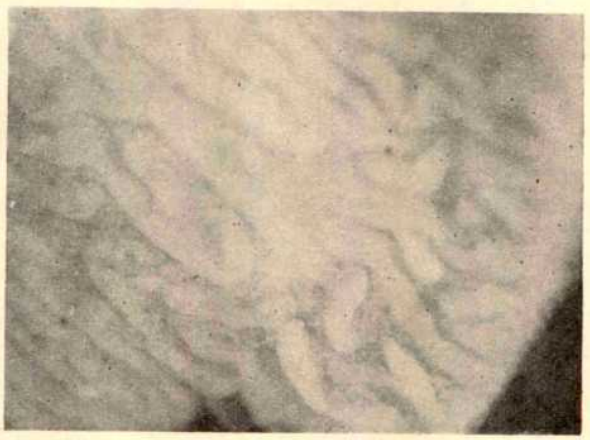

Fig. 3. Dissection microscopic appearance of mucosa of small intestine of rhesus monkey. There are extra-broad, branching and interconnected villi. These were mostly found in the duodenum

and 2). Extra broad leaves curved in places, and irregularly arranged leaves branching occasionally or apparently interconnected, formed a distinct third group (Fig. 3).

It was observed that ten specimens in the duodenum showed the third type of villi, seven revealed leaf-like villi arranged regularly, and one specimen failed to show villi because of excess mucus.

Out of forty-six specimens taken from the jejunum, thirty-three showed leaf-like villi, three finger-like, seven mixed finger- and leaf-like and two showed extra-broad curved villi. One specimen did not show any villi, the surface being denuded mechanically.

Out of twenty-four specimens taken from the terminal ileum, sixteen showed classical leaves, three finger-like villi, three mixed pattern and two showed extra-broad curved villi.

Table 1 shows the overall distribution of different types of villi in the small intestine of the rhesus monkey.

Histological examination showed that the ratio of villus height to crypt varied between 6 : 1 and 3 : 1 depending on the type of villi, usually showing a high value in the case of finger-like villi and a lower value with leaf-like or extra-broad curved villi. The margin was well formed and showed both columnar and mucous cells. The corium of the villi usually contained a number of cells enmeshed in thin connective tissue. These cells were usually mononuclears or lymphocytes and occasionally plasma cells.

Table 1

Type of villus	Number	Percentage
Leaf	56	65
Finger	6	7
Mixed	10	12
Extra-broad curved	14	16

The duodenum in rhesus monkey showed a distinctive villus pattern with little more than half showing broad curving, branched villi. Finger-like villi were not found in the duodenum. The jejunum and ileum showed a broadly comparable pattern with a predominance of leaf-like villi. Lineback[1], who investigated intestinal villi, also found that the majority of villi in the jejunum had leaf-like and tongue shapes. We cannot, however, agree with his observation that the villi have a more and more typical finger-like form the more closely the ileum is approached.

We have classified villi on the basis of clear-cut extreme patterns, but many intermediary stages connecting one to the other were discernible. Between a finger-shaped and a tongue-shaped villus the difference was one of flattening, which in some cases was found only at the base of the villus while its top still retained a tubular configuration. Between a tongue-shaped and a leaf-shaped villus the difference was only one of width and was well bridged by intermediary sizes. Moderately broad and narrow leaf-like villi could be seen in the same piece. It appeared that there was a wide spectrum of varying shapes of villi with finger-like villus at one end, typical leaf-like shapes somewhere in the centre and broad curved, branching interconnected villi at the other end, the gaps in between being bridged by intermediary stages.

GENETICS

Spontaneous Reduction of Somatic Chromosomes in *Haplopappus gracilis*

THE occurrence of spontaneous[1], as well as induced[2], haploidy has been observed in several plant genera. Haploidy has been reported in cultures from secondary phloem tissue of carrot[3], and haploidy and somatic pairing have also been noted in cultured stem tissue of *Haplopappus gracilis*[4]. Recently, haploid cells were observed to occur spontaneously in leaf primordia of young seedlings of *Haplopappus gracilis*[5]. The purpose of this communication is to report spontaneous reduction in the number of somatic chromosomes in the root meristem of *Haplopappus gracilis*.

Aceto–orcein squash preparations were made of root tips from 2-day-old seedlings, which had been pretreated with a 1 : 1 mixture of 8-hydroxyquinoline and naphthalene monobromide (alpha) according to the technique of Mitra[6]. The normal karyotype, consisting of four chromosomes, one longer submedian pair and one subterminal pair with satellites on the short arms, was observed in all of the root tips examined (Fig. 1). In one root tip, however, three metaphase configurations with two chromosomes, one member of each pair, were seen (Figs. 2 and 3). The chromosomes in Figs. 2 and 3 may represent haploid complements. This interpretation is based on comparative measurements of the width of the individual chromosomes in Figs. 1–3. An alternative view is that chromosomal configurations in these cells represent instances of somatic pairing similar to that observed by Mitra and Steward[4]. In order to evaluate these interpretations, microspectrophotometric analysis of Feulgen-stained somatic cells having the reduced number of chromo-

Fig. 1. Metaphase chromosomes of *Haplopappus gracilis* ($2n = 4$) root tip cells (× 1,800)

Figs. 2 and 3. Metaphase chromosomes in haploid root tip cells of *Haplopappus gracilis* (× 1,800)

somes is required. The observed reduction in chromosome number was probably not induced by the pretreatment, since no other cases of somatic reduction were observed in several hundred root tips pretreated in a similar fashion.

The observation of Lima-De-Faria[5] seems to indicate that the presence of the haploid set of chromosomes is enough to produce well-differentiated tissues in leaf primordia of *Haplopappus gracilis*. However, since only a few 'haploid' cells were seen in one of many root tips examined, and no 'haploid' sectors observed, it would be premature to state that two chromosomes are sufficient to produce normal tissue in the root meristem.

Successful clonal isolation of *Haplopappus gracilis* cells grown in culture has been reported[7]. The isolation and study of haploid clones would be of great genetic interest. If diploidy could be induced in such haploid clones, a homozygous strain of cells would be available for investigation.

This work was aided by grants from the National Institutes of Health, United States Public Health Service, the Saul Singer Foundation, and the Charles H. Silver Fund.

MISCELLANEOUS

Presenting the Results

IN the recent article by Prof. Robert B. Grieves and Dibakar Bhattacharyya[1], Fig. 2 shows a relation between two variables with the statement ". . . The residual DSS concentrations are related in Fig. 2 to the ratio of DSS to trivalent iron in the feed. As x_t/z_t was increased, x_r remained relatively constant and then rose sharply above a feed ratio of approximately 1·0.". In view of the close attention given to statistical aspects of data analysis in other parts of the article, the statement about the data of Fig. 2 appeared somewhat questionable. Accordingly, I read off the numbers from the graph as best I could with a piece of superimposed graph paper and replotted the data on log–log co-ordinates. The data suggested a relation of the form $x_r = \sqrt{2x_t/z_t}$, so I prepared a graph as shown in Fig. 1. Within the variability of the data, it does not appear to me that the data can be considered approximately constant below x_t/z_t of 1, but rather that a regular increase is observed over the full range of the values. Certainly the variability of the data does not warrant a definite conclusion on the relationship.

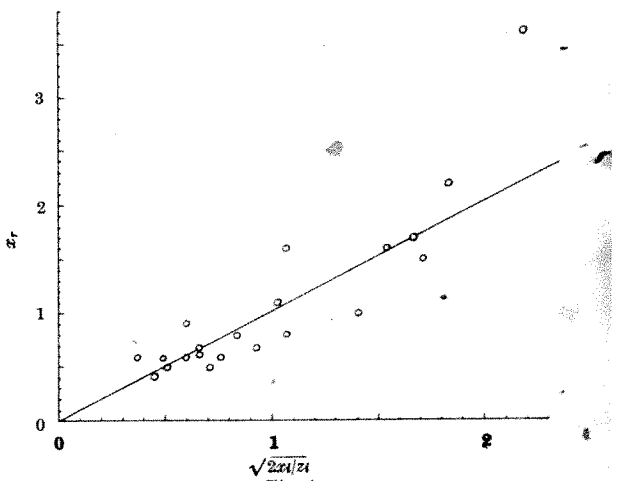

Fig. 1

The foregoing comments are submitted partly to make the point that the use of figures to present data and arguments makes it difficult for the reader to examine the data independently and test the conclusion offered by the author. I realize that limitations of space make such tabular presentations difficult, but I am disturbed at the quantity of literature which is produced without tabulation of the supporting values in a form where related calculations can easily be made. As a result, there is often a tendency to accept the author's statements because of the difficulty of examining the data separately.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Wednesday, June 1

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. M. H. P. Bott and Dr. G. A. L. Johnson: "The Controlling Mechanism of Carboniferous Cyclic Sedimentation".

ROYAL SOCIETY OF MEDICINE, HISTORY OF MEDICINE SECTION (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Dr. Richard Hunter. "J. Casaubon The Journal of a 17th Century Kentish Practitioner".

Thursday, June 2

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion Meeting on "The Chemistry and Biology of Immunoglobulins", organized by Prof. R. R. Porter, F.R.S.

GEOLOGICAL SOCIETY OF LONDON, VOLCANIC STUDIES GROUP (at Burlington House, Piccadilly, London, W.1), from 2 p.m. to 7 p.m.—Colloquium on "Alkali Basalts and their Associates".

Monday, June 6

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr Michael Sela (Rehovot). "Molecular Basis Antigenicity".*

Monday, June 6—Wednesday, June 8

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2)—Conference on "Design and Construction of Large Steerable Aerials"

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN PURE OR APPLIED MATHEMATICS—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (May 31).

LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Canterbury, Kent (May 31)

LECTURER OR ASSISTANT LECTURER (preferably with a medical degree or an honours degree in physiology and research experience) IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (May 31).

ASSISTANT LECTURER IN THE DEPARTMENT OF METALLURGY of the Faculty of Science—The Registrar, The University, Manchester, 13 (June 1).

RESEARCH FELLOW IN THE INSTITUTE OF SOUND AND VIBRATION RESEARCH for the fundamental study of the noise from high performance, high speed, direct injection diesel engines—The Deputy Secretary, The University, Southampton (June 1).

ASSISTANT DEPARTMENTAL LIBRARIAN (preferably with a degree) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (June 2)

LECTURER (honours graduate interested in general and social psychology) IN PSYCHOLOGY—The Principal, Lanchester College of Technology, Priory Street, Coventry (June 2).

TERMINABLE LECTURER (science or medical graduate) IN EMBRYOLOGY (Developmental Biology) IN THE DEPARTMENT OF ANATOMY—The Secretary, The University, Aberdeen (June 4).

ASSISTANT LECTURER IN SOCIOLOGY—The Secretary, The University, Northcote House, The Queen's Drive, Exeter, Devonshire (June 6).

LECTURER OR ASSISTANT LECTURER IN PURE MATHEMATICS—The Registrar, The University, Leeds, 2 (June 6).

RESEARCH ASSISTANT (graduate with research experience or expecting to graduate in Summer 1966) to Prof Monica M. Cole for work in vegetation/soil/geomorphology relationships in the Southern Pennines over a three-year period—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (June 6).

UNIVERSITY DEMONSTRATOR IN THE DEPARTMENT OF PHYSICS—The Registrar, University of Nottingham, University Park, Nottingham (June 6).

RESEARCH ASSISTANT (with special qualifications in educational psychology) IN EDUCATION—The Registrar (Room 39, O.R.B.), The University, Reading (June 7)

ASSISTANT LECTURER (perferably with an interest in ecology, experimental taxonomy, cytotaxonomy, algology, or quaternary palaeobotany) in the Department of Botany—The Secretary of the University Court, The University, Glasgow (June 8).

LECTURER OR ASSISTANT LECTURER (graduate in medicine, veterinary science, dentistry or biology) IN THE DEPARTMENT OF HISTOLOGY—The Registrar, The University, Liverpool, quoting ref. CV/60 (June 8).

PROFESSOR OF COMPUTER SCIENCE and DIRECTOR OF THE UNIVERSITY COMPUTER UNIT WITHIN THE SCHOOL OF MATHEMATICAL STUDIES—The Principal, Brunel College, Woodlands Avenue, Acton, London, W.3 (June 10).

LECTURER OR ASSISTANT LECTURER (chemical engineer) IN THE DEPARTMENT OF POLYMER AND FIBRE SCIENCE, to work in the field of polymer technology—The Registrar, University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1 (June 11).

LECTURERS (2) (with experience either in (*a*) control engineering applied to process control or servo systems or (*b*) synthesis and design of logical systems and computer circuits) IN ELECTRICAL ENGINEERING—The Secretary, The Queen's University, Belfast, Northern Ireland (June 11).

RESEARCH ASSISTANT (with a degree in zoology or in forestry and preferably previous experience in research involving field studies) to work with the LECTURER IN FOREST ZOOLOGY on investigations into the ecology and biological control of forest insects—The Secretary, The University, Aberdeen (June 11).

LECTURER or ASSISTANT LECTURER IN PHILOSOPHY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (June 12).

LECTURER IN COMPUTER SCIENCE WITH SPECIAL REFERENCE TO NUMERICAL ANALYSIS—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (June 13).

LECTURER or ASSISTANT LECTURER (with an interest in electrochemistry or thermodynamics) IN CHEMISTRY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (June 13).

LECTURER (with interests in the theoretical or experimental aspects of modern control techniques) IN CONTROL ENGINEERING IN THE SCHOOL OF ENGINEERING SCIENCE—The Registrar, University College of North Wales, Bangor, North Wales (June 13).

LECTURER (preferably interested in biometrical and/or natural population genetics of angiosperms) IN THE DEPARTMENT OF GENETICS—Dr. Sydney Smith, Department of Zoology, University of Cambridge, Downing Street, Cambridge (June 14).

ASSISTANT LECTURER (preferably with special interests in locational studies) IN THE FIELD OF ECONOMIC GEOGRAPHY—Dr. W. W. Black, Sedgwick Museum, The University, Cambridge (June 15).

DIRECTOR OF THE COMPUTATION LABORATORY—The Registrar, The University, Hull (June 15).

LECTURER or ASSISTANT LECTURER (with research experience in low temperature physics) IN PHYSICS—The Registrar, The University, Nottingham (June 15).

ASSISTANT IN THE FRUIT-GROWING SECTION OF THE DEPARTMENT OF HORTICULTURE, Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Registrar of the University (June 18).

ASSISTANT LECTURER IN VETERINARY ANATOMY—The Registrar and Secretary, The University, Bristol (June 18).

RESEARCH ASSISTANT (preferably with some research experience in an appropriate field) IN THE DEPARTMENT OF ZOOLOGY to participate in work concerned with the effect of antimetabolites on embryos—Dr. F. Billett, Department of Zoology, University of Southampton, Southampton (June 18).

RESEARCH SCIENTIST or SENIOR RESEARCH SCIENTIST (with a Ph.D. degree in physics or mathematics or appropriate postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability, and preferably a previous interest in atmospheric radiation) IN THE DIVISION OF METEOROLOGICAL PHYSICS, Commonwealth Scientific and Industrial Research Organization, Aspendale, Melbourne, Victoria, Australia, to take charge of the Division's research activities in the field of atmospheric radiation—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 420/215 (June 18)

UNIVERSITY DEMONSTRATOR (with an honours degree in an appropriate pure science, for example, biochemistry or physiology or agricultural science, and preferably some teaching and/or research experience) IN ANIMAL NUTRITION—The Secretary, School of Agriculture, University of Cambridge, Downing Street, Cambridge (June 18).

ASSISTANTS IN GEOLOGY (one without restriction on special interests, the other preferably with emphasis on geophysics) IN GEOLOGY—The Secretary to the University Court, The University, Glasgow (June 20)

RESEARCH FELLOW (engineer or mathematician) IN STRUCTURAL THEORY for research on structural containers at postgraduate level—The Administrator, Department of Engineering Science, University of Oxford, Oxford (June 20).

TEMPORARY LECTURER or ASSISTANT LECTURER IN PSYCHOLOGY—Prof H. Kay, Department of Psychology, The University, Sheffield (June 20).

ASSISTANT LECTURER (medical, veterinary or biology graduate, with an interest in research on insecticides for a higher degree) IN MEDICAL ENTOMOLOGY—Prof. D. Bertram, Department of Entomology, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1 (June 22)

DEMONSTRATOR (preferably with some postgraduate experience) IN BIOCHEMISTRY AND AGRICULTURAL BIOCHEMISTRY—The Registrar, University College of Wales, Aberystwyth (June 25).

AGRICULTURIST (with a degree or diploma in agriculture and experience of planning field experiments) FOR THE FIELD EXPERIMENTS SECTION—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting ref. 1052/85 (June 30).

BIOLOGIST to assist with research on bee behaviour—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (June 30).

BIOLOGIST (with at least a good honours degree) FOR RESEARCH ON MICROBIAL PATHOGENS OF INSECTS OF AGRICULTURAL IMPORTANCE—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (June 30).

LECTURER IN THE DEPARTMENT OF PURE MATHEMATICS OR DEPARTMENT OF STATISTICS, University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30).

LECTURER/SENIOR LECTURER IN BIOLOGY in the School of Biological Sciences, University of Sydney, Australia, mainly for administrative duties—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30)

PROFESSOR OF TEXTILE PHYSICS at the University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30).

SENIOR LECTURER or LECTURER IN MECHANICAL ENGINEERING at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, June 30).

SENIOR LECTURER or LECTURER IN PLANT SCIENCE (Entomology), a SENIOR LECTURER and LECTURER IN CHEMISTRY; a SENIOR LECTURER and LECTURER IN PHYSICS, and a SENIOR LECTURER and LECTURER IN MATHEMATICS at Njala University College, Sierra Leone—The Inter-University Council, 33 Bedford Place, London, W.C.1 (June 30).

SENIOR LECTURER or LECTURER IN BIOCHEMISTRY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, July 1).

READER IN APPLIED MATHEMATICS in the School of General Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 4).

LECTURER or SENIOR LECTURER IN GEOGRAPHY at the University of Tasmania—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 8)

VETERINARY OFFICERS, Grade II (at least 23, member of the Royal College of Veterinary Surgeons, and one year's appropriate postgraduate experience) with the Ministry of Agriculture, Fisheries and Food—The Civil Service Commission, 23 Savile Row, London, W.1 (August 1).

ASSISTANT LECTURER (graduate, or with a professional qualification and some industrial experience) IN CHEMISTRY, Grade B, to teach primarily in courses for chemical technicians and O.N.C. Sciences—The Principal, Medway College of Technology, Horsted, Maidstone Road, Chatham, Kent.

JUNIOR RESEARCH OFFICER IN GEOLOGY—The Registrar, University College of Wales, Aberystwyth.

LABORATORY INSTRUCTORS (with a good honours degree in chemistry, preferably with some graduate work, and interested in teaching modern laboratory techniques to undergraduates)—The Departmental Secretary, Department of Chemistry, The University of British Columbia, Vancouver, 8, B.C., Canada.

LECTURER and an ASSISTANT LECTURER (with a good honours degree in electrical engineering or an honours diploma in technology) IN THE DEPARTMENT OF ELECTRICAL AND ELECTRONIC ENGINEERING—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1, quoting Ref EE.

MASTER to teach Chemistry to "A" level—The Headmaster, Malvern College, Worcestershire.

PHYSICIST/PHYSICAL CHEMIST (experienced graduate, preferably with some knowledge of chemistry) to take charge of research projects on instrumentation methods for the control of manufacturing processes in the food industry—The Director of Research, British Food Manufacturing Industries Research Association, Randalls Road, Leatherhead, Surrey.

POSTDOCTORAL BIOCHEMIST for work on problems of brain metabolism, including study of control and transport phenomena and energy metabolism in slices and isolated cells—The Director, Metabolic Reactions Research Unit, M.R.C., Biochemistry Department, Imperial College, London, S.W.7.

RESEARCH ASSISTANT (with, or about to submit for the Ph.D. degree, and preferably experience of chemical kinetics or spectroscopy) IN THE DEPARTMENT OF CHEMISTRY, to work with Dr. B. P. Levitt on studies of chemical kinetics of electronic excitation by measurement of light emission from shock-heated gases—Dr. P. B. Levitt, Chemistry Department, Imperial College, London, S.W.7.

SENIOR LECTURER IN PSYCHOLOGY—The Secretary, Wolverhampton College of Technology, Wolverhampton, quoting Ref. MB. 15/1.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Medical Research Council. Special Report Series No. 307: A Search for Genetic Effects of High Natural Radioactivity in South India. By H. Grüneberg, G. S. Bains, R. J. Berry, Linda Riles, C. A B. Smith and R. A. Weiss. Pp. vii+59+4 plates. (London: H.M. Stationery Office, 1966) 11*s*. net. [74

The Printing, Packaging and Allied Trades Research Association. PATRA Critical Appraisals. Test Report—17: Web Offset—a Technical Survey. By A. F. Waters. Pp. 142 (Leatherhead: The Printing, Packaging and Allied Trades Research Association, 1965.) [144

Hospital Library Services Surveyed: Papers given at the Hospital Libraries and Handicapped Readers Group Conference and Week-end School held at Sorby Hall, University of Sheffield, July 1964. Pp. 63. (London: The Library Association, 1965. Available from the Hon. Secretary, National Library for the Blind, Northern Branch, 5 St. John Street, Manchester, 3) 12*s*. 6*d*. [194

Memoirs of the Geological Survey—Scotland The Geology of Northern Skye: Explanation of the Portree (80) and Parts of the Rubha Hunish (90), Applecross (81) and Gairloch (91) Sheets. By Dr. F. W. Anderson and Dr. K. C. Dunham. Pp x+216+4 plates. (Edinburgh and London: H M. Stationery Office, 1966) 42*s* net. [194

Twelfth Annual Report of the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme for the year to 31 December 1965. Pp. 8. (London: The Royal Society and the Nuffield Foundation, 1966.) [194

Ambassade de France, Service de Presse et d'Information. France's Economic and Social Council. Pp. 12. (London: Ambassade de France, Service de Presse et d'Information, 1966) [194

Journal of Cell Science, Vol. 1, No. 1 (March, 1966). Edited by H. G. Callan and A. V. Grimstone. (Formerly the *Quarterly Journal of Microscopical Science*.) Pp. 1–144. Subscription (one volume of four parts each year) 160*s* net; 27 50 dollars. Single parts 50*s*. net; 8 50 dollars. (London: Cambridge University Press, 1966. Published for the Company of Biologists, Ltd.) [194

IS SCIENCE REALLY INTERNATIONAL?

RECEIVED doctrine holds that science is in some sense supranational. Ever since Davy and Faraday went jaunting in Europe at the height of the Napoleonic Wars, it has been permissible to pad out public speeches with declarations that "science knows no frontiers" or that "the laws of physics are the same the whole world over". As a result, the idealism of young people has been harnessed to the view that science is potentially a substitute for diplomacy. Teach enough people enough physics, and international tensions will melt away in a flood of reason. That is how the theory goes. It is a puzzle to know how it can be so widely held when there is so much evidence to contradict it.

The fact that the laws of Nature are invariant under geographical displacement is, of course, a truism, but a memorable one. For one thing, it is a rallying-cry in the defence of the cultural integrity of the conceptual structure of science. The same problems simultaneously confront people in different parts of the world, and the fact that their solution can be helped by the purposeful but independent efforts of the professional community as a whole is one of the reasons why science is at once stimulating and moving.

There are also important practical consequences of this principle. It is hard for groups of people to pursue eccentric lines of argument for long once their eccentricity has been shown to entail internal contradiction. It is hard for Ruritanians, say, to believe their part of the Earth is flat when the rest of it is known to be spherical. The same intellectual unity of science has also led to the recent sensible awareness that there are limits to the extent to which secrecy can be imposed on scientific discoveries. Then the common problems of science bring people together; they travel, frequently as indifferent to local disturbances as Davy and Faraday were, and they strike up close relationships with each other.

With such an auspicious foundation, it is natural to expect that science will be a great co-operative endeavour, and this expectation is frequently supposed to be a fact. Unfortunately, however, it is not a truism but, at best, a half-truth. Reality does not match the expectation. Science may be the same everywhere, but the institutions of science are not organized for a common attack on the common problems. On the contrary, international rivalry, even chauvinism, is rife. Nobel prizes, like Olympic gold medals, are regarded as feathers in national caps. For various reasons, not all of them pleasant, international collaboration as it exists is much less real, and much less effective, than it could be.

Some things, of course, are being done. There is plenty of talk. There are bilateral agreements between nations which extend programmes of cultural exchange into science—and which serve chiefly as reminders that things were recently even worse. There are international groups under the umbrella of organizations such as the United Nations which perform valuable tasks. (There is also, as always, Unesco.) There are practical and powerful institutions for tackling common scientific problems, of which CERN remains the prototype and shining example. (Because the justification of apparently comparable organizations, such as the European Launcher Development Organization, is political as well as technical, it is not surprising that they are less effective.) Then there are valuable co-ordinating bodies like the OECD, and invaluable means of sharing ideas and efforts such as those which have grown up between Britain and the United States in academic research, because of the tight cultural links between the two countries.

This list is impressive but full of gaps. It would be surprising if it affected directly as much as 10 per cent of the activity in research and development of any advanced nation. For every triumph there is at least one sad case where collaboration could be made more effective. The deficiencies of present arrangements are particularly glaring in Western Europe, where—despite OECD and its good works—the gallop towards economic integration and possibly towards political integration as well is not yet matched by parallel tendencies in science and technology. Yet the opportunities and the benefits are potentially so great that collaboration in science in Western Europe deserves urgent special treatment.

In Western Europe there are many ways quickly to multiply the benefits of present collaboration. Thus a great deal could be done to get more from what is spent on academic research in Western Europe. There would be rapid rewards for arrangements making it easier for people, and especially students embarking on research, to move from one country to another. The training of young research people is the way in which universities and institutes traditionally re-invest their intellectual capital. If Western Europe is indeed one cultural entity, it is a great waste if the right students do not find their way to the right institutes of research, irrespective of nationality. In other words, there is a case for asking that postgraduate awards by, say, the British Science Research Council should be tenable anywhere in Europe.

There is also a need for fuller consultation between European grant-giving agencies. At present the pattern of academic research in European countries derives from the independent decisions of public and private grant-givers, tinged occasionally with pointless mimicry. In time, of course, individual scientists ensure by their applications for new grants that good ideas are widely spread, but that sometimes takes time.

Another obvious field in which European collaboration needs to be strengthened is in co-operative industrial research. In the larger nations co-operative research organizations are now flourishing. Their growth has been rapid in the past few decades, and has come about because well-established industries such as steel and textiles have been persuaded that a common attack on common problems need not prejudice the independence or the competitiveness of individual companies. But what is true of one nation's industry is now true for the whole of Europe. In other words, there is a case for a thoroughgoing integration of co-operative research in Europe.

These are important questions, but they are also untidy. All kinds of considerations apart from science and technology are involved. Because they raise the possibility that nations or industries might limit their freedom to determine the whole of their own affairs for the sake of a more effective attack on common problems, matters of

sovereignty are involved. Their difficulty is no reason for not tackling them.

Where the organization of European science is concerned, the ministerial meetings which the OECD has sponsored promise to be valuable, even if they have not yet done more than enable officials to know the names of those to whom they correspond in other countries. There is also a need for a more particular discussion of the common needs of Western Europe, either within OECD or at Strasbourg, in the Council of Europe. Then it was good to learn, last week, that Sir Harrie Massey, the chairman of the British Council on Scientific Policy, is to take personal responsibility for the international implications of British science policy. It is to be hoped that he will give himself a wide brief, and that he will urge his European colleagues to put stuffing into the old and most empty boast that science is already international.

MONEY TO SPEND

ONE of the cheerful parts of the report of the Council on Scientific Policy, published last week, is the statistical evidence it provides of the rapidly changing pattern of spending on research and development in Britain. There are a number of striking tendencies—some of them, at least, in the right direction. The declining emphasis on defence research and expenditure is the most heartening item of all. Over a decade, the proportion of the country's research and development expenditure provided by the defence agencies has declined from 59·1 per cent to 33·7 per cent (in 1964–65). In the past few years the defence departments of the Government have provided money at the roughly constant rate of £250 millions a year within a steadily rising budget which had grown to £756 millions in 1964–65, and the chances are that an increasing proportion of the defence money is anyway being spent on civil work. To welcome this is not, of course, to take a stand against defence research as such—that would be silly, for no country of importance manages to do without it. But there is no question that a decade ago the pattern of defence expenditure in Britain was lopsided. Now it is less so.

Naturally the universities and industry have benefited from this development. Over the past decade the value of research at universities has increased from £14 millions to £56 millions a year, and the value of industrial research and development from £200 millions to £508 millions a year. The change in the pattern of industrial research and development is especially to be welcomed because the proportion of it now financed by industry itself has increased over the decade from 39 per cent to 64 per cent. On the principle that the one who pays the piper calls the tune, this suggests that industrial research and development are now being directed more effectively towards the goals which should concern British industry—the commercial health and future of itself.

Where, then, are the snags? The sombre tendency in the statistics is that which shows that expenditure on research and development has become a static 2·6 per cent of the Gross National Product of the United Kingdom. Is this enough, or should the proportion be greater? This, it will be recognized, is a chicken and egg problem—which is the offspring, research and development or national prosperity? There will have to be a running battle on this issue in the years ahead, and the sooner it begins the better.

"BORN UNDER ONE LAW, TO ANOTHER BOUND"

Man Adapting

By Prof. René Dubos. Pp. xxii + 527. (New Haven and London: Yale University Press, 1965.) 10 dollars; 72*s*. net.

THE distinction between species, at the present time, is sometimes uncertain; the specific distinction between successive evolutionary stages is nebulous. This is not simply because of lack of evidence but because of the gradualness of the changes in the various factors that are used as criteria for a species. By all criteria our species is young, but our physiology and nutritional requirements probably retain many features that are well adapted because we share them with our predecessors. Dubos's basic thesis is that a person's genetic constitution defines potentialities; what actually happens depends on the environment and on nurture. He discusses in detail the extent to which our behaviour indicates incomplete adaptation.

Man Adapting starts, logically, with some examples of influences *in utero* and the effects of maternal care, or the lack of it, in infancy. There is then a section, in the Hippocratic tradition, on "Airs, Waters and Places" and one on rhythms. The interesting point is made that we are now exposed to an unprecedented amount of light and many of us to periodic inversions of the circadian rhythm. Animal behaviour is often modified by light and there is no reason to think that our own is not influenced also.

Primitive man lived an active life and had to tolerate a wide range of foodstuffs as well as intermittent privation. Modern man is sedentary and chooses to be more conservative and regular. Nutritional research has in the past concentrated attention on the needs of children or well-fed people leading active lives. In several places Dubos regrets the low esteem in which trophology is held and argues strongly for more work on novel foods, especially protein-rich foods, and on the needs of the sedentary and ageing. He goes so far as to suggest that contemporary forms of agriculture may become hobbies, like trout-fishing or cabinet-making, and be replaced by intensive methods in which the crop is the raw material for biochemical engineering. In studying nutrition particular attention should be given to the microbiota of the gut. Many experiments are quoted showing that not only the action, but the very physical structure, of the normal gut depends on the organisms growing in it. It may well be that the process of adaptation to a novel food depends primarily on microbial changes.

This discussion leads naturally to a discussion of pathogenicity and here Dubos is in his element. He quotes many examples of ubiquitous organisms that become pathogens when the host is stressed by crowding, amino-acid deficiency, or in other ways. He accepts specific aetiology, or the germ theory of disease, as "the most powerful single force in the development of medicine during the past century", but points out the enormous improvements in health brought about by people who did not know of it or even, like Ozanam and Florence Nightingale, rejected it. In the view of Dubos, people and animals adapt to changes in their environment, and the result is called disease when the attempt is unsuccessful. He devotes a chapter to the idea that some pathogens could be exterminated, but regards this as unlikely.

To an increasing degree, and throughout an increasing area, we have, in the past few centuries, been changing our physical and psychological environment in an unprecedented way. Dubos argues that we have not had time to adapt to these changes and they now come so fast that we probably never will have. He discusses the new chemicals to which we are now deliberately or inadvertently exposed. A blanket prohibition would be both impracticable and unreasonable, for traditional food-

stuffs contain many potentially harmful constituents and the search has, so far, been superficial. Instead, he suggests that a new drug, insecticide, food additive or process, which seems to be harmless and to be advantageous to the public as well as the manufacturer, should be used tentatively with close supervision. To circumvent the mania for secrecy in commercial and official circles, the supervision would have to be done by an outside body such as the St. Louis Committee for Nuclear Information, which Dubos singles out for praise. The conclusion, naturally, would not have the form "This is safe"; nothing effective is ever safe. Instead, as with vaccination, the conclusion would be semiquantitative: "This procedure will probably injure ten people per million exposed, but seems to have more than compensatory advantages".

There is in this book no Rousseauesque back-to-nature appeal and it will give little satisfaction to the noisy mystical faddists who advocate similar restraint. It should give even less satisfaction to those who direct medical research, for they are roundly criticized for their preoccupation with fashionable topics. A phrase may be quoted: "Any activity, however trivial, that deals with submicroscopic particles or subcelluar chemical phenomena is labelled 'fundamental', whereas efforts to formulate, investigate, or teach the phenomena of life as experienced by the whole organism are considered scientifically unsophisticated".

Dubos has written many informative and iconoclastic books. This is his best. It is compulsive reading and is enlivened by many quotations of historical and contemporary interest. Praise must, however, by tempered by a protest at the abominable method used for citing references; titles are given, otherwise one is left to choose more or less at random among the group attached to each chapter.

N. W. PIRIE

INDICATOR GEOBOTANY

Plant Indicators of Soils, Rocks and Sub-surface Waters
Edited by A. G. Chikishev. Authorized translation from the Russian. Pp. xi+210. (New York: Consultants Bureau, 1965.) 27.50 dollars.

THE close relationship between vegetation distributions and the geographical environment has long been accepted in ecological work. The use of this relationship in applied biogeography and geobotany, however, has developed only since 1945 with the desire to open up new lands in the U.S.S.R., Australia and Africa and to find new sources of scarce minerals. The impetus has come from the geographical sciences, particularly in the U.S.S.R., where indicator geobotany has originated as a special branch of biogeography and has become an effective tool in mineral exploration and in geological and hydrogeological surveys concerned with the search for underground water, with highway construction and the development of industrial sites. The publication in English translation of *Plant Indicators of Soils, Rocks and Subsurface Waters*, edited by A. G. Chikeshev, brings a summary of this work to the English reader.

The book comprises the collection of papers presented at the 1961 conference on "Indicator Geobotany", which was one of a series held since 1956 to bring together the scientists working in this field at the All-Union Research Institute of Hydrogeology and Engineering Geology, where a special laboratory dealing with indicator geobotany research has been established, the Institute of Geography of the U.S.S.R. Academy of Sciences, the Laboratory of Aerial Methods at the All-Union Aerogeological Trust and other institutions within the country. The papers cover a wide range of topics, and record the Russian achievements under widely differing geographical conditions in the different parts of the U.S.S.R. Several papers describe the use of geobotanical methods in hydrogeological surveys in the arid steppe where plant indicators assist in the location of underground water, its depth and mineral content. Others evaluate the relationship between the present vegetation and the structure of the upper layers of peat deposits which has an important bearing on suitability for highway construction. One paper discusses the procedural features of indicator research in different types of country and, in forest zones, emphasizes the need for careful analysis of floral lists since even slight variations in the abundance of a given species may reflect important habitat changes. Several papers demonstrate the value of plant communities in the recognition of soil types and of the geomorphological elements of river valleys. One details the ease with which, both from air photographs and ground survey, the dense growth of large larch trees set in an undergrowth of alder enables kimberlite pipes to be distinguished from the surrounding carbonate rocks carrying a sparser vegetation and so assists the search for diamonds. Another concerned with the search for saline domes in oil and gas exploration underlines the close link between vegetation distribution and the nature and intensity of surface geochemical phenomena determined by geology and geomorphology; and shows that whereas halophytic communities reveal the presence of a dome even where the saline nucleus is beneath a cover of 5–20 metres, a quite different vegetation occurs if the dome produces sufficiently marked relief to promote leaching of the more soluble salts thereby causing a lower salinity over the area of the dome than in surrounding areas.

Thirty-three papers clearly and simply demonstrate the value of indicator geobotany in numerous different areas each of limited extent. To the practising biographer, B. V. Vinogradov's paper on "Ecological Compensation and Replaceability and the Extrapolation of Plant Indicators" is a refreshing reminder of the complexity of relationships of vegetation with environment and the care needed in the use of plant indicators. After distinguishing between climatic, edapho-climatic and climatic influences, he emphasizes that relatively poor soils in a hot climate may provide the same nutritional condition as potentially richer soils in a cold climate, that moderate or inadequate soil moisture in the humid zone is compensated for by surplus soil moisture under arid conditions, etc. In consequence a species like *Carex appropinquata* Schum, which occurs under conditions of moderate moisture in the forest zone, may indicate substantial moisture in the steppe zone. With climatic-geochemical compensation, similar plant groupings may develop on normal soils with an unfavourable water or thermal régime in the steppe or tundra zone and also on soils with a high content of toxic metallic compounds in the forest zone. Thus *Festuca sulcata*, *Stipa* spp. steppe, the normal vegetation of the dry steppes, occurs on the serpentinites of the forest zone of the humid Southern Urals. I have observed a similar phenomenon in the Kalgoorlie district of Australia. Both instances recall Duvigneaud's findings in the Katanga where some species characteristic of cupriferous ground occur elsewhere only in extreme habitats such as ill-drained dambos and arid rock outcrops.

Vinogradov illustrates further the effects of climatic geochemical compensation by reference to kimberlite pipes which may be distinguished by a dense tree cover in humid areas and by the absence of trees in warm dry areas—the differences doubtless arising from the effects of the different concentrations of mineral salts under different climates.

In order to exclude the phenomena of edaptic compensation and indicator replaceability extrapolation within geographical landscapes characterized by a consistent vegetation, moisture, soils, relief, geology relationship is essential. Examples, accompanied by maps, of such landscapes are given. An admirable paper presenting the diagrammatic scheme of succession of indicator inter-

pretations of a geobotanical map follows; this is illustrated by a series of interpretational maps of salinization, age and genesis of soil-forming rocks, depth of bedding and level of mineralization of the first water-carrying horizon, and immediate prospects for agricultural use from the geobotanical map of the north Caspian region.

This collection of papers portrays the Russian achievements in the field of indicator geobotany or, as I should prefer to call it, applied biogeography. They reveal the potential of this field of study and support my contention that, particularly in the southern continents, applied biogeography can make a valuable contribution in land assessment for agriculture, forestry and other uses and in mineral exploration. These vast areas of savannas are undeveloped, sparsely settled, frequently by poverty-stricken people. There much basic biogeographical work has already been undertaken by lone individuals. It is to be hoped that the publication, in English, of the Russian work will provide support for those in Britain ready to assist the emergent African countries, eager to promote the development of the Australian outback and anxious to aid the Latin-American countries. Britain cannot afford to neglect the development of co-ordinated biogeographical research which would assist friendly nations and at the same time help to resolve some of its own problems, notably those concerned with disease incidence. The publication of *Plant Indicators of Soils, Rocks and Sub-surface Waters* is at once timely and challenging.

MONICA M. COLE

COMPONENTS OF ROLLING MILLS

Rolling Mills

By A. I. Tselikov and V. V. Smirnov. Translated from the Russian by M. H. T. Alford. Translation edited by W. J. McG. Tegart. Pp. ix + 405. (London and New York: Pergamon Press, Ltd., 1965.) 160*s*. net.

TSELIKOV is well known for his writings on rolling and rolling mills, and *Rolling Mills*, translated from the Russian, is a collection of his principal works on the mechanical plant requirements for the hot and cold rolling of typical steelworks products, including tubes. Much of the text was originally written more than 12 years ago, and to that extent some of the descriptions are dated, but the co-author Smirnov has been responsible for some revision of the text and illustrations.

The book runs to four hundred pages, is well illustrated, and is complete with a good index and bibliography extending to two hundred references, although most of the latter are to Russian literature that has not been translated. The standard of translation of the text is good and the terminology chosen is that in regular use in the West. Units are in the c.g.s. system, but there is frequent reference to Russian standards. These are used, for example, to denote the sizes of some rolled sections, for specifying the material of some plant components, and for describing fits of components. Without the key to the standards some value is lost. There are the occasional misprints, but to most readers these will be obvious and are not likely to cause confusion.

The book is restricted to mechanical plant requirements, however, and does not deal with either rolling theory or rolling practice, other than where necessary to explain the function of the plant. For some items only a simple description of the plant is given, but for many others the basic theory required for designing is given, and it is in these cases that the book is of most interest and likely to be of most value.

The work is divided into six parts, the first of which gives a background of mill terminology and mill classifications and is supported by detailed layouts of typical installations covering the range from primary mills to re-rolling mills. Typical planning parameters are listed. This is standard treatment of the subject but a necessary introduction.

Part 2 which follows with consideration of the component parts such as rolls and their adjustment and changing, bearings, guides and housings, introduces the theory of design in many cases. Inevitably some parts are covered in much more detail than others. Repeaters, for example, receive sparse mention, and although references are given these are in Russian. Part 3 on transmission equipment covers the design of spindles and couplings and gives a description of typical gearing. Fly-wheel theory is included, but there is no mention here or elsewhere of the characteristics or the control of the driving motors.

Special purpose mills is the subject of Part 4 and this includes description of tube and wheel mills. Mills with vertical rolls are also included in this section, which is one illustration of the dating of this book, because such mills are scarcely 'special purpose' in modern plant. Nevertheless, there is a useful description of the transmission of drive to this type of mill.

Auxiliary machines associated with rolling mills are covered in Part 5. In the chapter on shears there is a useful treatment of both resistance to cutting and the shear forces arising with these machines. Similarly, saws receive detailed treatment. Straightening machines are also well covered and methods of estimating power requirements are given for coilers. The section concludes with descriptions of tables, manipulators, chariots, transfers and cooling beds including methods of estimating required size for specified cooling conditions. The book concludes, in Part 6, with the elements of lubricating systems and methods of calculating their capacity.

The inclusion of the theory of design with some of the description of plant should make this a suitable text-book both for students and for practising designers. There are very few books that cover this branch of engineering adequately and this publication is a notable exception. It should be a worth-while acquisition for anyone concerned with the engineering of rolling mills, and although the plant descriptions are already dating, the basic approach to the design of some of the component parts should be of value for some time to come.

R. GREEN

LANGUAGE MECHANISMS

Speech Disorders

Aphasia, Apraxia and Agnosia. By Lord Brain. Second edition. Pp. ix + 201. (London: Butterworth and Co. (Publishers), Ltd., 1965.) 47*s*. 6*d*.

THE correct use of language depends on the integrity of certain areas of the brain, and in particular of its largest, most recently evolved part, the cerebral hemisphere. In right-handed people, damage to the left, but not to the right, cerebral hemisphere is apt to impair comprehension of speech, and the formulation of meaningful utterances, as well as ability to read and write. Nor do lesions in the various parts of the hemisphere affect all language functions equally. The further back the lesion, the more difficulty in comprehension; the nearer the front, the more trouble in expression. The nearer the lesion is to the visual receiving area, the more likely is reading to be affected. The nearer to the auditory receiving area, the more is comprehension of spoken speech involved. Damage to a certain area, the temporal lobe, disproportionately affects memory for verbal information. Nor does speech expression deteriorate all of a piece. Some patients have outstanding difficulty in naming—finding the precise word to suit the case. They are given to circumlocution. Others experience maximal difficulty in producing syntactically correct sentences. Their speech is telegrammatic in style and sparse in amount. Others are verbose to a degree, perhaps in private jargon, grossly mutilated

language which can nevertheless be to some extent deciphered by the attentive listener.

The varieties of aphasic manifestations are fascinating to observe, and indeed to read about. The theoretical issues raised are important. What brain mechanisms are involved in language function? Where are they located? How do they work? Here are major scientific problems which cannot be resolved by normal studies. To what extent can they be resolved in the light of existing knowledge of the affects of brain damage in man?

Speech Disorders appears opportunely at a cross-roads in the investigation of language disorders.

In spite of periodic pessimistic pronouncements by individuals unacquainted with the literature, the effect on language skills of damage to various parts of the brain is unusually well documented. Generations of clinicians have recorded verbal behaviour of such patients in the utmost detail. Some of the conclusions drawn go well beyond the data which was usually collected in an uncontrolled fashion. Criteria for the acceptance of hypotheses have become more stringent since psychology took its place among the life sciences, and concepts that had previously found ready acceptance now come under close and suspicious scrutiny. These include generalizations by clinicians about correlations between anatomical site of damage and nature of deficit and conclusions drawn from these as to the manner in which the brain functions. However, it is unfair to criticize the older clinicians for failing to use methods developed at a later date; it is foolish to ignore their observations, as this leads merely to redundant researches. The modern investigator, armed with efficient methodology, does well to note the older results, regard them as pilot studies, and use them to form hypotheses which can be put to the experimental test. He should not necessarily be disappointed if some of them prove to be correct.

Lord Brain's book is the ideal guide for this purpose. Written in a concise and exact manner, it succeeds remarkably in guiding the reader through a highly complex literature, each point being amply documented. The book is exceptionally well organized for easy reference; the author's judgments are balanced and never dogmatic. His own concept of the 'word scheme' is a valuable aid to this exposition, and is consistent with recently proposed models of brain function. With its full discussion of classical findings, and its ample consideration also of more recent results, this book will contribute greatly to the pooling of resources from a variety of sciences for use in the investigation of aphasia, which Lord Brain has himself so effectively advocated. M. KINSBOURNE

INFORMATION AND INVENTION

Third Annual Meeting of the Committee for International Co-operation in Information Retrieval Among Examining Patent Offices (ICIREPAT), at the Patent Office of the Federal Republic of Austria, Vienna, September 17th through 26th, 1963

Edited by Harold Pfeffer. Pp. v+347. (Baltimore, Md.: Spartan Books, Inc; London: Macmillan and Co., Ltd., 1964.) 110*s*. net.

FEW information retrieval systems face so severe a test as patent classifications, and few information specialists have as much experience in searching as patent examiners. This volume is therefore doubly welcome, since it represents a progress report on several years of work, on both operational and research levels, about which all too little has been available hitherto. The Committee for International Co-operation in Information Retrieval among Examining Patent Offices (ICIREPAT) is an informal committee of experts from eighteen countries, formed in 1961 on the initiative of the U.S. Patent Office. It has held several meetings, and set up a research associates programme under which members of one office can be seconded to another for extensive periods of research.

The book contains something of a mixture of papers: progress reports from several offices and research associates, technical reports on systems for arrangement, storage and testing, and a number of research memoranda presented but not read to the 1963 conference. Those that were read, being delivered to a relatively small and known audience, are plainly set out and much more readable than most work in this field. There is a great deal of data, especially in the research reports, and no one concerned with the design or testing of information retrieval systems can afford to neglect them. The methodologies are also of prime interest, in the comparative tests for example, since they are based, not on maximum retrieval (as in most such tests), but on the two chief factors in actual patent searching: speed, and the discovery of even a single anticipation. In his report on project "Carburettors", G. J. Koelewijn sets out a scale of values by which retrieved patents may be comparatively evaluated; in an interesting proposal for combining machine and manual (peephole) systems, Otto Schon suggests four 'specifications' against which the performance of information retrieval systems may be judged. Throughout, indeed, the emphasis is on practical results, and other important factors receiving attention include the layout of specifications, coding of chemical compounds (the Dyson–International Union for Pure and Applied Chemistry system was preferred), and the need for controlling terminology, not merely in obvious ways like synonyms, but also in settling fundamental questions such as the detail into which a compound term should be analysed.

Contrary to the statement from Leon Rolling that to-day "classifications are gradually replaced by systems of independent keywords", one finds repeated emphasis on the need for a structured vocabulary. Several offices, including the British, Japanese, Dutch, and apparently the Russian, make use of facet analysis in establishing basic categories for terms, pointing to the role of hierarchical linkage coupled with freedom to combine terms from different categories. The Japanese report that the ratio of specific search to generic search is roughly fifty–fifty. The research associate from the British office, D. C. Snow, names six fundamental categories: operations, matter, articles and apparatus, energy, attributes and conditions, signals; J. H. Callow, principal examiner at the British office, makes a strong case for a universal classification scheme, in which each field "should be developed in great detail with a faceted classification to enable maximum use to be made of mechanised searching". The spirit of international co-operation is everywhere in evidence, and while the difficulties are many and various, a considerable effort in this direction is clearly being made.

From its nature, this book will be used more for consultation than as a descriptive account of information retrieval in general, and as such it has much to offer. But though the aim is so specific, and the concentrations of data make tough going most of the way, several contributions examine basic questions as well, and deserve the attention of all who are faced with the problems of organizing information, even though they may not be directly concerned with patents. It is a pity that such a useful work should suffer from two noticeable defects: a liberal sprinkling of misprints and the lack of an index. The latter is surely relevant to the needs of examiners also, and a detailed contents table, with descriptive titles, makes some amends, but gives no hint of the discussions of steroids, nuclear reactors, glass technology, and the other important subjects concealed under "Progress Reports". Perhaps this might turn out to be an advantage, though, if it makes readers work through the whole book instead of concentrating only on what is relevant to their own specialized interests.

D. J. FOSKETT

Physics

Second edition. Pp. xvii+686. 47*s*. 6*d*.

Physics—Laboratory Guide

Second edition. Pp. vii+86. 12*s*. 6*d*.

(Physical Science Study Committee.) (Boston, Mass.: D. C. Heath and Company; London: George G. Harrap and Co., Ltd., 1965.)

THE profound influence of the physics course elaborated by the Physical Science Study Committee in the United States on the practice of physics teaching in secondary schools the world over is a remarkable example of the present-day revolution in thinking about education. For perhaps the first time, teachers of physics in schools were presented with a thoroughly tested package of teaching resources—modern texts, teachers' guides, films, apparatus, laboratory guides, problems, examinations, in-service training courses. The contents of the package were guaranteed, for its progenitors included such men as Francis Friedman, Philip Morrison, Eric Rogers and Jerrold Zacharias: and their teams included many distinguished school teachers. The course placed its emphasis on the fundamental principles of physics (with dynamics, wave motion and electromagnetism contributing to the basic dialogue between the continuous and the particulate). This was achieved with a minimum of formal mathematics and with no more than an occasional reference to the applications of physics.

Now, almost ten years since the early discussions, the 'feedback' from some six thousand teachers who have taught the course to some six hundred thousand students in American senior high schools has been used most skilfully to produce this second edition. In those years the course has been exported widely, translated into many languages (including Russian—but unofficially) and has markedly influenced the thinking which has informed the work in Scotland on the 'Alternative O Grade' course and in England and Wales on the Nuffield Foundation physics courses.

The exposition of the material in this new edition has been considerably improved; new end-of-chapter problems have been added and additional excellent photographs provided. Major changes are to be found in the chapters on the magnetic field, electro-magnetic induction and electro-magnetic radiation, while the revision of the work on vectors has clarified the concepts discussed. The small section on electrical circuits has been separated from the treatment of the motion of charges in the electric field, while the section on optical instruments has been deleted. Some new experiments, including a version of the Millikan experiment, are described.

The reputation of this unique course can only be enhanced by this new edition, for the treatment can now withstand the most searching criticism of the scientific community. E. J. WENHAM

Light-sensitive Systems

Chemistry and Application of Nonsilver Halide Photographic Processes. By Dr. Jaromir Kosar. (Wiley Series on Photographic Science and Technology and the Graphic Arts.) Pp. xv+473. (New York and London: John Wiley and Sons, Inc., 1965.) 115*s*.

THE term 'photography' is usually applied to the recording of a lens image by the use of a film coated with silver halide. Yet the first known photograph was produced ten years before the birth of silver halide photography by utilizing the hardening action of light on a bitumen layer. It is therefore fitting that in *Light-sensitive Systems*, the first book of a new series on photographic science and technology, Dr. Kosar deals with processes in which light acts to produce a chemical change in substances other than silver halide. Because these light-sensitive materials have much lower overall sensitivity than the silver halide process (the first photograph required an exposure of twelve hours), they have traditionally been used mainly as steps in the photographic production of matrices for printing operations, in which it is possible to make the exposure to a light source of high intensity. During the past two decades there has been a large increase in the use of non-silver products for the duplication of engineering drawings and for the reproduction of documents in offices.

Dr. Kosar discusses the action of light on inorganic compounds, particularly ferric salts, colloids containing dichromate, unsaturated organic compounds and diazonium salts: he also considers the formation or destruction of dyes and light-initiated polymerizations. The final chapter describes the process of thermography in which a record is made on heat-sensitive paper.

For each topic the literature has been successfully reviewed up to the end of 1964: much of the information has been obtained from patents. Some description is also given of technological applications, but detailed information must be sought elsewhere. The present work will be invaluable to research workers requiring ready access to previous work which hitherto has been widely scattered. The organization of each chapter into numbered sub-headings makes reference easy.

Proof reading has been well done and errors are few. A minor criticism is the lack of consistency in the representation of a benzene ring in structural formulae. In the majority a plain hexagon is used, but occasionally, often for one formula out of several on a page, Dr. Kosar has followed the recent fashion of inserting the double bonds of one Kekulé form in order to make clear the distinction from a *cyclo*hexane ring. D. J. FRY

Stationary Phase in Paper and Thin-Layer Chromatography

Edited by K. Macek and I. M. Hais. (Proceedings of the 2nd Symposium held at Liblice, June 10–12, 1964.) Pp. 258. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 85*s*.

DURING the three-day symposium on which this book is based, some fifty papers were presented on various aspects of stationary phase effects in paper and thin-layer chromatography; gas chromatography was specifically excluded although its use crept into K. Macek's investigation of aqueous two-phase systems. Twenty-one of the contributions are given in English, while the remainder, together with the greater part of the discussion periods, are printed in German.

Only five of the papers are more than ten pages long, most being covered in two to seven pages, which scarcely allows for full treatment of any subject. Useful contributions include a review of the use of liquid ion-exchangers in paper chromatography by E. Cerrai, M. Brenner's article on polyzonal thin-layer chromatography, R. Consden on the cellulose–water complex and a description of the influence of the activity of aluminium oxide on the chromatographic properties of aromatic hydrocarbons by J. Fohl and N. Kucharczyk.

The greatest emphasis throughout is on theoretical aspects of biochemical applications and nearly half the lectures were of an 'introductory' or review nature. On the whole there is little material here that is not available elsewhere scattered through the literature. However, the assembly of this information in one book provides a useful service for those interested in this somewhat limited but basic aspect of chromatography. The inclusion of the discussion periods following the various sections of the symposium is also of value, bringing out views not usually expressed in published papers. The message that comes across through all these papers is that it is not feasible to isolate the influence of the stationary phase from the effects of the other components of the chromatographic system. D. C. ABBOTT

FIREBALLS ASSOCIATED WITH THE BARWELL METEORITE

By H. G. MILES
Lanchester College of Technology, Coventry
AND
DR. A. J. MEADOWS
Astronomy Department, University of Leicester

ON December 24, 1965, at about 1612 h U.T., meteoritic fragments fell in a fairly restricted area in and about the village of Barwell, Leicestershire (long. 1° 20′.2 W., lat. 52° 33′.9 N.). The sighting of a very bright fireball and the associated sonic effects were recorded over a wide area, particularly in the counties of Warwickshire and Leicestershire.

Eye-witness accounts have been collected by the University of Leicester (Prof. P. C. Sylvester-Bradley), the British Astronomical Association (H. G. M.) and by one of us on a B.B.C. television programme, "Sky at Night", devoted to this event (H. G. M.). Analysis has shown the existence of three fireballs over the Midlands, all travelling in an approximately north-north-easterly direction. It has also shown that two of these were the result of a single object exploding over a point near the Gloucestershire–Warwickshire boundary. One of these resulted in the fall at Barwell. The meteorite fragments have been classified as olivine-hypersthene chondrites. No evidence has yet been found for meteoritic falls associated with the other two fireballs.

Meteorological Conditions

The Meteorological Station at Birmingham Airport reported that at 1600 h G.M.T. on December 24, 1965, the cloud cover at Coventry was 8/8th cloud at 6,000 m with much cloud at various lower levels. Reports from Coventry and the surrounding districts indicated that the cloud distribution was very irregular, resulting in one observer reporting a completely overcast sky and yet another only a few kilometres away reporting a relatively clear sky. Many observers also reported the presence of extensive cirrostratus. The general picture for the area was summed up to be:

cirrus/cirrostratus
↑
altostratus
↑
stratus

with varying amounts of each in any one locality.

From information obtained from the Meteorological Office, Bracknell, the height of the tropopause in the Midland area was estimated to be about 9,800 m at 1200 h G.M.T.

Track of Fireballs

Because of the irregular cloud distribution, people who saw a fireball tended to be clustered in reasonably well-defined areas; this left large regions from which no observations were received. Furthermore, because of the restricted visibility, most observers saw only one fireball. Six people, however, saw two objects and several others could not correlate the direction of the flash which attracted their attention with the direction in which they later saw the fireball.

An analysis of the reports has shown that three separate fireballs were observed from the Coventry area. One of the main difficulties of the analysis has been the sorting of the observations, as few of the reports came from people with astronomical knowledge or with training in reporting this type of phenomenon. In spite of this, the overall standard of the reports was high and, although possibly not given in the best way, much information could be extracted. Most of the observers in the Coventry area were interviewed by one of us (H. G. M.) and the accuracy of their reports assessed.

To clarify our discussion of the fireballs, we shall assign numbers to the tracks corresponding to the order in which they became evident during the analysis:

Track 1—travelling in an approximately north-north-easterly direction, passing over the eastern boundary of Coventry.

Track 2—travelling in an approximately north-north-easterly direction passing near Rugby.

Track 3—travelling in an approximately north-north-easterly direction passing over the western boundary of Coventry.

Track A—the track of the original fireball which produced fireballs 1 and 3.

Fireball 1. Thirty-four observations were obtained of this object. Preliminary investigation showed that the track, when extended, passed through Barwell; subsequent analysis has been based on the assumption that this fireball was responsible for the meteoritic fall in that area. The correctness of this assumption has been strengthened by an investigation of the distribution of the meteoritic fragments which suggests an approach from a direction slightly west of south.

Because of thick cloud immediately to the east of Coventry, most of the observations of this fireball were made from positions to the west of its track. Only one of the five made from the eastern side could be assessed as reasonably accurate. Several observers, however, reported the passage of an object overhead, and each gave an indication of whether it was slightly to the east or to the west. The direction of the track was thus found to be 023° ± 0·5° east of north. A high percentage of the observing positions were relatively near to the track and consequently the height of the bolide could not be determined very accurately. The angle of descent was found to be 20° ± 2° to the horizontal. Ten people who were outdoors at the time, 9–14 km from the impact point, but close to the track, reported no visual effects, but some heard a noise like thunder. This helps to confirm an extinction point, seen by two observers, at a height of 9·5 km (± 1 km) in a position within 1 km of 1° 26′.2 W., 52° 26′.3 N.

Fireball 3. The existence of this bolide became apparent when some observers in Coventry reported seeing an object to the west of the city. It was also indicated by the reports from the Nuneaton and Loughborough areas. Unfortunately, the quality of many of the twenty-eight observations of this fireball was not so high as in the

previous case, but from the few accurate reports it was found possible to determine the track as 020° E. of north with an accuracy of ±2°. The object travelled across the west side of Coventry, passing over a point within 0·5 km of long. 1° 31′.2 W., lat. 52° 25′.5 N. The angle of descent could not be determined accurately, but a value of 13° to the horizontal and an extinction height of 10 km at a position within 3 km of 1° 18′ W., 52° 50′ N., are the most probable values.

Fireball A. If tracks 1 and 3 are produced backwards they converge on a point in the region of long 1° 49′ W., lat. 51° 56′ N. Using the angles of descent already given, a convergence of heights occurs in about the same region. This indicated the possibility of a break-up of a single fireball in the vicinity of the position quoted. The validity of this possibility was strengthened by an observation made from the Birmingham area in which the break-up of a fireball was witnessed. The observer reported that one component descended at an angle a few degrees greater than the original angle of descent and the other at an angle slightly less. He said that the two components were visible for only a short time after separation; however, he was unable to say whether the loss of sight was due to a natural extinction or to interference by cloud. Because of the extreme scarcity of observations in the Birmingham area the latter explanation is more likely to be the correct one.

Fireball 2. From the outset of the investigation, it was apparent that observers in the Coventry area who saw a fireball in the eastern part of the sky could not all have seen the same object. The subsequent analysis was hindered by the absence of reports from eastern and north-eastern Warwickshire due to considerable low cloud. Observations from the Rugby area clarified the situation. One observer saw the flash and trail of an object directly overhead and almost immediately saw another object crossing the sky in the Coventry direction at a much lower altitude. The existence of two objects was further verified by observers situated to the west of Rugby who saw a fireball either to the west or to the east.

The thirty-six observations of this fireball were distributed evenly to the east and west of the track, although most of those from the western side came from a very restricted area. The bolide travelled in a direction roughly parallel to fireballs 1 and 3—the most probable value being 023° east of north with a possible error of ±2°. The track passed to the west of Rugby and ended at a point of extinction above the position long. 1° 11′.5 W., lat. 52° 32′.2 N.; however, there may be an error in a lateral direction of 1·5 km. The angle of descent could not be determined accurately as the bolide was only observed over a relatively short track, but the most probable value is within a few degrees of 20°.

Observations outside the Warwickshire–Leicestershire area.

(i) An observer from Cirencester reported an object in the east travelling in a north-north-easterly direction. This was most likely fireball 2.

(ii) An observer from Harwell (Berkshire) reported an object in the north-west at an altitude of 40°. If this object had been fireball *A*, the altitude would have been lower. If track 2 is extended backwards, the height obtained is similar to that of fireball *A* in the corresponding position. Because the bolide was followed over a considerable angle in the sky and because no separation was reported, it is concluded that the object was fireball 2.

(iii) An observer from north of Worcester reported seeing a single object low over the Malvern Hills.

(iv) An observer from Oswestry (Shropshire) reported seeing two fireballs travelling on parallel tracks low down in the south-south-east.

(v) Eight observations from the Staffordshire area reported objects in the east and south-east. It is thought that they refer to fireball 3, but the accuracy of the reports was such that this could not be confirmed.

(vi) Six observations from the Reading–Aylesbury area reported a fireball to the north which dropped vertically to the horizon. All reported a single object. If the object seen was one of the aforementioned fireballs, no explanation can be put forward to explain why the others were not seen.

Fig. 1 shows the probable tracks of the various fireballs. Fireballs *A* and 2 are shown with parallel tracks. The probable errors involved in deriving these tracks would not contradict the supposition that these two bolides derived from a single body separating, say, at the top of the stratosphere. There is a slight possibility, however, that they may already have been separated in space. (For a recent discussion of meteorite swarms, see Nininger[1].)

Observations not included in the foregoing. Nine observations were received reporting an object with a long tail travelling in a north-east to south-westerly direction. These reports are reasonably consistent and suggest a track passing near Grantham (Lincolnshire), Rugby, and Stroud (Gloucestershire). No attempt has been made to explain these reports.

Visual Appearance of the Fireballs

The main bodies of all three bolides were reported to have been spherical in shape. The reports conflict somewhat as to the presence, or absence, of tails. Fireball 3 definitely developed a noticeable tail, yellow in colour. Fireball 2 possibly developed a small tail. Fireball 1 probably formed a tail during the last part of its flight. Both 1 and 2 left white dust trails behind them. The trail left by 2—at least during the latter part of its flight—was definitely corkscrew in shape. Because of the extensive cloud cover, it is difficult to say precisely how long these trails lasted. That from fireball 2, however, certainly endured for several minutes. There is general agreement among observers that the central regions of

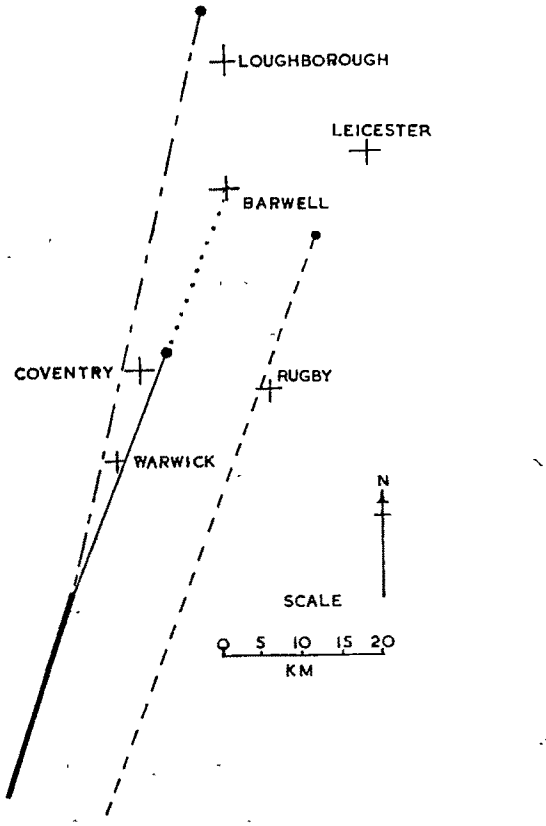

Fig. 1 Probable tracks of the fireballs: ———, Track 1; – – – –, track 2; — — — — —, track 3; ▬▬, track *A*. ●, extinction point

both 1 and 2 were orange-red in colour towards the end of their flight. Reports from earlier along their tracks suggest that they may then have had a whitish tinge. Both 1 and 2 were noted by a few observers to shed sparks.

Fireball 2 is reported by several witnesses to have blown up at the point which is recorded in Fig. 1 as its "extinction point". The reports indicate that four major fragments resulted from the explosion. One piece was shot upwards, the other three downwards. No such explosion was observed for fireball 1.

From the tracks of fireballs 2 and 3 and their estimated final extinction points, it is possible to make a tentative guess at the areas where they finally fell. If either of these bolides produced enough solid material to reach the ground in appreciable quantities (which is by no means certain), then fireball 2 would probably have deposited material somewhere around Leicester and fireball 3 somewhere around Nottingham.

Acoustic Phenomena

Numerous reports of acoustic phenomena have been received from along the tracks of the fireballs. Many people, of course, detected the sound effects without observing the related visual phenomena. The reports are mainly concentrated in a region extending from Wiltshire in the south to Leicestershire in the north. The area covered is about 150 km long (in a south-south-west–north-north-easterly direction) by 50 km wide. This elongated shape for the acoustic field is typical for a bolide trajectory with a low angle of inclination to the Earth's surface[2]. The sound effects seem to have been particularly intense south of Rugby and in the Coventry area. In the latter region breakages (for example, of electric light bulbs) were reported. There also seem to have been zones where less noise was received than would be expected. A particularly obvious 'silent' zone was in the region between Coventry and Barwell.

The reports of sound effects, as might be expected, are considerably more confused than the visual sightings. There are, for example, several reports from observers in the Coventry area who noted the passage of a fireball and then recorded the length of time before any noise was heard. Even over this very small area, the time intervals reported vary from a few seconds to more than 2 min. Apart from the normal subjective errors in recording the passage of time, there are two other possible causes contributing to this scatter. The first is that both fireballs 1 and 2 seem to have produced acoustic phenomena. It seems possible that noise from both fireballs would be audible in Coventry, and at other points along their tracks, if the conditions were suitable. Therefore, observers in Coventry may have been detecting noises from two different sources. This suggestion receives some support from one witness in Coventry who heard two separate sets of acoustic phenomena spaced about a minute apart. It is further supported by the fact that the Coventry observations can, to some extent, be separated into two groups—one with a delay time of half a minute or less, and the other with a delay time of a minute or more. The second possible cause of scatter lies in the differences between the types of sound which were reported. Some witnesses have reported only a bang, others heard a bang preceded by a prolonged rumble, others again heard a bang followed by a rumble. These delay times can also be reconciled in a different way: by assuming that fireball 1 was subsonic in the Coventry region and that the noises came from fireballs 2 and 3 which were still supersonic. There is, in fact, only one direct report of a sonic boom from fireball 3, although several reports of 'rushing' noises have been received from along its track.

Several reports from south of Warwick indicate that three distinct sonic bangs were heard there. These were probably connected with fireball 1. It is also certain that fireball 2 produced at least two sonic bangs and possibly more. It should be added that most meteorite falls are said to produce three detonations during their passage through the atmosphere[3].

Besides numerous reports of normal sonic phenomena, there have been a few reliable reports of electrophonic noises[4]. (These are hissing noises heard well before any other sonic effects.) One observer, for example, reported hearing noises of this type before he saw the bolide break through the cloud cover towards him.

Witnesses in Barwell itself have given consistent accounts of the actual sounds heard at impact. These are typically described as starting with a 'swishing' noise and ending with a succession of dull thuds.

Details of the Fall at Barwell

The final angle of descent can be estimated fairly accurately for one of the pieces that fell at Barwell, because it penetrated the roof of a factory and then a floor below. It struck from a generally south-easterly direction at an angle of somewhat less than 80°. The positions of some of the other fragments which are near buildings or fences indicate that they, too, were falling almost vertically just before impact. It should be noted that the final direction of fall of a meteorite fragment is not necessarily related to the direction of the parent bolide[5].

There are considerable disparities between the depths of penetration of the various meteorite fragments. Thus one piece was found lying on the ground, whereas another piece of similar size and falling on to a similar surface was buried to a depth of more than half a metre.

The meteorite fragments so far recovered from Barwell have been found over an approximately circular area (Fig. 2). There is no obvious graduation in the size of the fragments across this area, although an extended swarm of smaller fragments lies on the southern side. This latter feature would suggest that the meteorite approached from a generally southerly direction, since typically the larger meteorite fragments carry further. Previous meteorite falls which have been investigated in detail have tended to give an appreciably elongated distribution extending over several kilometres, for example, the Brudenheim meteorite[6]. The different distribution of the Barwell meteorite may be due to a final break-up late in flight. This is supported by the lack of secondary burning on the surfaces of the fragments, and by the fact that several pieces which come from various places in the distribution area can be fitted together very accurately. The final break-up must therefore have occurred after the passage of the meteorite through the region of retardation (that is, after it reached a subsonic velocity). The region

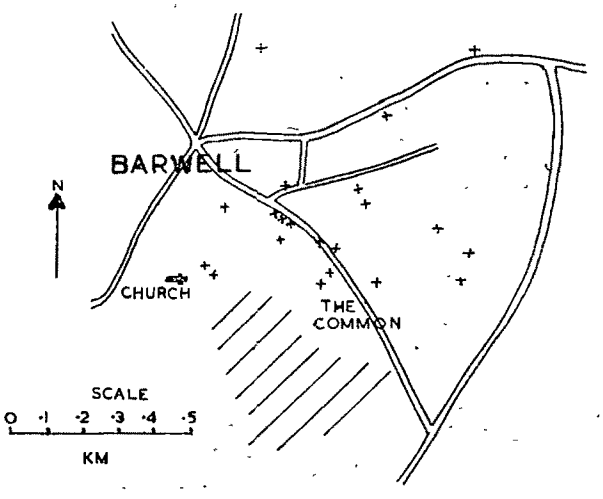

Fig. 2. Barwell. +, Principal falls. Hatched area, small fragments

of retardation may be taken to coincide with the extinction point, which, for the fireballs considered here, coincided with the tropopause. The final fragmentation must therefore have occurred at a height of less than 10 km. It should be added that the meteorite fragments are somewhat friable and do not appear to possess an unusual compressive strength.

One fragment of the meteorite was picked up immediately after impact. It is reported to have been warm to the touch initially, cooling to the ambient temperature within 25 min.

PHOTOPERIODIC TIMING MECHANISMS IN INSECTS

By DR. A. D. LEES
Agricultural Research Council Unit of Insect Physiology, Department of Zoology, Cambridge

RESPONSES to seasonal changes in day length have now been described in a wide range of insects[1]. Several morphogenetic processes are controlled by this factor, but the arrest of growth (diapause), so often found in hibernating or aestivating insects, and seasonal changes in form (polymorphism), are two of the most familiar. Although they vary in detail, the response curves of most species show a very sharp transition when the daily photoperiod is of intermediate or critical length. Recent work on the green vetch aphid *Megoura viciae* provides a typical example. Form determination in this insect is controlled maternally. Parent viviparae that have developed in long days give birth to similar viviparous, parthenogenetic daughters, while parents from short-day conditions produce egg-laying females (the oviparae). In the clone under investigation the critical photoperiod is close to 14 h 45 min. These are the conditions under which approximately half the individuals develop as vivipara-producers and half as ovipara-producers. But this is a point of considerable instability since the photoperiod has only to be lengthened or shortened by 20 min in order to shift the response to completion in either direction.

Results of this kind indicate that insects possess an intrinsic timing mechanism of considerable accuracy. However, there is at present little agreement as to the type of biological clock which may be involved. One view[2] is that the mechanism has analogies with the hour-glass or interval timer and, as such, is concerned in measuring the length of the dark component in the 24-h cycle. Some additional evidence which favours this concept will be presented in the present article. The second hypothesis is based on the belief that the clock embodies an oscillator which is closely coupled to the endogenous circadian systems that govern a wide range of daily rhythms. The latter idea, in one of its forms, has been advocated particularly by Bünning[3] and has been supported experimentally by the work of Bünning and Joerrens[4] on the photoperiodic control of pupal diapause in the lepidopteran *Pieris brassicae*. According to Bünning, time measurement depends on an endogenous 24-h rhythm of photosensitivity which is itself initiated and phased by light. After the rhythm has been phase-set by the onset of light in the first cycle, the period of the rhythm is assumed to remain constant at 24 h even if the external conditions (such as the cycle length) are changed. The rhythm is regarded as first passing through a photophile half-cycle of 12 h when any incident light will be diapause-promoting; this is followed by a second (scotophile) half-cycle when light will be diapause-inhibiting.

Bünning's model is consistent with the obvious effects of normal short and long day cycles, since diapause tends to be induced if the daily photoperiod is 12 h or less, while it is prevented if the photoperiod lengthens to 13–14 h and therefore extends into the scotophile. Bünning and Joerrens tested the hypothesis further by introducing short light "breaks" into inductive long dark periods. Their theory requires that there should be one peak of light sensitivity during the course of the dark half-cycle. This was found, but unfortunately the light interruptions were not continued to the end of the dark period. Work on other Lepidoptera, including *Ostrinia nubilalis*[5], *Pieris rapae*[6] and *Pectinophora gossypiella*[7], as well as in the aphid *Megoura*[8], has shown that in all these species there are two peaks of sensitivity to such interruptions, one at the beginning and the other towards the end of the dark period.

It is also noticeable that the evidence for the photopromotion of diapause is much less satisfactory than the evidence for photoinhibition. For demonstrating the former, Bünning and Joerrens used 24-h cycles containing dark periods of more than 12 h which therefore extended into the photophile. Although diapause was slightly enhanced by light interruptions that fell within this half-cycle, it is evident from the normal response curve that uninterrupted long night cycles of comparable length tend to produce a response which lies near the threshold and is therefore highly variable. The use of very long dark periods in 24-h cycles may also be misleading for another reason. If the dark period exceeds the critical length by an appreciable amount, sub-terminal light breaks may still leave an uninterrupted dark period of more than critical length and an extra "inflexion" in the response curve may be generated.

Pittendrigh[9] and Minis[10] have offered an alternative hypothesis, similarly based on the belief that circadian rhythms are intimately involved in photoperiodic time measurement, but one which also takes into account the bimodal response to light interruptions. Their "coincidence model" rests on the assumption that diapause inhibition in *Pectinophora* depends on the temporal relationship between a light-induced enzyme response and an independently phased substrate oscillation. The hypothetical substrate rhythm in the larva is regarded as having the properties of other circadian processes in the same insect. One such system is the oviposition rhythm of the parent moth. With 24-h cycles containing two separate light periods (one a pulse and the other a more extended photoperiod), the moth responds as if to a single continuous photoperiod. The degree of separation of the two components then decides whether the light pulse is accepted as "dawn" or "dusk" and whether the ensuing phase shift is an advance or a delay. If comparable phase shifts were to occur in the substrate rhythm in response to early and late light interruptions, the peak of the entrained rhythm might be brought to coincide either with the end of the main photoperiod or with the light break itself. Diapause would then be inhibited. On the other hand, "coincidence" might not be achieved in the transitional "resetting zone" and diapause would occur. So far, this model has not been fully tested.

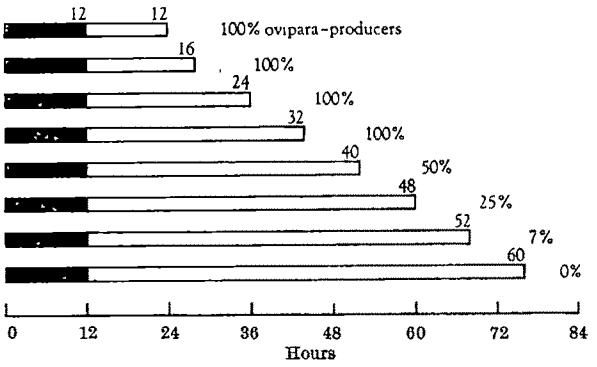

Fig. 1. Response of the aphid *Megoura* to cycles of illumination containing a continuous dark phase (12 h) of more than critical length

Observations on the aphid *Megoura* have led to an entirely different concept, namely, that the photoperiodic clock is an interval timer, apparently unconnected with the circadian system. The dark period is of central importance in time measurement. This is seen if very long intervals of light are alternated with dark periods of more than critical length (Fig. 1). Even if the photoperiods now far exceed the normal "long day", the parent aphids still develop as ovipara-producers; indeed, Fig. 1 shows that one long 12-h dark period every 2 days is sufficient to annul the effects, if any, of the longer light phases.

At the same time, light break experiments demonstrate that the "dark reaction" involves more than the simple interconversion of two chemical substances. The effects of 1-h interruptions of low intensity light (30 ft.-candles) are illustrated in Fig. 2. The length of the dark period (10·5 h) has been chosen so that it exceeds the critical length (9·75 h) by only a small margin. The bimodal response referred to previously can clearly be seen: the light breaks are highly effective at the beginning and during the last two-thirds of the dark period, no oviparae being formed. But during the intermediate phase the response becomes exceedingly refractory to light. Even high intensity white light (5,000 ft.-candles) is usually without effect if the aphids are irradiated 4 h after the beginning of darkness.

Although sensitivity changes produce striking inflexions in the response curve, it would be unsafe to conclude that these are necessarily the manifestations of an endogenous rhythm. Two considerations suggest otherwise.

(1) The response to dark-period interruptions has proved to be independent of the length of the "main" light period, at least within very wide limits. In Fig. 2*A*, the main photoperiod was 13·5 h in length. Figs. 2*B* and *C* show the response to 1-h light break scanning a 10·5-h dark period, when the main light phase has been extended by 12 h to 25·5 h, or reduced by 5·5 h to 8 h. Obviously, the form of the response is almost unchanged.

These results cannot be accounted for by Bünning's hypothesis In several of the cycles shown in Fig. 1 the long light period extends into Bünning's scotophile phase, yet does not annul the inductive effect of the 12-h dark period. The outcome is the same with the cycle of 25·5 h light, 10·5 h dark (Fig. 2*B*), in which the main light period entirely occupies the first scotophile phase. Further, the ensuing dark period with its scanning light interruptions now coincides with the photophile phase of the second day; yet it is clear that ovipara-production is diminished and not enhanced.

These observations appear to be equally irreconcilable with Pittendrigh's model, which requires that the substrate rhythm should entrain to a similated photoperiod defined by the beginning of the main light period and the end of the subsidiary light break. In the experiments just described, this varies from 9·5 h (Fig. 2*C*) to 34 h (Fig. 2*B*). There are no higher organisms in which the limits of entrainment are known to be as wide as this[11].

(2) Cycles longer than 24 h and incorporating a long or very long dark period which is scanned with light breaks have frequently been used for detecting possible circadian periodicities in plants. The work of K. C. Hamner, in particular, has shown that in some short day plants (such as Biloxi soybean), light interruptions may cause an apparently rhythmic flowering response, in conformity with Bünning's hypothesis[12]. In one series of experiments by Hamner, soybean plants were exposed to cycle lengths ranging up to 72 h, and including a constant "main" light period of 8 h. Light perturbations introduced into the dark period tended to inhibit flowering if they occurred about 16, 40 or 64 h after the beginning of the main light phase, that is, during Bünning's first, second and third scotophile phases.

A number of experiments of similar design have been carried out with the aphid *Megoura*. One example of the results, all of which were alike, is given in Fig. 3. It will be seen that the 1-h light breaks, which were spaced in 4-h steps in a 64-h dark period, failed, with one exception, to reduce the inductive effect of the long nights. In this unique cycle, which evoked a complete reversal of response,

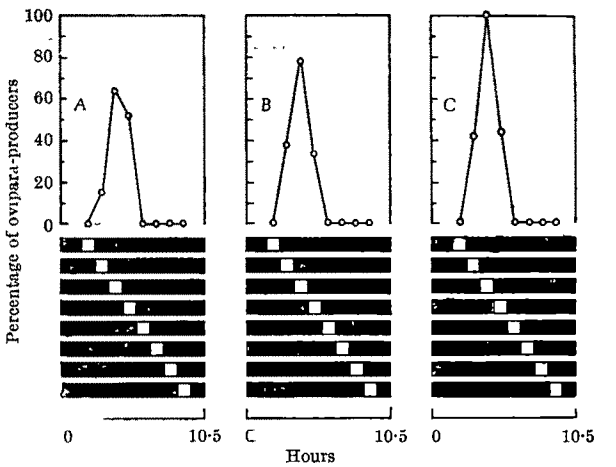

Fig. 2. Photoperiodic reactions in *Megoura*. The three groups of cycles shown in *A*, *B* and *C* all contain a 10·5-h dark phase scanned by 1-h light interruptions. In each group the scanned dark period was preceded by a constant "main" photoperiod (not shown). The duration of this light phase was 13·5 h in *A*, 25·5 h in *B* and 8 h in *C*. In the controls (uninterrupted dark period of 10·5 h) 100 per cent of the aphids produced only oviparous progeny

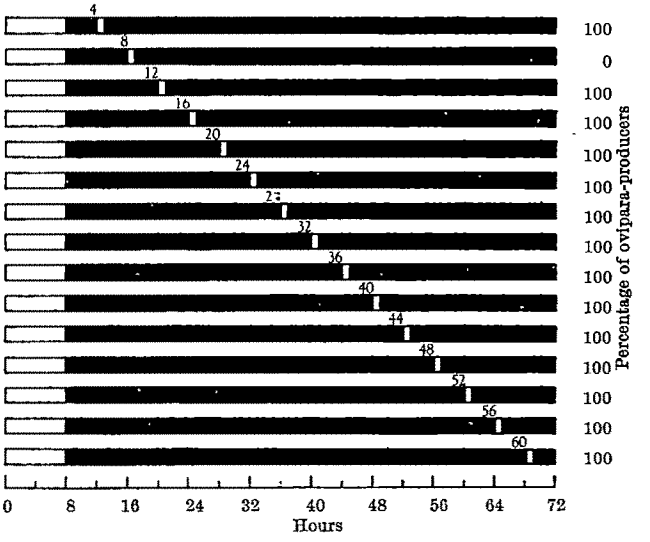

Fig. 3. The effect of introducing 1-h light interruptions into a very long dark period. In the controls (uninterrupted dark period of 64 h) 100 per cent of the aphids produced only oviparous progeny

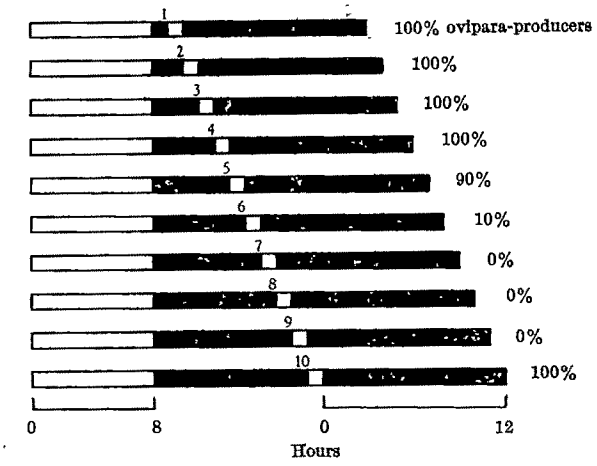

Fig. 4. Photoperiodic reactions in *Megoura*. The effect of introducing 1-h light breaks at different points in the dark period on the response to a subsequent uninterrupted dark period of more than critical length (12 h)

the light break occurs 8 h after the beginning of darkness. Nevertheless, although the long dark phase is obviously highly photosensitive at this point, no trace of a second or third response maximum can be observed with light breaks placed 24 or 48 h further into the dark phase.

While this result provides no indication that the response is rhythmic, it is not, at first sight, easily reconciled with the interval timer hypothesis since, no matter where the light interruptions are placed, each cycle still contains a residual uninterrupted dark period that exceeds the critical length. The explanation of this finding was provided by the observations summarized in Fig. 4. As in the previous experiment, all cycles started with a main light period of 8 h and the following dark period was again scanned by 1-h light breaks; but this series differed in that each interruption was followed by a constant long night of 12 h. When the duration of the dark period, prior to the interruption, did not exceed 4 or 5 h, the long night had the effect expected and was fully inductive. Further, it could also be shown that in such cycles the length of darkness required for complete induction was precisely the critical length, namely, 9·75 h. This must mean that after an early light break the timing process is begun anew.

The response is entirely different if the light breaks follow dark periods of 6–9 h duration (Fig. 4). Induction is then totally inhibited until the dark period before the interruption again exceeds the critical length. This inhibitory effect, which is strikingly reminiscent of the phenomena described by Schwabe[13] in certain short day plants, is also influential outside the cycle in which it occurs. It is well displayed when long days of normal length (such as 16 h light, 8 h dark) are interpolated in a sequence of short days (such as 12 h light, 12 h dark). Table 1 shows that one long day (*L*) is sufficient to cancel out the inductive effect of 2–3 intervening short days (*S*).

Table 1

Regime	Percentage of ovipara-producers
SLSLSLSLS.....	0
SSLSSLSSL.....	0
SSSLSSSLS.....	30

Clearly, this type of regime should be contrasted with those in which adjacent "short days" are separated by long periods of continuous illumination (as in Fig. 1). This result is of interest since it shows that a long day effect is not achieved merely by the absence of inductive long nights, but is at least partially caused by the fact that the short night moiety of the long day cycle is terminated by light after 6–9 h. It should be pointed out, however, that the inhibition is not obtained if the light period preceding the curtailed dark phase is of insufficient length. This is why the cycle 8*L*, 56*D*, 1*L*, 7*D* (Fig. 3) is fully inductive, even though it includes a light-interrupted dark period of 7 h.

The similar effects caused by the introduction of light breaks into dark periods of more than critical length account also for the dual low threshold regions in Fig. 2. But it is now clear that the mode of action of light is entirely different, depending on whether the breaks come early or late. The two photoreactions can be further characterized by means of their action spectra. The response to 1-h interruptions of monochromatic light, placed 1·5 h after the beginning of a 10·5-h dark period, is plotted in Fig. 5. Interference filters with an average bandwidth at half-peak transmission of 7 mμ were used with a tungsten source and light energies measured with a calibrated vacuum photocell. It is sufficient to expose young larvae to eight consecutive interrupted cycles. The curve shows that minimum energies are required at 450–470 mμ in the blue region of the spectrum. The response falls off rapidly both in the near ultra-violet and in the green above 500 mμ. No minor inflexions have yet been established with certainty.

The pronounced blue sensitivity observed in this insect appears to be typical of the photoperiodic responses of arthropods, particularly when these have been tested by extending the main photoperiod with filtered light (the probable equivalent of an early dark period interruption[1,14]). In its general form the aphid action spectrum resembles the spectral sensitivity curve for diapause inhibition in the red spider mite, *Panonychus ulmi*[15].

Since the light energy which drives the photoperiodic response is so strongly dependent on wave-length, it may be assumed that absorption is similarly selective. The photoreceptor should then be a pigment, presumably orange in colour. Unfortunately, the exact site of the receptor is still in doubt. It has been shown that the compound eyes do not form the light pathway and that light acts directly on the brain[16], as it also does on the pupa of the silkmoth, *Antheraea pernyi*[17]. Yet visual

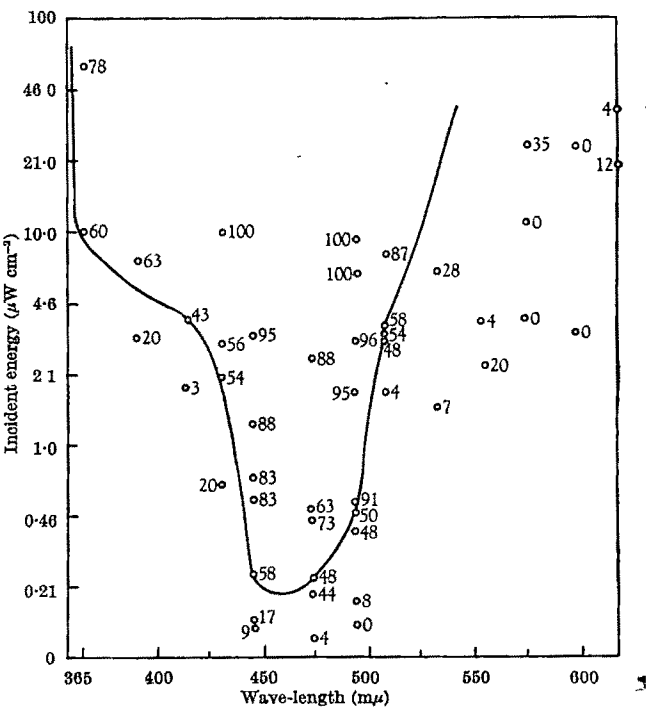

Fig. 5. Action spectrum for the photoperiodic control of progeny type in *Megoura*. Semilogarithmic plot showing the response to 1-h interruptions of monochromatic light introduced into a 10·5 h dark period 1·5 h after its inception. The "main" photoperiod of 13·5 h was of white light (100 ft.-candles). The intensity of the response is given by the percentage of aphids that produced viviparous progeny. These values are also shown by their respective points and the curve is drawn at approximately the 50 per cent response level

Glucuronic Acid

FREE AND COMBINED

Chemistry, Biochemistry, Pharmacology, and Medicine

edited by **Geoffrey J. Dutton**

The first book dealing comprehensively with this compound which has dramatically risen to the forefront of research in biological chemistry. Assembling findings from chemical, biochemical and pharmacological areas, **Glucuronic Acid** correlates important facts from these fields, and indicates which problems might next be tackled.

October 1966, about 575 pp., approx. 176s.

Cell Synchrony

STUDIES IN BIOSYNTHETIC REGULATION

edited by **Ivan L. Cameron and George M. Padilla**

This book is a compendium of research approaches in the field of cellular growth and replication. It presents a broad coverage of many cell systems from fungi and bacteria to mammalian cells. Each of the eighteen chapters deals comprehensively with a separate cell system in which regulatory processes are investigated by techniques of cell division synchrony.

July 1966, 392 pp., 120s.

Neuroendocrinology

edited by **L. Martini and W. F. Ganong**

This two volume treatise reviews all aspects of the broad and rapidly expanding field of neuroendocrinology. The contributors discuss the anatomy, physiology, and biochemistry of neuro hormones. Emphasis is placed upon the interaction of the neuro hormones with other hormones.

Volume 1, September 1966, about 675 pp., approx. 200s.
Volume 2, December 1966, about 700 pp., approx. 200s.

VOLUME 3 OF

Survey of Progress in Chemistry

edited by **A. F. Scott**

CONTENTS: J. A. BASSHAM, Photosynthesis. R. M. FRISTROM, Flame Chemistry. W. H. SAUNDERS, Jr., Kinetic Isotope Effects. JAMES D. MORRISON, Asymmetric Reduction. MARVIN H. LEHR, Stereoregular Polymers. *Author Index—Subject Index*

August 1966, about 300 pp., approx. 62s. 9d.

Venomous Animals and Their Venoms

edited by **W. Bücherl, V. Deulofeu and E. E. Buckley**

This three volume treatise compiles the latest developments in the fields of taxonomy, distribution and habitat of the venomous animals, as well as the biochemistry, pharmacology and toxicology of their venoms. Volume I contains the chapters on the venomous mammals and the first part of the large section on venomous snakes.

November 1966, about 650 pp., approx. 208s.

IN TWO VOLUMES

Mixing Theory and Practice

edited by **Vincent W. Uhl and Joseph B. Gray**

Provides a complete and practical summary on the theory and practice of mixing. The contributors have developed the underlying theory and consolidated the available information on mixing mobile and viscous liquids, solids, solid-liquid, and gas-liquid systems. Treatment ranges from critical reviews of available knowledge to improved correlations and new syntheses of present information.

Volume 1, August 1966, 341 pp., 124s.
Volume 2, in preparation

ANNOUNCING VOLUME 6 OF

Advances in Chemical Engineering

edited by **Thomas B. Drew, John W. Hoopes, Jr. and Theodore Vermeulen**

November 1966, about 425 pp., approx. 124s.

PERGAMON PUBLICATIONS

1965 Transactions of the Third International Vacuum Congress, Stuttgart, Germany

Volume I: Invited papers

Edited by **H. Adam**

The main subjects of this meeting gave an interesting and, in the widest sense, an important insight into the significance of high vacuum for our present science and technology.

Contents: M. Auwarter—Die Bedeutung des Hochvakuums fur die wissenschaftliche und technische Entwicklung; K. Bier—Dynamics of rarefied gases; A. van Itterbeek, J. Witters, R. Vrambout: Excitation of spin waves and Kerr-effect on thin ferromagnetic films; J. R. Balmer: Research in Great Britain on vacuum deposited conducting resistive and insulating thin films; C. A. Neugebauer: Structure and properties of thin films; W. M. H. Sachtler: Sorption on solids; J. Hengevoss: Gas sorption of low temperature surfaces; E. V. Kornelsen—Developments in the measurement of low pressures; J. Kistemaker *et al*—Some physical aspects of sputtering; L. Rey—Freeze drying; G. S. Grossart—Vacuum system of nimrod; P. S. Choumoff—The role of vacuum technology in space research; M. von Ardenne and S. Schiller—Advances in vacuum metallurgy.

162 pages/June 1966 hardcover 75s./$12.00

Vol. 2—Session Papers, to be published in 3 parts—Autumn 1966

Reproductive Biology and Taxonomy of Vascular Plants

Edited by **J. G. Hawkes,** *University of Birmingham*

This volume contains the reports of papers presented at a conference held by the Botanical Society of the British Isles at the University of Birmingham. The papers presented deal with the breeding systems and other aspects of the reproductive biology of flowering plants.

Contents: K. Mather—Breeding systems and response to selection; D. Lewis—The genetic integration of breeding systems; J. L. Harper—The reproductive biology of the British Poppies; J. L. Fyfe—The reproductive biology of some leguminous crops; F. L. Breese—Reproduction in Ryegrasses; L. van der Pijl—Pollination mechanisms in Orchids; J. B. Free—The foraging behaviour of bees and its effect on the isolation and speciation of plants; D. A. Webb—Dispersal and establishment: what do we really know?; P. F. Wareing—Ecological aspects of seed dormancy and germination; J. L. Crosby—Reproductive capacity in the study of evolutionary processes; A. Nygren—Apomixis in the Angiosperms, with special reference to *Calamagrostis* and *Poa;* G. Haskell—The history, taxonomy, and breeding system of apomictic British *Rubi;* T. G. Walker—Apomixis and vegetative reproduction in ferns; S. M. Walters—The taxonomic implications of apomixis; D. H. Valentine—Opening remarks; General discussion.

174 pages/June 1966 hardcover 30s./$5.00

Progress in Aeronautical Sciences

Volume VII

Edited by **D. Kuchemann,** *Royal Aircraft Establishment, Farnborough*

This book is devoted to vortex motions, a specific aspect of fluid mechanics, itself only one particular aeronautical science. The papers were either presented at a recent symposium on the subject or are a survey of particular aspects of the discussion.

Contents: M. Roy—On the rolling-up of the conical vortex sheet above a delta wing; R. Legendre—Vortex sheets rolling-up along leading-edges of delta wings; J. H. B. Smith—Theoretical work on the formation of vortex sheets; M. G. Hall—The structure of concentrated vortex cores; N. Rott and W. S. Lewellen—Boundary layers and their interactions in rotating flows; B. R. Morton—Geophysical vortices; R. Wille—On unsteady flows and transient motions.

228 pages/1966 hardcover 90s./$13.50

Progress in the Chemistry of Fats and Other Lipids

Volume VIII, Part 3

R. T. Holman, *Hormel Institute, University of Minnesota*

This latest edition in an already well-established series deals with the chromatography of lipids, covering such topics as column chromatography, paper chromatography and recent developments in thin layer chromatography.

Contents: Recent developments in the thin-layer chromatography of lipids; Paper chromatography of lipids; Column chromatography of lipids.

132 pages/1966 flexi-cover 40s./$6.50

Infrared Physics

This journal has been established for the publication of scientific papers concerning infrared physics and its application. It is largely concerned with infrared theory, experiment, and instrumentation as applied to infrared detection and transmission, and to problems of atmospheric, meteorological, geophysical, astrophysical and space research. Published quarterly. Specimen copy and subscription rates available on request.

examination shows the brain tissue of the aphid to be colourless—a circumstance which suggests that the pigment is in low concentration, and in this respect resembles the plant pigment, phytochrome[18].

The dilute nature of the pigment may possibly be advantageous if the action spectrum is to be used for deducing its absorption characteristics. Nevertheless, a close match cannot perhaps be expected until the filtering effect of the cuticle overlying the brain is taken into account. And the possible influence of wave-length on quantum yield and on light scattering[19] is quite unknown. Despite these uncertainties, however, the position of the absorption maximum and the apparent absence of a near ultra-violet peak support the view[20,21] that the chromophore in insects and mites is a carotenoid hydrocarbon.

With later interruptions of the dark period (for example, 7·5 h after its inception) threshold dose rates are effective over a shorter time course, and there are also significant changes in the action spectrum. With 30-min interruptions, a broad band is still found in the blue, but light sensitivity now extends to somewhat longer wave-lengths. The upward arm of the response curve is displaced 30–50 mμ towards the yellow. Red sensitivity is increased, but is still very low.

The fact that the action spectra for early and late interruptions are different, but by no means entirely dissimilar, militates against the suggestion of Bünning and Joerrens (for *Pieris brassicae*[4]) that there are separate blue and red receptors. It seems more likely that time measurement is carried out by means of a linked sequence of dark reactions, probably involving some form of pigment conversion. There are at least four steps, each of which can be defined by the response to light: (1) During the first few hours of darkness, the dark reaction is completely reversible by blue light of low intensity. (2) After 3–4 h of darkness, sensitivity to all wave-lengths rapidly diminishes to zero. Presumably the absorbing pigment is still present, but some other essential component is missing from the system. (3) From about 5 h to the end of the critical dark period, photosensitivity is regained, the dark reaction becoming increasingly responsive to blue-green light. But complete reversibility is no longer possible. Perhaps the irradiated pigment is changed to an unavailable form; at all events, incident light has the distinctive effect of inhibiting earlier (and possibly later) cycles containing dark periods longer than the critical duration. (4) By the end of the critical period the dark reaction is complete, and is then immune to light.

Since it is well known that carotenoids readily form photolabile complexes with proteins[22], it seems possible that this type of association may also be involved in the functioning of the arthropod interval timer.

NEWS AND VIEWS

Pharmacology in the University of London: Prof. G. A. H. Buttle

PROF. G. A. H. BUTTLE will retire from the Wellcome chair of pharmacology in the School of Pharmacy, University of London, on September 30. Gladwin Buttle's career may be roughly divided into three phases. He went to St. John's College, Cambridge, and afterwards to University College Hospital, where he obtained his medical qualification in 1924. Then in 1926 he joined the Wellcome Physiological Research Laboratories at Beckenham, Kent, where he worked until 1939, first on the actions of some toxins and later on bacterial chemotherapy. Buttle and his colleagues in 1936 were the first to show that sulphanilamide protected mice against experimental meningococcal infections and thus paved the way for the introduction of this drug for the treatment of meningococcal meningitis in man. He was also concerned with the introduction into chemotherapy of 4 : 4′-diaminodiphenyl sulphone which, under the name 'Dapsone', is now the mainstay in the treatment of leprosy by drugs. During the Second World War, Buttle became officer-in-charge of No. 1 Base Transfusion Unit in the Middle East, where he performed wonders in the collection and distribution of blood. In 1942 he was awarded the O.B.E. Later he served in north-west Europe. The third phase of Buttle's career began in 1945, when he was appointed to his present post, in which he has been brilliantly successful as a teacher, administrator, and supervisor of the researches of his pupils and colleagues. He has himself done important work on the transmission of tumours in animals.

Buttle has won the admiration, affection and respect of pharmacologists the world over. We wish him many happy years of retirement.

Prof. E. W. Horton

DR. E. W. HORTON has been appointed to the Wellcome chair of pharmacology in the University of London, tenable at the School of Pharmacy, in succession to Prof. G. A. H. Buttle who is retiring. Dr. Horton, who is thirty-six years old, will take up his appointment on October 1. He was educated at the University of Edinburgh, where he took first-class honours in the B.Sc. degree and graduated M.B., Ch.B. in 1955. The following year he held a full-time research appointment in the Department of Pharmacology under the then Prof. J. H. Gaddum. He then became a member of the scientific staff of the Medical Research Council, Division of Physiology and Pharmacology, National Institute for Medical Research, and later director of therapeutic research and head of the Department of Pharmacology at the Miles-Ames Research Laboratories. In 1963 he was appointed senior lecturer in physiology at the Medical College of St. Bartholomew's Hospital. Dr. Horton's research work has been mainly concerned with the biological properties of certain naturally occurring substances. In collaboration with Dr. D. F. Elliott and Dr. G. S. Lewis, he isolated bradykinin and determined its structure. More recently, he

has been concerned with the identification, distribution and pharmacological actions of the prostaglandins.

Research at East Malling

THE report for 1965 of the East Malling Research Station gives an impressive account of the volume and scope of research at present in progress. It contains twenty-eight research papers, and nearly one hundred additional publications by members of the staff are also listed. The research programme of the Station as a whole is a balance between fundamental and applied studies, all of which contribute to a greater understanding of the factors which influence and control the growth and cropping of fruit plants. The titles illustrate the breadth of the research, and range from "A Polythene Fence to Keep Beetles from Strawberries" to "Some Effects of Gibberellin on the Anatomy of Apple Leaf Discs".

The studies centred around the root observation laboratory are particularly interesting. In this underground laboratory, which has been in use now for about 5 years, observations can be made on undisturbed tree roots growing in soil. Diurnal fluctuations in the growth of cherry roots and nutational movements of apple root tips have been demonstrated using time-lapse cinematography. Nematode infection of roots is being investigated. The construction of a second root observation laboratory (now in use) will make it possible to widen the scope of these fundamental observations on the hitherto much-neglected subject of tree root growth.

One line of research in the pomology section is concerned with attempts to prolong the effects of a single deblossoming of the annual cropping of biennial varieties of apples such as Miller's Seedling. The beneficial effects of laborious deblossoming of half the branches in a bearing year is short lived because the fruitlets produce a hormone which travels to the non-fruiting branches to suppress the development of fruit buds. Ringing of the bases of deblossomed branches has resulted in a more regular supply of good-sized fruit without reduction of crop.

The sterile culture of isolated stem tips is among the research projects of the plant physiology section. If successful, this technique would make growing material available for experimental work during the winter. The possibility that cultured stem tips may become a source of plants free from virus is also being investigated. The importance of growth-promoting and growth-inhibiting substances in the control of shoot growth and flower initiation is being examined. Attempts to extract gibberellins from fruit trees have not yet been successful, but the identity of a growth-inhibitory substance has been established.

In the fruit nutrition section, the responses of trees to irrigation and tolerance to drought are being investigated in relation to form and development of the root system. The influence of soil moisture on the availability of mineral nutrients is also being examined. Intensive experiments have been undertaken to provide information about the rate at which various nutrients are taken up by trees during the year, and to examine the pattern of their distribution within the plant.

Abstracts for Geography

IN the past 6 years, beginning in 1960, geomorphologists have increasingly appreciated the value of *Geomorphological Abstracts*, edited and published as a private venture by Dr. Keith M. Clayton, reader in geography at the London School of Economics. Twenty-seven parts had appeared up to December 1965 and circulation is now world-wide. Encouraged by this success, it has now been decided to cover, probably as six parts a year in each of the four series, the whole field of geography. *Geographical Abstracts A—Geomorphology* will be a continuation of *Geomorphological Abstracts*, but will be numbered with the year and part (1966/1); *Geographical Abstracts B* will cover biogeography, climatology and cartography, the series being edited by Dr. E. M. Yates; *Abstracts C* cover economic geography and are edited by Dr. F. E. Ian Hamilton; *Abstracts D* cover social geography, edited by Dr. Christopher Board. The editors are all members of the Joint School of Geography of King's College and the London School of Economics, and Dr. Clayton continues as publisher under the guise of Geo Abstracts, London School of Economics, W.C.2. Subscription to the whole series has been fixed at £9 or 25 dollars, *A* and *B* being £1 16*s*. each (5.00 dollars), *C* and *D* £2 14*s*. (7.50 dollars) each. Recognizing the great value of this self-sacrificing labour of love, the Royal Society has supported the expansion of the venture, and it certainly deserves to succeed. Some of the abstracts used, especially of works in East European languages, are the English summaries now commonly given; in other cases, authors have provided their own summaries; in all the remainder the abstracts are signed, and one notices how many, especially of the younger university lecturers, have given their collaboration, but a heavy burden has clearly fallen on the editors. All abstracts are in English. Workers in each field will find this an indispensable tool and no serious library covering geography can afford to be without the whole series.

Information for Geologists

AMERICAN geologists are the latest to establish a computer-based information service. The Geological Society of America and the American Geological Institute have agreed to spend 1·5 million dollars of the National Science Foundation's money in the next three years on a project to document geological literature referring to parts of the world other than North America. (The U.S. Geological Survey already runs an abstracting service for its own parish.) The decision to use computers has been forced on the Geological Society of America by the increasing difficulty of keeping its annual *Bibliography and Index of Geology Exclusive of North America* up to date. The current volume, which contains 5,700 abstracts, is three years late. It is hoped that under the new system abstracts will be published monthly at a rate of 20,000 a year.

National Academy of Sciences

THE following were elected new members of the National Academy of Sciences during the 103rd annual meeting of the Academy: PROF. P. BERG, professor of biochemistry, Stanford University School of Medicine; J. BIGELEISEN, senior chemist, Brookhaven National Laboratory; PROF. R. BRESLOW, professor of chemistry, Columbia University; B. B. BRODIE, chief, Laboratory of Chemical Pharmacology and Laboratory of Physiology and Pharmacology of the Autonomic Nervous System, National Heart Institute; T. L. CAIRNS, director of basic sciences, E. I. du Pont de Nemours and Company, Inc.; PROF. E. J. COREY, professor of chemistry, Harvard University; PROF. H. R. CRANE, professor of physics, University of Michigan; PROF. K. DAVIS, professor of sociology, University of California, Berkeley; PROF. H. W. EMMONS, Gordon McKay professor of mechanical engineering, Harvard University; PROF. V. L. FITCH, professor of physics, Princeton University; PROF. R. L. GARWIN, senior staff member, Watson Scientific Computing Laboratory, IBM Corporation, and adjunct professor of physics, Columbia University; PROF. N. H. GILES, Eugene Higgins professor of genetics, Yale University; PROF. E. L. GINZTON, professor of applied physics and electrical engineering, Stanford University; PROF. A. M. GLEASON, professor of mathematics, Harvard University; PROF. C. GROBSTEIN, professor of biology, University of California, San Diego; J. G. HARRAR, president, Rockefeller Foundation; PROF. G. K. HIRST, director, Public Health Research Institute of the City of New York,

adjunct professor of microbiology, New York University College of Medicine; PROF. E. A. KABAT, professor of microbiology, Columbia University College of Physicians and Surgeons; PROF. A. R. KANTROWITZ, director, AVCO-Everett Research Laboratory, and professor, Massachusetts Institute of Technology; PROF. I. KAPLANSKY, professor of mathematics, University of Chicago; PROF. H. G. KHORANA, co-director, Institute for Enzyme Research, and Conrad A. Elvehjem professor in the life sciences, University of Wisconsin; E. F. KNIPLING, director, Entomology Research Division, Agricultural Research Service, U.S. Department of Agriculture; PROF. D. E. KOSHLAND, JUN., professor of biochemistry, University of California, Berkeley; PROF. W. M. KROGMAN, professor of physical anthropology, Graduate School of Medicine and the Evans Institute of Dentistry, University of Pennsylvania; PROF. R. B. LEIGHTON, professor of physics, California Institute of Technology; P. LEVINE, director, Immunohematology Division, Ortho Research Foundation; PROF. V. B. MOUNTCASTLE, professor and director, Department of Physiology, Johns Hopkins School of Medicine; PROF. N. M. NEWMARK, professor of civil engineering and head of department, University of Illinois; PROF. D. E. OSTERBROCK, professor of astronomy, University of Wisconsin; PROF. R. D. OWEN, professor and chairman, Division of Biological Sciences, California Institute of Technology; PROF. F. J. PETTIJOHN, professor of geology, Johns Hopkins University; PROF. G. C. PIMENTEL, professor of chemistry, University of California, Berkeley; E. RACKER, chief, Division of Nutrition and Physiology, Public Health Research Institute of the City of New York; PROF. F. RATLIFF, associate professor (psychology and biophysics), Rockefeller University; PROF. H. A. SCHERAGA, Todd professor and chairman of the Department of Chemistry, Cornell University; PROF. J. STEINBERGER, professor of physics, Columbia University; PROF. H. E. SUESS, professor of geochemistry, University of California, San Diego; PROF. E. W. SUTHERLAND, JUN., professor of physiology, Vanderbilt University; S. M. ULAM, research adviser, director's office, Los Alamos Scientific Laboratory; PROF. O. H. WANGENSTEEN, distinguished service professor of surgery, University Hospitals, and director of the Department of Surgery, University of Minnesota; PROF. S. I. WEISSMAN, professor of chemistry, Washington University; PROF. C. YANOFSKY, professor of biology, Stanford University.

University News:

Adelaide

DR. R. W. R. RUTLAND has been appointed to the chair of geology in succession to Prof. A. R. Alderman.

Canterbury, Christchurch

DR. B. G. WYBOURNE, formerly an associate physicist at Argonne National Laboratory, has been appointed to the newly created second chair of physics, University of Canterbury, Christchurch.

Cardiff

DR. F. JACOBY has been appointed to a personal chair in the Department of Anatomy, University College of South Wales and Monmouthshire.

London

PROF. G. D. DAWSON, professor of experimental neurology in the Institute of Psychiatry, has been appointed to the second chair of physiology at University College.

Sheffield

R. KILPATRICK, at present senior lecturer in pharmacology and therapeutics, has been appointed to the chair of pharmacology.

Southampton

DR. S. H. CROWDY, a research botanist at Imperial Chemical Industries, Ltd., has been appointed to the chair of botany.

Appointments

DR. A. H. KEIL has been appointed professor and head of the Department of Naval Architecture and Marine Engineering at the Massachusetts Institute of Technology, in succession to Prof. C. R. Soderberg, Institute professor (emeritus), who has been serving as acting head of the Department since February 1965, when Dr. H. G. Stever left to become president of the Carnegie Institute of Technology.

Announcements

AN international conference on "Crystal Growth" will be held in Boston during June 20–24. Further information can be obtained from the Conference Secretary, 40 Acorn Park, Cambridge, Massachusetts.

THE 461st meeting of the Biochemical Society will be held in the Heriot–Watt College, Edinburgh, on June 17. Further information can be obtained from the Administrative Officer, the Biochemical Society, 20 Park Crescent, London, W.1.

THE fifth congress of the Fédération Internationale de la Précontrainte will be held in Paris during June 11–18. Further information can be obtained from P. Gooding, Prestressed Concrete Development Group, Terminal House, Grosvenor Gardens, London, S.W.1.

A SYMPOSIUM on "Liquid Helium Technology" will be held by the International Institute of Refrigeration at Boulder, Colorado, during June 16–18. Further information can be obtained from Cryogenic Division, National Bureau of Standards, Boulder, Colorado.

THE fourth congress of the European Federation of Chemical Engineering and the International Chemical and Petroleum Engineering Exhibition will be held simultaneously in London during June 15–24. Further information can be obtained from the Institution of Chemical Engineers, 16 Belgrave Square, London, S.W.1.

THE Australian and New Zealand Association for the Advancement of Science has announced that its thirty-ninth Congress will be held in Melbourne during January 16–20, 1967. Further information and enrolment forms can be obtained from Mr. L. Mann, organizing secretary, 39th ANZAAS Congress, University of Melbourne, Parkville, N.2, Victoria.

A SYMPOSIUM on "Magnetohydrodynamic Electrical Power Generation", arranged by the International Atomic Energy Agency and the European Nuclear Energy Agency, will be held in Salzburg during July 4–8. Further information can be obtained from the Division of Public Information, International Atomic Energy Agency, Karntnerring 11, 1010 Vienna I.

FROM August 1, 1966, Chelsea College of Science and Technology will become a grant-receiving School of the University of London. After the Government, on the recommendation of the Robbins Report, decided that all colleges of advanced technology should be granted university status, it was agreed that in this case it would be best for Chelsea to join the University of London. This has now been approved by the Senate and Court of the University and will be implemented from the beginning of the next session.

THE Psycholinguistics Research Unit of the Medical Research Council, which has been housed in the Institute of Experimental Psychology, University of Oxford, since its establishment in October 1963, will be transferred to the University of Edinburgh from October next. Thereafter the title of the Unit will be changed to Speech and Communication Research Unit. Prof. R. C. Oldfield, who has been directing the Unit in an honorary capacity while holding the chair of psychology at Oxford, is joining the scientific staff of the Council in October and will become the Unit's full-time director.

RESTRICTION OF DEOXYRIBONUCLEIC ACID TEMPLATE ACTIVITY IN CHROMATIN IS ORGAN-SPECIFIC

By PROF. JOHN PAUL and R. STEWART GILMOUR
Department of Biochemistry, University of Glasgow

IT is of crucial importance to the understanding of the molecular basis of cytodifferentiation to determine whether there is a specific restriction of the template activity of deoxyribonucleic acid (DNA) in chromatin. This communication reports experiments which show that there is a specific restriction of this kind.

When chromatin is used as a primer for the synthesis of polynucleotides by bacterial ribonucleic acid (RNA) polymerases, the rate of RNA synthesis is much lower than when DNA is the primer[1,2]. Some specimens of chromatin are less efficient primers than others, and it has been claimed that "repressed" chromatin can be separated from "non-repressed" chromatin; the priming activity of the former is less than that of the latter[3]. Moreover, histones inhibit the synthesis of both RNA by RNA polymerase and DNA by DNA polymerase *in vitro*[1,4,5]. For these reasons it has been suggested that only a restricted range of DNA sequences is available for transcription in chromatin, the majority being masked by basic proteins; this is in analogy with the appearance of RNA-synthesizing "puffs" in the giant chromosomes of diptera[6]. However, this assumption is specious because the rate of transcription may be influenced by many factors other than the specific masking of DNA. For example, chromatin and synthetic nucleohistones are rather insoluble in dilute salt, and Sonnenberg and Zubay[7] have shown that shearing chromatin by sonication increases its solubility and makes it a more efficient primer for RNA synthesis. To test the hypothesis it is necessary to determine (for example by molecular hybridization) whether RNA formed on a chromatin template is transcribed from every kind of DNA sequence in the primer or from a restricted range of DNA sequences.

We have already reported that RNA is transcribed *in vitro* from only 5–10 per cent of the DNA templates present in calf thymus chromatin[8]. Two further questions immediately arise from this observation. (1) Is the RNA formed *in vitro* homologous with RNA formed in the same organ *in vivo*? We shall show in this article that it is. (2) Is there a difference in the range of DNA molecules available as templates in chromatin from different organs? We shall show that there is such a difference. In particular, RNA is transcribed from some common DNA sequences in rabbit bone-marrow and thymus chromatin but, in addition, some unique sequences are available in thymus chromatin which are not available in bone-marrow chromatin; similarly, unique sequences are available in bone-marrow chromatin which are not available in thymus chromatin.

To test the first question the following experiments were performed. Nuclei were first prepared from calf thymus tissue[8]. A fraction of these was used to prepare chromatin; another fraction was used to prepare RNA ("normal" RNA). The chromatin was immediately added to an incubation mixture containing *Micrococcus lysodeikticus* RNA polymerase[9] and tritium-labelled ATP, UTP, GTP and CTP[8]. The polynucleotide material formed after 4–5 h incubation was isolated and purified. To permit the prediction of saturation values, varying amounts of this labelled RNA were then hybridized with constant amounts of calf thymus DNA by the method of Gillespie and Spiegelman[10]. Later, annealing mixtures were made up in which constant amounts of DNA and constant amounts of labelled RNA (at a concentration approaching that required to saturate the DNA) were heated at 65° C for 17 h in the presence of varying amounts of "normal" thymus RNA. The amounts of labelled RNA which remained hybridized to DNA were then determined. Fig. 1 shows that, as the concentration of "normal" RNA is raised, increasing amounts of labelled RNA are prevented from annealing with DNA. By constructing double reciprocal plots it can be shown that, at an infinite concentration of "normal" RNA, all the labelled RNA would be excluded; this provides evidence for the identity of the two kinds of RNA. To exclude artefacts, RNA from *Escherichia coli* was also used to compete out the labelled RNA. It did compete with some of the labelled RNA, but analysis of linear regressions derived from the data showed that only a small part of the RNA was affected.

A similar experimental design was used to test whether RNAs prepared *in vitro* with rabbit thymus and bone-marrow chromatin templates were homologous, first with "normal" RNAs from the homologous tissues, and second with "normal" RNAs from the heterologous tissues. Nuclei were prepared from each organ; chromatin and "normal" RNA were prepared from them. The chromatin was used as a primer to make labelled RNA as before. Fig. 2 shows that when labelled RNA made with a thymus chromatin primer was hybridized with DNA in the presence of increasing amounts of "normal" thymus RNA, marked competition occurred; the line extrapolated to approximately zero, indicating a high degree of homology between the two RNAs and confirming the previous experiment. On the other hand, when the same labelled thymus RNA was hybridized with DNA in the presence of "normal" bone-marrow RNA, the competition curve was less steep. Fig. 3 presents the results obtained when the experimental system was reversed. In this case it could be demonstrated that "normal" bone-marrow RNA and labelled RNA made in the presence

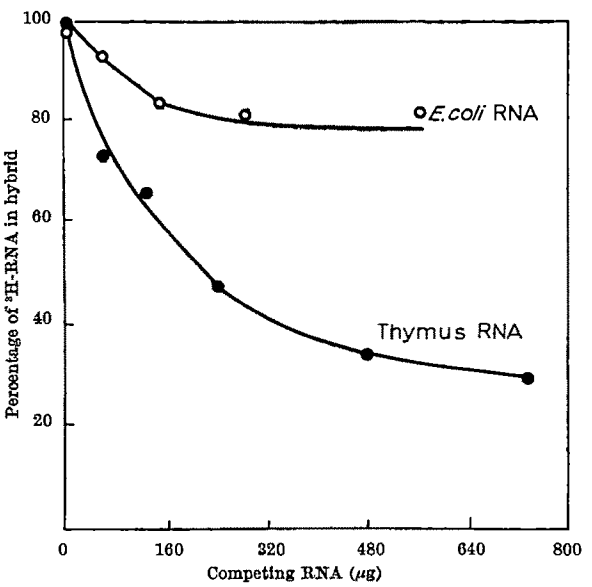

Fig. 1. Test for homology between calf thymus RNA and tritiated RNA made *in vitro* with a primer of calf thymus chromatin. Annealing mixtures contained 1 μg calf thymus DNA, a near-saturating amount of synthetic chromatin-primed ³H-RNA and varying amounts of "normal" thymus RNA. As a control (upper curve) similar annealing mixtures were prepared in which *E. coli* RNA replaced "normal" thymus RNA. The lower curve can be shown to extrapolate to zero at an infinite concentration of "normal" thymus RNA

of a bone-marrow chromatin primer were essentially homologous. On the other hand, "normal" thymus RNA apparently competed less effectively with the labelled RNA for sites on DNA. The conclusion from these experiments is that in rabbit thymus and bone-marrow chromatin some common sequences of DNA are readily available for transcription by *M. lysodeikticus* polymerase; in addition, unique sequences are available in each type of chromatin. In both cases less than 10 per cent of the DNA is available for transcription—figures of 5 per cent for thymus and 7·5 per cent for bone marrow being calculated.

The data in Figs. 2 and 3 were not sufficiently precise to permit accurate calculation of the relative amounts of common and unique sequences of DNA transcribed in the two types of chromatin although theoretically this should be possible.

These experiments would seem to provide evidence that, as a consequence of cytodifferentiation in mammals, specific sections of the genomes are rendered unavailable for immediate transcription. The nature of the "masking" material is such that chromatin can be readily isolated with the specific pattern of masking undisturbed. These experiments do not provide any information about the nature of the mechanism except that, because the removal of proteins and RNA during preparation of DNA from chromatin makes all the DNA available for priming, the "masking" mechanism is probably effected by some of these.

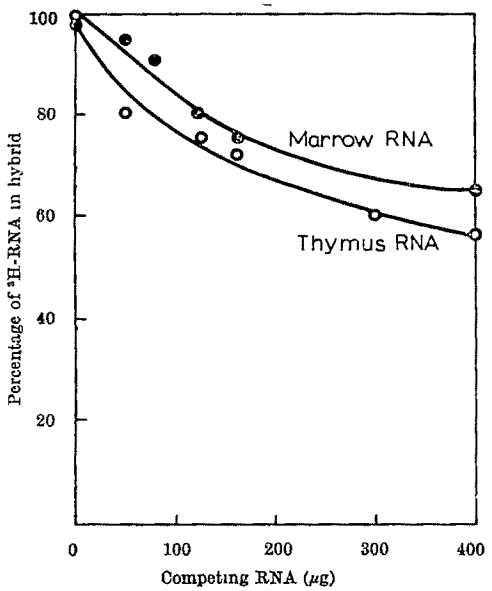

Fig. 2. Test for homology between rabbit thymus or bone-marrow RNA and RNA made *in vitro* with a rabbit thymus chromatin primer Annealing mixtures contained 1·4 μg rabbit DNA and a near-saturating amount of synthetic thymus chromatin-primed ³H-RNA. To each annealing mixture was added varying amounts of competing RNA, either "normal" thymus RNA or "normal" bone-marrow RNA

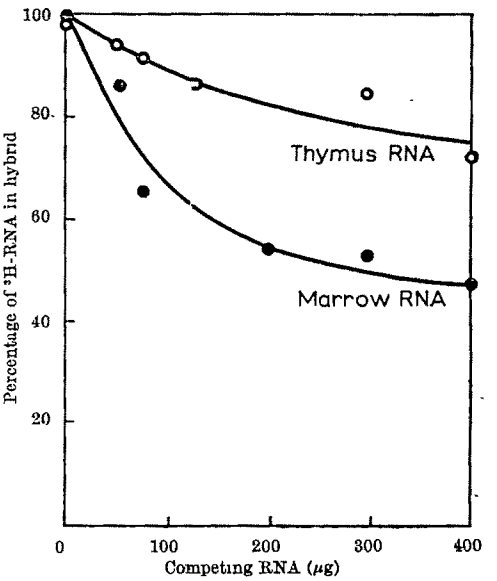

Fig. 3. Test for homology between rabbit bone-marrow or thymus RNA and tritiated RNA made *in vitro* with a rabbit bone-marrow chromatin primer. This is the complementary experiment to that shown in Fig. 2. The conditions were identical except that the synthetic ³H-RNA was made with bone-marrow chromatin instead of thymus chromatin

These experiments, in conjunction with observations on plant tissue[1] and diptera[2], suggest that in differentiated cells only a part of the genetic complement may be available for transcription. It would be convenient to have a word to describe this, and we propose "nome" (from the Greek *nomos*, meaning "the law"). The nome would be defined as that part of the DNA complement of a cell which is directly available for transcription by DNA-dependent RNA polymerase (*E.C.*2.7.7.6.).

This research was supported in part by a grant from the National Cancer Institute, U.S. Public Health Service, and in part by a grant from the Medical Research Council.

SYNTHESIS OF NUCLEIC ACIDS AND NUCLEAR PROTEIN IN REPLICATING ANIMAL CELLS

By DR. JOHN SEED
Department of Radiotherapeutics, University of Cambridge

RECENT investigations[1–5] have shown that in replicating animal cell cultures freshly derived from normal tissues, the process of net deoxyribonucleic acid (DNA), ribonucleic acid (RNA) and nuclear protein syntheses is closely associated during interphase. Similar relations between the accumulation of DNA and bound arginine have also been found in nuclei of replicating plant cells[6,7] and were suggested some time ago for DNA and histone[8].

These results were obtained by making physical measurements[9–12] on single cells. Some of my own experiments[1,2] were carried out in conjunction with time-lapse photography, a technique[1,2,13] that made possible the sorting out of the cell population with respect to age within the synthetic cycle, and also demonstrated that some 95 per cent of the cells in the cultures used[1] were in a cycle leading to division, a situation not readily obtained in other living systems. The value of this combination[1–4] of physical methods has been shown by the differences I have demonstrated, in the nuclear RNA and protein synthetic cycles, between replicating cells freshly derived

from normal tissues and those derived from tumours[1-5]: in the latter case, in contrast with freshly derived normal cells, a large part of the accumulation of nuclear protein and RNA is dissociated from the replication of genetic material DNA during interphase. I have suggested[1-4] that this dissociation reflects a fundamental loss of control in tumour strain cells.

Because of the importance of these results it would be of interest to separate and characterize the growth of various nuclear protein fractions by bulk biochemical methods, but it is difficult to attempt this except by using a population of cells synchronized with respect to mitosis. Such procedures are open to the objection that the method of production of synchrony may introduce into the cell cycle some feature not normally present (see, for example, the remarks of Schaechter *et al.*[14], Smith *et al.*[15] and Seed[4]): however, it is possible that certain mechanical methods[31] may be free from these objections.

A system of cells *in vivo* has been adopted by other authors[16-18] who have attempted to use regenerating liver as a synchronized dividing cell population for the investigation of the relations between DNA, RNA and nuclear protein synthesis in replicating cells. The deductions of these authors[16-18] are at variance with results obtained by single-cell methods, and it is the purpose of this article to point out why the conclusions from the regenerating liver system are unreliable so far as replicating cells are concerned.

It is well known that regeneration following partial hepatectomy results in a peak of DNA synthesis at around 20–26 h, with a subsequent wave of cell division at around 26–30 h: this process may again be followed by another less-well-synchronized cycle with mitosis some hours later (see, for example, the recent review by Bucher[19]). It is also established that after two-thirds hepatectomy, only some 20–30 per cent of the remaining cell population in the liver is in DNA synthesis at the peak of regeneration[20,21], while one-third hepatectomy may result in an even smaller response[19]. It seems extremely probable, therefore, that removal of a large part of the liver will also act as a stimulus to RNA and protein synthesis in the differentiated, non-replicating cells forming the majority of the remaining population; it will also probably result in increased demands on these cells[19].

My principal objection to the interpretation[16-18] of the protein and RNA experiments on regenerating liver is that no account has been taken of the effect of these non-replicating cells forming the bulk of the remaining cell population: this effect is very important.

Thus if we study the curves (Figs. 1 and 2) of Evans *et al.*[17], from the time of hepatectomy to the first mitosis, there is a similar timing of increase between the amount per cell of DNA and a histone (II) fraction, but a considerable decrease per cell in other protein fractions over much of the period. For example, in their[17] Fig. 1, following hepatectomy, one of the fractions (protein III) decreases by almost 20 per cent, another (protein II) by more than 20 per cent, another (protein I) by about 50 per cent and another (histone I) by almost 70 per cent, each averaged over the whole cell population: the last two figures demonstrate conclusively that effects from non-replicating cells are being observed because only about 20 per cent of the cell population in their experiment is actually taking part in a cycle of replication at the DNA peak (see the height of the DNA peak in their[17] Fig. 2, which is consistent with the work of Grisham[20] and Looney[21] previously cited on the percentage of synthesizing cells).

Once one has demonstrated that the regenerating liver system is showing major protein fluctuations derived from the non-replicating cells, then it is clear that results from that system, considered as a whole, cannot be taken to represent the behaviour of replicating cells so far as protein synthesis is concerned. Similar objections apply to the work of Umana *et al.*[18], who observe a drop of some 60 per cent in the histone/DNA ratio for the whole cell population in the first 10 h after hepatectomy, before DNA synthesis has begun: again the magnitude of this drop in histone content cannot be caused solely by the replicating cells which comprise only 20–30 per cent of the cell population at the DNA peak[20,21]. However, without taking into account the effect of the non-dividing cells forming the bulk of the population, these authors again go on to interpret their results in terms of the behaviour of replicating cells[18].

Furthermore, returning to Fig. 1 of Evans *et al.*[17], the beginning of the second cycle of synthesis following the first mitosis appears to have a form very different from that of the first cycle, following hepatectomy: the histone (I) fraction that rises most steeply here is the one that fell most rapidly after hepatectomy. Another marked inconsistency between the first and second cycles exists in the specific activity of nuclear RNA (see Fig. 2 of Holbrook *et al.*[16]): a maximum at about the middle of the first cycle is matched by a minimum at the middle of the second cycle.

A second objection is therefore the lack of a steady state in the system, due presumably to the different kinetics of the effect of hepatectomy on the replicating cells and the reaction of the non-replicating cells which form the bulk of the population.

Finally, the difficulty of relating observations of amino-acid uptake[16,18,22] into protein with net protein synthesis in regenerating liver has been emphasized by the experiments of Eagle *et al.*[23-25] with animal cells. These authors[23-25] grew animal cell cultures in medium deficient in one or more amino-acids essential to cell growth. Although under these conditions there was no net increase of bulk protein or total mass in the cultures, it was found that the cells continued to incorporate labelled amino-acids into their proteins at a high level for periods up to 72 h. In addition, it was found that replicating cultures incorporated labelled amino-acids into cell protein at an appreciably faster rate than could be accounted for by the amount of net synthesis or growth, and that they possessed a turnover rate similar to the non-growing cells. Eagle *et al.*[23-25] contrasted these results on animal cells with those obtained for bacteria[26-28] and yeast[29], where turnover in growing cells is much less than in non-growing cells. Conclusions similar to these with animal cell cultures have recently been reported by Bidwell *et al.*[30] for replicating plant cell cultures.

In addition to the observations I have made here, it would seem, therefore, that in order to obtain meaningful results on the accumulation of cellular protein for a new animal or plant cell at the next mitosis, methods measuring net amount of substance must be used[1-5].

PROPOSED MECHANISM FOR THE TURNOVER OF MYOSIN AND ITS RELATION TO MUSCULAR DYSTROPHY

By DR. JOHN F. ARONSON
Department of Biological Structure, University of Washington, Seattle

MANY cells and cell components have been shown through the use of isotopic atoms to be in a state of 'dynamic equilibrium' in the living animal.

The work of Kruh, Dreyfuss, Schapira and Gey shows that this is true of the muscle protein myosin. Using ^{14}C-labelled glycine, these authors measured a half-life for myosin of 30 days in the rat[1] and of 20 days for the mouse[2]. Myosin turnover in other vertebrate species is indicated by good amino-acid incorporation into myosin in adult rabbit muscle[3].

A half-life of 30 days shows that myosin is normally broken down and normally synthesized within the mature living muscle cell since the lifetime of muscle fibres is almost that of the animal. Most of the myosin of muscle is found in the structure of the *A* region and, more specifically, in the *A* filaments[4]. From this, it is clear that the structure of the *A* region turns over, either as a whole or by replacement of individual molecules. In some experiments with mice and rats there is a period following the incorporation of ^{14}C-glycine in which no isotope appears to be lost from myosin. This period is almost equal to the half-life of myosin, and Dreyfuss, Kruh, Schapira and Gey have suggested that the isotope is incorporated into a structure equivalent to the *A* filaments and is not lost until this structure breaks down[1,2].

This article indicates a possible mechanism leading to the breakdown of the *A* filaments and the turnover of myosin.

Muscle is sensitive to heat in a manner which reflects the stability of its 'molecular architecture'. The temperature at which obvious changes in the non-enzymatic structure of the *A* region have been detected is about 50° C for short periods of heating[5,6].

In vivo experiments on the thermal stability of muscle are complicated because either the relaxing or the stimulating system may be more sensitive to heat than the myofibrillar material and because the internal milieu cannot be defined accurately or changed easily. Glycerinated muscle is more amenable to experimental analysis under a variety of conditions and there is evidence to show that it is functionally intact[7] and has an appearance under the electron microscope comparable to that of non-glycerinated muscle[8]. Whether it is equivalent in other respects remains an open question.

Birefringence, a distinguishing property of the *A* region in vertebrate muscle, was used as a measure of the sensitivity of the *A* filament to heat, since a large decrease in birefringence occurs on heating[5] and the amount of the decrease can readily be measured. The data to be considered are based on the determination of a transition temperature as a measure of the stability of the *A* filaments. This value is defined in these experiments as the temperature of heating which causes a 20 per cent decrease in the birefringence of a glycerinated muscle fibre. (Muscle was glycerinated in 50 per cent glycerol, 0·02 M KCl, 0·002 M EDTA, 0·005 M phosphate at a final *p*H of 7·0 (23° C). The initial treatment was for twenty-four hours at 0° C followed by storage in fresh glycerol solution at about −10° C. Mouse carcasses were glycerinated without dissection but were tied in a standard position. Rabbit psoas muscle was separated into small fibre bundles and tied to sticks with slight stretching.) The usual experimental procedure consists in heating for 2 min in 0·1 M potassium chloride and 0·005 M phosphate at *p*H 7·0. Details of this transformation will not be presented here, but the pertinent properties are that the birefringence decreases to less than half its initial value over a range of about 3° C and this loss of birefringence is correlated with a loss of *A* filament structure seen under the electron microscope.

Heating muscle fibres for prolonged periods decreases the transition temperature (Fig. 1) and the question arises whether appreciable thermal denaturation occurs at body temperature and, if so, whether this could be the factor regulating muscle turnover. Referring to Fig. 1, it seems unlikely, although not impossible, that a half-life of 30 days could be explained on a basis of *in vivo* thermal denaturation at the normal rabbit body temperature of 39·4° C. (ref. 9). A half-life of years seems a more reasonable estimate.

With the method available, it is difficult to assess the physiological validity of this conclusion since (1) glycerinated muscle was used (2) 0·1 M potassium chloride at *p*H 7 is a very crude approximation to the physiological environment, (3) an extrapolation of log $1/t_{0.8}$ against $1/T$ may not be applicable to this type of transition, and (4) the transition temperature defined as a 20 per cent decrease in birefringence cannot be interpreted exactly nor can it be measured with high precision. For these reasons, the data were not elaborated on.

The measured value of the transition temperature in Fig. 1 clearly occurs at lower temperatures with longer heating times and, as an estimate, we can consider that heating for 22 h gives a value 5° C below that obtained by heating for 2 min. This point is pertinent to the measure-

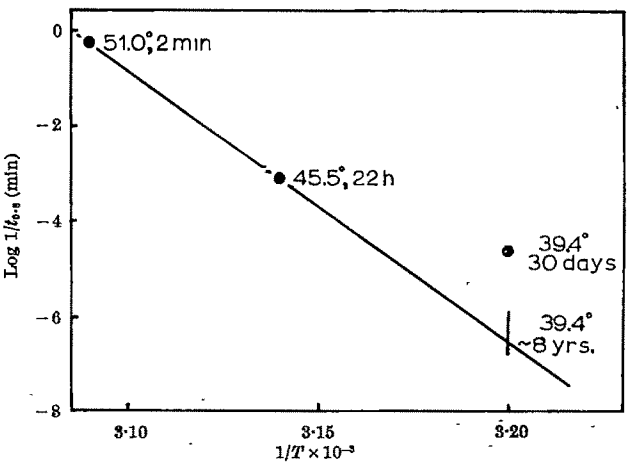

Fig. 1. A plot of the transition temperature ($t_{0.8}$) against $1/T$. T is the absolute temperature and $t_{0.8}$ is the time of heating which caused a drop in retardation to 0·8 of the initial value. Glycerinated rabbit psoas in 0·1 M potassium chloride, *p*H 7·0

ments which follow, since they were all obtained with 2 min heating times.

A good *in vivo* experiment which will establish whether thermal denaturation of the *A* region is of physiological importance in muscle turnover seems difficult to carry out. Biochemical investigations of turnover in poikilothermic animals may be one means of approaching this problem. A consideration of certain pathological conditions, the muscular dystrophies, may also provide pertinent *in vivo* information. The two types of dystrophy considered here are (1) those dystrophies induced by vitamin E deficiency in a wide variety of vertebrates (ref. 10, p. 636) and (2) the genetically determined dystrophy found in 129/*Re* strain mice which are homozygous for the recessive autosomal gene *dy* (ref. 11).

This latter dystrophy was studied because it was thought that muscles from these mice might be more sensitive to heat and provide an *in vivo* correlation between decreased thermal stability and the increased rate of myosin turnover which has been observed[2]. Such genetically controlled changes in the thermal stability of specific proteins have been demonstrated in micro-organisms[12]. Table 1 shows that there is no indication of a significant difference in the transition temperatures of muscle from dystrophic mice and muscle from normal controls and certainly none of a magnitude to affect appreciably the rate of denaturation at body temperature.

Some effects of vitamin E deficiency have been investigated in detail and there is evidence that a major property of vitamin E is its protective action as an intracellular antioxidant[13], either free or built into structure. Deficient animals have higher levels of lipid peroxide[14] in addition to the characteristic muscular dystrophy. Wills[15] has studied the effect of succinyl peroxide (a model lipid peroxide) on enzymes, and has shown that those enzymes which are sensitive to sulphydryl inhibitors are particularly sensitive to low levels of succinyl peroxide and to somewhat higher levels of hydrogen peroxide. Amino-acids containing sulphydryl groups as well as histidine protected these enzymes against inactivation much as they protect against free radicals and peroxides arising from X-irradiation. In parallel with this, nutrition experiments have shown that sulphur-containing amino-acids counteract in part the dystrophy arising from vitamin E deficiency[16].

The increased lipid peroxide levels characteristic of vitamin E deficient animals have not been found in 129/*Re* strain mice with the genetically determined dystrophy[17]. These mice do, however, have a higher level of dialysable sulphur-containing compounds than is found in their non-dystrophic littermates and a much higher percentage of this sulphur is in the oxidized form[18]. This latter observation suggests some similarity between the two dystrophies and prompts the idea that muscular dystrophy may result from the action of metabolic factors which decrease the average lifetime of muscle proteins through oxidation rather than reflecting a property of the myofibrillar structure *per se*. This view is emphasized because of the similarity of interpretation of two types of chemical treatment which decrease the transition temperature of glycerinated muscle fibres.

Salicyl-(γ-hydroxymercuri-β-methoxypropyl) amide-*o*-acetate (mersalyl, Winthrop Laboratories), a monofunctional organic mercurial with binding specificity for sulphydryl groups, reduced the transition temperatures at *p*H 7 by about 10° C for rabbit, frog and mouse skeletal muscle (Table 2). This observation suggests that *in vivo* factors which affect the sulphydryl groups of myosin may decrease the stability of the *A* filaments. The magnitude of this decrease in stability is large enough for thermal denaturation to occur at body temperature.

Table 1

Muscle	*N*	*Dy/Dy*	*N*	*Dy/dy*	*N*	*dy/dy*
Thigh	5	52·3° C	2	53° C	4	52·7° C
Back	3	52·3° C			3	53° C
Lower leg	4	51·1° C			4	51·2° C
Muscle average		51·9° C control				52° C dystrophic

Transition temperatures of glycerinated mouse muscle in 0·1 M potassium chloride at *p*H 7. *dy/dy* denotes the homozygous dystrophic mouse which gives a pathological picture of progressive muscular dystrophy. *Dy/Dy* and *Dy/dy* mice appear normal. The *dy/dy* animals were glycerinated in two groups, one when about 45 days old and the other when about 75 days old. *N* is the number of individuals measured in each category

Treatment of glycerinated rabbit and mouse skeletal muscle with 1 per cent hydrogen peroxide for 1 h gave a decrease in the transition temperature of about 10° C as is shown in Table 3. Likely sites of chemical change are the sulphydryl group of cysteine and the imidazole group of histidine. With longer treatment the transition temperature continued to decrease.

Table 2

Animal	*p*H	Mersalyl pretreatment (−)	Mersalyl pretreatment (+)	Difference (° C)
Rabbit	7·0	50·5° C	42·7° C	7·8
Frog	7·0	43·5° C	32·1° C	11·4
Mouse	7·0	51° C	39° C	12

Transition temperature of glycerinated muscle in 0·1 M potassium chloride at *p*H 7 after pretreatment with 0·5 mM mersalyl in 0·1 M potassium chloride at *p*H 7. The transition temperature was determined after washing the pretreated fibres for at least 1 h to remove excess mersalyl.

Table 3

Animal	Hydrogen peroxide pretreatment (−)	Hydrogen peroxide pretreatment (+)	Difference (° C)
Rabbit	51° C	42° C	9
Mouse	51° C	41° C	10

Transition temperature of glycerinated muscle pretreated with 1 per cent hydrogen peroxide in 0·07 M potassium chloride. The transition temperature was determined in 0·1 M potassium chloride at *p*H 7.

On the basis of these considerations it is proposed that intracellular oxidation affecting imidazole and sulphydryl groups decreases the ability of myosin to form a stable aggregate. This chemically modified myosin is eliminated from the *A* filament at body temperature in a process which may involve the breakdown of the whole *A* filament[1,2]. It is presumed that the myosin is denatured when released from the aggregate and that the muscle cell has some means of recognizing and catabolizing 'denatured' myosin.

There are several possible sources of low levels of peroxides and of free radicals in the normal animal which could, if the *A* filaments accumulate damage, account for the rate of myosin turnover. Parenthetically, it is suggested that anserine, carnosine and other low-molecular-weight histidine-containing compounds found in vertebrate muscle are there in a protective role

The structure of the *A* filament appears to be sensitive to the same types of effects which affect normal function both in binding to actin and in splitting adenosine triphosphate[19,20], so there should be a good correlation between the loss of myosin function and the release of ineffective myosin from the *A* region. The advantage of maintaining a normally functioning muscle fibril through elimination of damaged molecules is clear.

This work was supported by a grant from the U.S. Public Health Service administered by Dr. John H. Luft.

OXIDIZING AGENTS AS POTENTIATORS OF THE RETINOTOXIC ACTION OF SODIUM FLUORIDE, SODIUM IODATE AND SODIUM IODOACETATE

By PROF. ARNOLD SORSBY

Wernher Research Unit on Ophthalmological Genetics (Medical Research Council), Royal College of Surgeons of England

AND

R. HARDING

Royal Eye Hospital, London

ELSEWHERE we have shown[1] that in the rabbit a single intravenous injection of 50 mg sodium fluoride/kg body-weight produces, usually within 24–48 h, a characteristic retinal lesion—generally a sharply defined broad band of oedema one disk distance below the disk, followed in the succeeding days by pigmentation. This effect was, however, seen in only twelve out of sixty-three treated animals. It was also shown that if rabbits were fasted for 24 h prior to the injection the incidence of retinal lesions rose to about 70 per cent (nineteen out of twenty-seven). Other potentiating factors—raising the incidence of lesions to about 50 per cent—were dinitrophenol, triiodothyronine and synthalin *B*. Experimentally induced 'Alloxan' diabetes had no potentiating effect.

In a search for yet other potentiating agents, *N*-ethylmaleimide, an inhibitor of —SH enzymes, was used. A series of such inhibitors had already been found ineffective by themselves as retinotoxic agents[2]. After trials of maleimide in the maximum dose tolerated (5 mg/kg) also proved ineffective, it was used as an adjuvant to fluoride. In a series of preliminary experiments, twenty-one rabbits were given an intravenous injection carrying 50 mg sodium fluoride/kg body-weight and 5 mg *N*-ethylmaleimide/kg body-weight in 4–6 ml. of solution; six animals died within 24 h, and of the remaining fifteen all but one showed a typical fluoride lesion, generally within 48 h.

At this stage the *N*-ethylmaleimide in stock had all been used and with a fresh supply disconcerting results were obtained. Four rabbits treated with 40 mg/kg and six with 50 mg/kg with the maleimide as an adjuvant were all negative. The possibility that the previous maleimide had become oxidized in storage was suggested by Dr. H. W. Reading, and chemical tests of such residue as was available supported this. Dr. W. H. Inman, Dr. Frank Rose and Dr. E. H. P. Young of Imperial Chemical Industries, Ltd., kindly arranged for two oxidized derivatives of maleimide to be prepared for our use—*N*-ethylmaleamic acid and epoxysuccinic acid. Both these agents proved remarkably non-toxic: intravenous injections of doses of up to 125 mg/kg were well tolerated by the rabbit and were not retinotoxic. As adjuvants to sodium fluoride the two agents differed markedly from each other. Fluoride together with doses of 5 mg, 10 mg, and 125 mg/kg epoxysuccinic acid gave no lesion in the three rabbits tried. In contrast, sodium fluoride 50 mg/kg with 10 mg/kg of ethylmaleamic acid gave typical fluoride lesions of the retina in the five survivors of seven animals tried.

These observations were followed up by a more systematic attempt with various oxidizing agents as adjuvants to sodium fluoride. As with —SH enzyme inhibitors, a series of oxidizing agents had been tried earlier as potential retinotoxic substances and except for sodium periodate and iodine pentoxide—both related to sodium iodate, an established retinotoxic agent—all had been found ineffective[3].

As in previous investigations, young adult Dutch rabbits were used, and the procedures were those already recorded. Ten oxidizing agents were tested as adjuvants in rabbits treated with sodium fluoride 50 mg/kg, but only one—potassium permanganate—was used in investigations of other retinotoxic agents.

Table 1 sets out the various oxidizing agents used as adjuvants to sodium fluoride 50 mg/kg intravenously. In all cases the oxidizing agent was injected first, followed immediately by the fluoride. It will be seen that *p*-benzoquinone, sodium sulphate and borax gave no result, while the remaining agents, three sodium salts—persulphate, perchlorate and chromate—and four potassium salts—dichromate, permanganate, bromate and nitrate—gave a high incidence of lesions: fourteen out of sixteen survivors were affected with typical fluoride lesions.

These observations were taken to establish the potentiating effect of oxidizing agents on the retinotoxic action of sodium fluoride, and also suggested that potassium permanganate in a dose of 10 mg/kg was probably as well tolerated as any of the oxidizing agents and only this substance was used in subsequent trials.

Table 2 sets out the results obtained with sodium iodate. The retinotoxic dose of iodate is 25 mg/kg and this gives lesions in all animals so treated. To test the potentiating action of potassium permanganate on iodate, smaller doses of iodate that give only occasional results were used: thus a dose of 17·5 mg/kg gave lesions in 0–20 per cent of animals treated, and 15 mg/kg gave only one affected in a series of nine (ref. 4). It will be seen from Table 2 that all the rabbits treated with sodium iodate 17·5 mg/kg and with potassium permanganate 10 mg/kg showed retinal lesions, and that with different doses of iodate between 15 and 20 mg/kg and different doses of permanganate between 5 and 15 mg/kg, eight out of nine survivors were affected.

Table 3 shows the results obtained with potassium permanganate 10 mg/kg as adjuvant to subliminal doses

Table 1. OXIDIZING AGENTS USED WITH SODIUM FLUORIDE (50 MG/KG BODY-WEIGHT) INJECTED INTRAVENOUSLY IN IMMEDIATE SEQUENCE IN THE RABBIT

Agent	Dose (mg/kg)	No of animals used	Effect on the retina: Typical fluoride lesion	None	No. died
Sodium persulphate	100	4	2	—	2
Sodium persulphate	75	1	1	—	—
Potassium dichromate	10	2	2	—	—
Potassium permanganate	5	2	2	—	—
Potassium permanganate	10	1	1	—	—
Potassium bromate	75	1	1	—	—
Sodium chromate	15	2	2	—	—
Sodium perchlorate	50	4	2	1	1
Potassium nitrate	30	2	1	1	—
p-Benzoquinone	25	2	—	1	1
Borax	1,000	1	—	1	—
Sodium sulphate	750	1	—	1	—

Table 2. EFFECT OF ADJUVANT DOSES OF POTASSIUM PERMANGANATE (5–15 MG/KG) ON SUBLIMINAL DOSES OF SODIUM IODATE (12·5–20 MG/KG)

Dose of sodium iodate (mg/kg)	Dose of potassium permanganate (mg/kg)	No. of animals used	No. of retinal lesions: present	absent	No. died
12·5	5	1	—	1	—
15	15	3	1	—	2
17·5	10	5	5	—	—
18·5	5	1	1	—	—
20	5	2	1	1	—

Table 3. EFFECT OF POTASSIUM PERMANGANATE 10 MG/KG AS ADJUVANT TO SUBLIMINAL DOSES OF RETINOTOXIC AGENTS

Retinotoxic agent	Effective dose (mg/kg)	Incidence of retinal lesions with full doses (per cent)	with smaller doses	Doses (mg/kg) used with potassium permanganate as adjuvant	No. of animals used	Retinal lesion present	absent	No died
Sodium iodate*	25	100	17·5 mg/kg: c. 20 per cent	17·5	5	5	—	—

of three other retinotoxic agents. It is clear that sodium iodoacetate repeats the positive results seen with iodate: in both cases a dose that would give only some 20 per cent of results was almost entirely effective when permanganate was given as an adjuvant. No such results were seen, however, with diphenylthiocarbazone and di(*p*-aminophenoxy)pentane.

(1) *The potentiating effect of oxidizing agents on sodium fluoride.* Borax, *p*-benzoquinone and sodium sulphate have proved ineffective, but the results are conclusive in showing that inorganic oxidizing agents, with the possible exception of sodium sulphate, powerfully potentiate the retinotoxic action of fluoride. The significance of the two failures recorded with sodium perchlorate and potassium nitrate (in addition to positive results) needs to be explored further. In the light of these findings, the potentiating effect of dinitrophenol and triiodothyronine on fluoride previously reported becomes more explicable, for both substances are fairly powerful oxidizing agents.

(2) *The limitations of the potentiating action.* Sorsby and Harding[4] have shown that fasting for 24 h, which had proved the most effective potentiating factor with fluoride, was equally effective with sodium iodate, for in the fasted rabbit doses of 17·5 mg/kg and 15 mg/kg gave retinal lesions in twenty-seven out of thirty-one animals treated (against three out of twenty unfasted rabbits). Fasting was, however, without effect on the action of sodium iodoacetate, diphenylthiocarbazone and di(*p*-aminophenoxy)pentane. The potentiating effect of fasting was therefore limited to only two of the five established retinotoxic agents. In the present investigation, oxidizing agents have been seen to be effective rather more widely—in three out of the five agents: fluoride, iodate and iodoacetate.

(3) *The mode of action of retinotoxic agents.* Whether the five known retinotoxic agents, each of which rapidly produces a lesion on single intravenous injection when effective, have a common mode of action is still open to question. The differences in ophthalmoscopic appearances and in the histological picture are not such as to warrant the assumption of a different mechanism, but the available evidence from the investigation of potentiating factors does suggest that diphenylthiocarbazone and di(*p*-aminophenoxy)pentane probably act in a different manner from iodate, iodoacetate and fluoride. For the time being no clear answer is possible, for the evidence from investigations of protection against the retinotoxic effect is still more puzzling. It is known that cysteine and other thiol donors are protective against the action of iodate[5,6], but no such protection is seen with any of the other retinotoxic agents. In contrast, there is no evidence that the use of inhibitors of —SH enzyme systems leads to retinal lesions—an assumption made by Noell[7] for the action of iodoacetate, but not supported by work on other thiol inhibitors[2].

EFFECT OF ADRENALINE AND ADRENERGIC BLOCKING AGENTS ON THE BASAL OXYGEN CONSUMPTION OF THE PERFUSED RAT HEART

ADRENALINE has several well-known effects on the physical and chemical activities of cardiac muscle. The metabolic effects include increased glycogenolytic and lipolytic activities and increased oxygen consumption (Qo_2). The latter effect, first described by Barcroft and Dixon[1] in 1907, has generally been considered secondary to the increase in the stroke-work of the heart. However, some investigators have suggested that at least part of the increased oxygen consumption reflects a direct effect on cardiac metabolism[2]. Recently, this has been confirmed by studying the oxygen consumption after the addition of adrenaline to arrested perfused rat hearts[3] and to dog hearts under controlled haemodynamic conditions[4]. Challoner and Steinberg[3] suggested that the effect of adrenaline on oxygen consumption of the arrested rat heart (basal Qo_2) was secondary to the lipolytic effect, as the addition of free fatty acids to the perfusate may increase the oxygen uptake in a perfused heart.

We have studied the effects of adrenaline on basal Qo_2 in rat hearts perfused with a modified Krebs Ringer bicarbonate buffer gassed with a mixture of 95 per cent oxygen and 5 per cent carbon dioxide. 10 mmoles glucose and 1 per cent albumin (bovine, fraction V, Sigma) were always added to the buffer. The hearts were perfused in a Morgan perfusator as described previously[5]. By this method the perfusate can be supplied to the heart through the aorta as well as through the left atrium, thus permitting the heart to perform a physiological type of work *in vitro*. The aortic pressure was continuously recorded with a Statham '*P23Gb*' transducer. After transfer to the perfusator the hearts were allowed to work against a diastolic pressure of 75 cm of water for 10–15 min. The minute volumes under these conditions were 25–30 ml. The hearts were arrested by exchanging a portion of the perfusate with a similar medium in which potassium had been substituted for sodium, giving a final concentration

of potassium of 35 m.equiv./l. in the perfusate. When the pumping activity had ceased, the flow direction of the perfusate was reverted to retrograde perfusion through the aorta. Qo_2 was calculated from the arterio-venous pO_2 differences measured with a Clark oxygen microelectrode and a Beckman 'Physiological Gas Analyser', and from the oxygen solubility constant. Flow-rates were measured with a Palmer phototransistor drop counter. Perfusions were carried out at a temperature of 32° C. The total volume of perfusate was 40 ml. in all experiments.

In one series of experiments the perfusate was enriched with palmitic acid (40 μmoles/g albumin), in another series with 5 mmoles each of sodium pyruvate, sodium lactate and β-hydroxy-butyric acid. The effect of adrenaline on basal Qo_2 could be demonstrated regardless of the type of perfusate used and even when no glucose was added. This indicates that at least part of this effect in arrested hearts is mediated through mechanisms other than that of increasing the availability of substrates. We therefore suggest that the effect is not secondary to increased lipolysis or glycolysis, but reflects a more direct metabolic action of adrenaline.

In the experiments presented here we have studied the effects of adrenergic blocking agents on the adrenaline-induced increase in basal Qo_2. Fig. 1 shows the oxygen consumption of one heart in the working and arrested states in a typical experiment. Following potassium-induced arrest the Qo_2 curve fell steeply for about 4 min. A further slight decline in Qo_2 was usually seen during the subsequent control period. The addition of 0·025 μg/ml. of adrenaline to the potassium-arrested hearts did not always affect the Qo_2 as measured by our method, in spite of the fact that this dose was sufficient to affect rate and force of contraction in the working heart. However, 10 μg adrenaline injected into the aortal tubing in the arrested retrogradely perfused heart, giving a final concentration of 0·25 μg/ml. in the perfusate, caused an increase in basal Qo_2 in all experiments. At lower potassium concentrations this amount of adrenaline would induce contractions in the arrested hearts. In the present experiments no physical activity could be detected by pressure recording or by direct inspection.

After the addition of 10 μg of adrenaline, as described earlier, the increase in the basal Qo_2 was about 50 per cent (Table 1) and occurred within 5 min. The adrenergic β-blockers DCI (1 - 3′,4′ - dichlorophenyl) - 2 - isopropyl-aminoethanol hydrochloride, Aldrich Chemical Co. Inc.), 2 μg/ml., and propanolol (1-isopropylamine-3-(1-naphthyl-oxy)-propan-2-ol, 'Inderal', I.C.I. Ltd), 0·2 μg/ml., added

† Standard error of the mean.

to the perfusate 5 min prior to the adrenaline completely abolished the adrenergic effect on basal Qo_2 (Table 1, Fig. 1). The adrenergic α-blocker phentolamine ('Regitin', Ciba) 2 μg/ml., on the other hand, did not block this effect of adrenaline. Like the glycolytic and lipolytic effects of adrenaline, the effect on basal Qo_2 thus seems to be mediated through the β-type of adrenergic receptors.

Adrenaline causes a rapid increase in the amount of cyclic 3′5′-adenosine monophosphate (AMP) in the rat heart[6–8]. This nucleotide accelerates reactions involving utilization of ATP (ref. 9). The increased rate of such energy-requiring reactions might contribute to the increase in basal Qo_2.

PRELIMINARY work which I carried out (unpublished) while at the Laboratory of Metabolism of the National Heart Institute does not confirm the lack of stimulation by adrenaline after β-adrenergic blockade as reported by Hauge and Øye. In a similar preparation, control Qo_2 after β-blockade was 0·17 as against 0·20 ml. oxygen/min/g dry weight determined after the addition of adrenaline ($\bar{d} = +0·03 \pm 0·003$ (S.E.), $p = 0·02$, $n = 6$). It must be pointed out that these were preliminary experiments and that a different β-blocker was used, 2 isopropyl-1-[2 naphthyl]ethanol hydrochloride, at different doses of both blocker (0·02 mg/ml.) and adrenaline (0·05 μg/ml.) than those used by Hauge and Øye. An α-blocker was not studied.

The mechanism of production of the 'metabolic' effect of adrenaline is not clear. The authors' conclusion that persistence of the effect in the presence of exogenous substrates would implicate a mechanism unrelated to substrate availability is not of necessity true. This will not be settled until the effect of both exogenous substrate and hormone on the substrate flow through the immediate endogenous oxidative precursor pool can be defined. The working hypothesis developed by Dr. Daniel Steinberg and myself is based on studies demonstrating the adrenaline-increased oxygen consumption in arrested rat heart to be accompanied by glycerol release and increased intracellular free fatty acid (FFA) concentration[1,2]. Separate studies have shown that exogenous FFA are able to increase intracellular FFA concentration[3] and that such exogenous FFA levels can stimulate oxygen uptake

through non-phosphorylation-dependent (oligomycin insensitive) pathways of mitochondrial oxidative electron flow[2-5]. We therefore suggest that the metabolic effect of epinephrine may be secondary to stimulation of endogenous substrate flow from lipolysis through such non-phosphorylating pathways.

Experimental evidence to date does not provide a definitive choice between Hauge and Øye's suggestion of a primary action of adrenaline on ATP utilization with secondary increase in oxygen consumption and our hypothesis of adrenaline-increased lipolysis with increased FFA flow through non-phosphorylating oxidative pathways.

MODIFICATION OF THE ELECTROKINETIC RESPONSE OF BLOOD PLATELETS TO AGGREGATING AGENTS

By DR. J. R. HAMPTON and DR. J. R. A. MITCHELL
Department of the Regius Professor of Medicine, Radcliffe Infirmary, Oxford

DESPITE widespread interest in the ability of blood platelets to adhere to each other, the mechanism by which they do so remains obscure. It is well known that a variety of substances, including adenosine diphosphate (ADP), adenosine triphosphate (ATP), noradrenaline, thrombin and collagen[1-3] will cause platelet aggregation in a stirred system. It has been suggested[4,5] that ADP provides a final common pathway for all these agents. The surface of platelets can be studied by measurement of their electrophoretic mobility, and we have shown[6] that low concentrations of the aggregating agents cause platelet surface charge to increase, while higher concentrations, of the order which cause aggregation if the mixture is stirred, reduce the surface charge. We have shown some differences between the behaviour of ADP and of noradrenaline in their effect on surface charge, and we considered that a study of the effect of various methods of inhibiting the changes in surface charge might shed light on the nature of these changes.

Blood was obtained by clean venepuncture from healthy volunteers and from patients with a variety of medical and surgical conditions, excluding those with recent myocardial infarction, pulmonary embolus, and inflammatory states, or patients who had recently undergone surgery. Platelet-rich citrated plasma was prepared as described by Emmons and Mitchell[7] and was diluted with nine volumes of platelet-poor plasma prepared by centrifugation at 750*g* for 15 min. The mixture was then brought into contact with unsiliconized glass and the post-contact electrophoretic mobility[8] was measured in the horizontal capillary apparatus designed by Bangham *et al.*[9] using a potential gradient of 2·66 V/cm and a temperature of 25° C. The mobility of the platelets is expressed as μ/sec/V/cm.

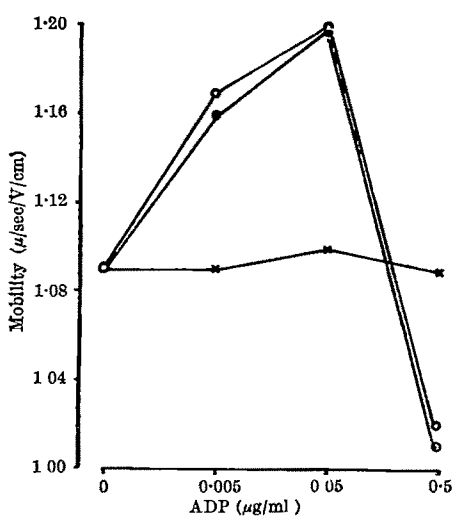

Fig. 1. The effect of 10^{-4} M NEM (×), and 10^{-4} M NEM plus equimolar l-cysteine (●), on the changes in platelet electrophoretic mobility induced by ADP ($n=3$). O, Control

The effect of a variety of agents was investigated: *n*-ethylmaleimide and *p*-hydroxymercuribenzoate (both from Sigma), which block sulphydryl groups; potassium cyanide, an inhibitor of cytochrome oxidase; sodium fluoride, an inhibitor of the synthesis of phosphopyruvate, and sodium monofluoroacetate (MFA), an inhibitor of aconitase and so of the tricarboxylic acid cycle. MFA is thought to exert its effect after conversion to monofluorocitrate (MFC)[10] and purified MFC was also studied. We assessed the effect of these substances on the changes in platelet mobility induced by ADP, ATP, noradrenaline (all from Sigma), thrombin ('Fibrindex', Ortho), and an extract of collagen[3]. At least two concentrations of each of these aggregating agents were used: a low concentration which we have shown to cause a maximal increase in mobility, and a higher concentration which causes a significant decrease in mobility[6].

The inhibitors were dissolved in 0·85 per cent sodium chloride solution and were added to the platelet-rich citrated plasma/platelet-poor plasma (PRCP/PPP) mixture. Parallel samples of the PRCP/PPP mixture to which saline alone had been added were set up as controls. None of the inhibitory agents was found to affect the post-contact electrophoretic mobility, and after the addition of the inhibitors, the mixtures were incubated at 25° C for 5 min. The agents known to change platelet mobility were then added, and 10 min later mobility was measured in the test and control mixtures.

A, Sulphydryl Blockers

(1) *n-Ethylmaleimide.* 10^{-4} M *n*-Ethylmaleimide (NEM) abolished both the increase in platelet mobility induced by 0·05 μg/ml. of ADP and the decrease caused by 0·5 μg/ml. This inhibition could be prevented if a source of thiol groups was supplied, in the form of equimolar l-cysteine (Sigma) as is shown in Fig. 1. Reduction of the concentration of NEM progressively reduced its effect, but its inhibitory action was still detectable at 10^{-7} M (Table 1).

Table 1. MEAN PERCENTAGE INHIBITION BY *n*-ETHYLMALEIMIDE (NEM) OF THE INCREASE IN PLATELET ELECTROPHORETIC MOBILITY CAUSED BY 0·05 μG/ML. OF NORADRENALINE AND ADP

Concentration of NEM (M)	Noradrenaline $n=3$	ADP $n=2$
10^{-3}	100	—
10^{-3}	74	—
10^{-4}	49	100
10^{-5}	37	63
10^{-6}	0	32
10^{-7}	—	6

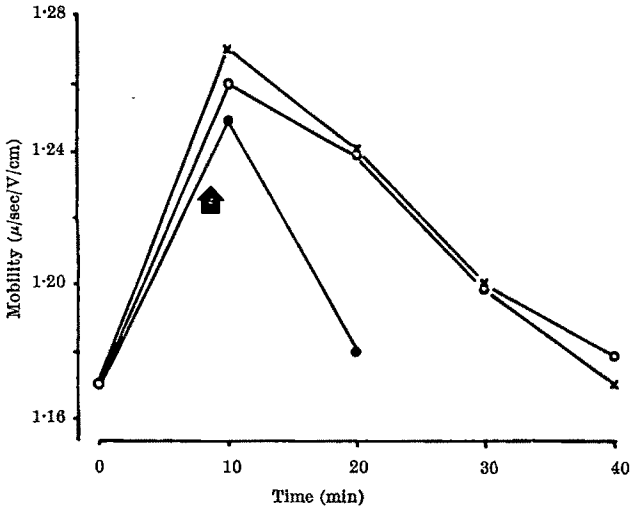

Fig. 2. The effect of 10^{-3} M NEM (●) and 1 mg MFA/ml. (×) on the time course of the platelet electrokinetic response to 0·05 μg ADP/ml. O, Saline

The changes in mobility induced by noradrenaline were also abolished by NEM, but higher concentrations of the latter were necessary (Table 1). Equimolar cysteine opposed the inhibitory action of NEM on the changes induced by noradrenaline in exactly the same way as it had done with ADP.

When NEM was added 9 min after the addition of 0·05 μg/ml. ADP or noradrenaline and the platelet mobility was measured 1 min later, the increase in mobility usually produced by these aggregating agents was found to be unaffected but the subsequent time course of this increase was markedly altered. In the control system, platelet mobility took 30 min to return to its initial level whereas, in the presence of NEM, mobility returned to its starting value in 10 min (Fig. 2). NEM is thus able to reverse the effects of ADP and noradrenaline as well as to prevent them.

10^{-3} M NEM was also found completely to abolish the increase and decrease in mobility induced by 0·5 and 5·0 μg/ml. of ATP, 0·01 and 1·0 u./ml. of thrombin and by dilute and concentrated extracts of collagen.

(2) *p-Hydroxymercuribenzoate.* The effects of *p*-hydroxymercuribenzoate (HMB) were similar to those of NEM. In a final concentration of 10^{-3} M it abolished both the increase and the decrease in mobility induced by ADP, ATP, noradrenaline, thrombin and collagen; this inhibition was prevented by l-cysteine in equimolar concentration. Like NEM, it rapidly reversed the effects of noradrenaline when added to a platelet mixture 9 min after the addition of the noradrenaline.

B, Monofluoroacetate and Monofluorocitrate

Monofluoroacetate (MFA) and monofluorocitrate (MFC) were found to have precisely similar effects; they did not alter the biphasic change in mobility induced by ADP and ATP. With noradrenaline, thrombin and collagen, MFA and MFC did not significantly affect the decrease in mobility induced by the higher concentrations, but they completely abolished the increase in mobility induced by the lower concentrations of these agents. The effect of MFA on noradrenaline is shown in Fig. 3. Abolition of the increase in mobility was found with MFA and MFC at 1·0 mg/ml.; at 0·1 mg/ml. they reduced the mobility change, and at 0·001 mg/ml. they had no effect. Though MFA and MFC could prevent the increase in mobility produced by noradrenaline, they were not able, as the sulphydryl blockers had been, to reverse the mobility change once it had occurred. Fig. 2 shows the effect of adding MFA 1·0 mg/ml. 9 min after noradrenaline had been added to a PRCP/PPP mixture.

C, Cyanide and Fluoride

$1·5 \times 10^{-3}$ M potassium cyanide and $2·5 \times 10^{-4}$ M sodium fluoride had no effect on the biphasic change in mobility induced by ADP, ATP, noradrenaline, thrombin and collagen.

D, Pyruvate Kinase

ADP can be removed from a system by the enzyme pyruvate kinase (PK) by way of the reaction:

Phosphoenolpyruvate (PEP) + ADP = Pyruvate + ATP

where the equilibrium of the reaction favours the production of ATP (ref. 4).

Saline solutions of PK and PEP (Sigma) were added to PRCP/PPP mixtures and the platelet mobility compared with control mixtures to which saline alone had been added. PEP in a final concentration of 0·005 μg/ml., PK in a concentration of 0·1 mg/ml., and a mixture of PK 0·1 mg/ml. and PEP 0·005 μg/ml. had no effect on the post-contact mobility of platelets.

PRCP/PPP mixtures were incubated with PK 0·1 mg/ml. and PEP 0·005 μg/ml. for 5 min at 25° C. ADP and the other aggregating agents were then added and the platelet mobility was measured in the usual way 10 min later. The increase and decrease in mobility induced by the two concentrations of ADP (Fig. 4) and of ATP was abolished by the enzyme system, and this effect was found to occur

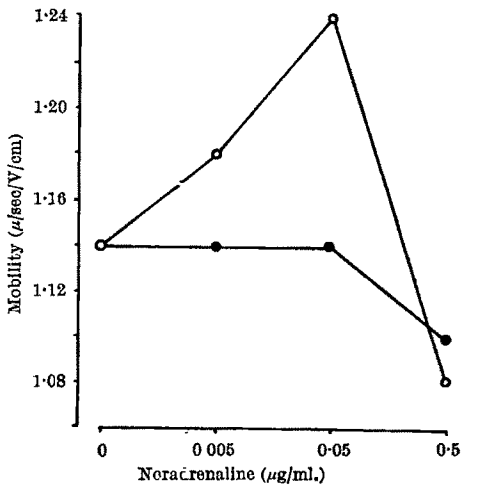

Fig. 3. The effect of 1 mg MFA/ml on the changes in platelet electrophoretic mobility induced by noradrenaline ($n = 4$). O, Without MFA; ●, with MFA

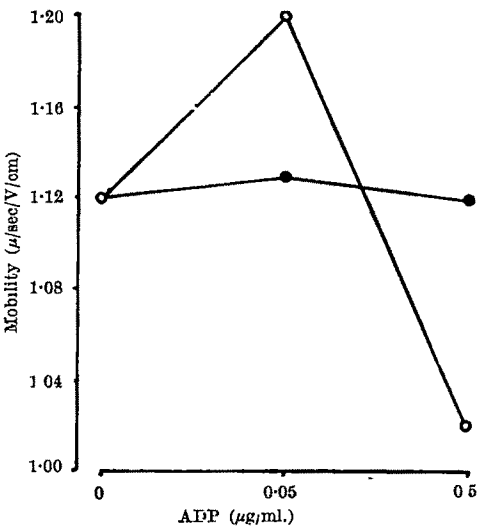

Fig. 4. The effect of PK and PEP (●) on the changes in platelet electrophoretic mobility induced by ADP ($n = 3$). O, Control

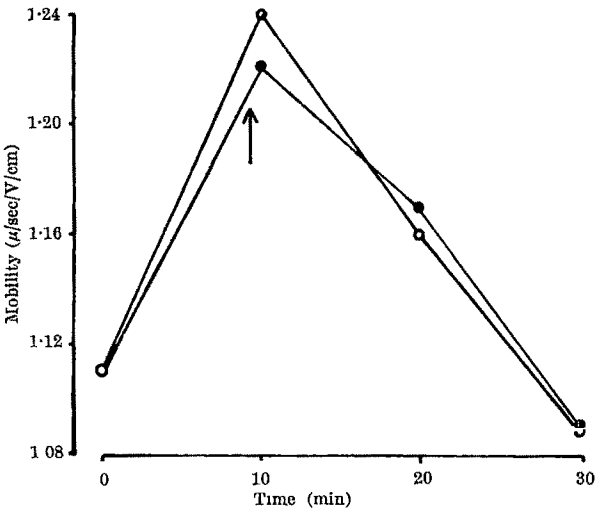

Fig. 5. The effect of PK and PEP (●) on the time course of the platelet electrophoretic response to 0·05 μg ADP/ml. ○, Saline

with concentrations as low as PK 0·001 mg/ml. and PEP 0·0005 μg/ml. When the enzyme system was added 9 min after the addition of ADP or ATP, and the platelet mobility was measured 1 min later, the usual change in mobility was still seen, and the subsequent time course of the change in mobility was unaffected (Fig. 5). Thus the enzyme system, like MFA and MFC, is capable of preventing the mobility changes but not of reversing them once they have occurred, differing in this respect from the sulphydryl blockers.

The enzyme system did not affect the changes in mobility induced by noradrenaline, thrombin and collagen.

E, Dipyridamole

A pyrimido-pyrimidine compound, dipyridamole (*RA8*, 'Persantin', Boehringer Ingelheim), has been shown to inhibit ADP-induced platelet aggregation *in vitro* in a concentration of 10^{-4} M, but to be without effect on noradrenaline-induced aggregation[11]. Its effect on the electrokinetic properties of platelets was studied by adding dipyridamole to citrated whole blood *in vitro* to give a final concentration of 10^{-4} M and preparing a PRCP/PPP mixture from the blood in the usual way. The agent had no effect on the post-contact platelet mobility or on the increase and decrease produced by low and high concentrations of ADP. The increase in mobility produced by noradrenaline was, however, abolished.

We have shown that ADP, ATP, noradrenaline, thrombin and collagen extract cause a biphasic change in the electrophoretic mobility of platelets, low concentrations producing an increase in mobility, while higher concentrations decrease mobility[6]. ADP, like the platelet, is negatively charged, and the increase in mobility caused by low concentrations is probably the result of simple adsorption of this 'exogenous' ADP on to the platelet surface. Since noradrenaline, which is positively charged, produces the same increase in mobility as ADP, we have suggested that this agent, and thrombin and collagen, act by releasing ADP from within the platelet on to its surface ('endogenous' ADP). The decrease in mobility produced by higher concentrations of all the agents is probably the result of adsorption of calcium which occurs when an appropriate charge density and spatial arrangement of ADP molecules has developed.

The effect of the various substances described in this article on the electrophoretic response of platelets to aggregating agents provides some parallels with, and some differences from, the results obtained by the aggregation technique of investigating platelet behaviour. Fantl[12] showed that thiol groups are present on the platelet surface, and *n*-ethylmaleimide and *p*-hydroxymercuribenzoate, which abolish the electrokinetic response of the platelets, have been found[13–15] to prevent aggregation by any of the agents at present recognized, and to cause disruption of pre-formed aggregates. Cyanide and fluoride have been shown to be without effect on either aggregation or electrophoretic response.

Monofluoroacetate has no effect on aggregation as measured by the optical density technique[15]. Its property of inhibiting the increase in electrophoretic mobility caused by noradrenaline, thrombin, and collagen has therefore no parallel when platelet function is assessed by measuring aggregation. Pyruvate kinase also behaves differently in the two systems: it inhibits aggregation by ADP, ATP, noradrenaline, thrombin and collagen[4,16], and yet does not affect the changes in mobility induced by the latter three substances.

We have already shown that there are significant differences between the electrokinetic actions of ADP and noradrenaline[6]; the former induces changes in platelet surface charge in the presence of inorganic ions, glucose and fibrinogen, while noradrenaline, thrombin and collagen require some other cofactor. The experiments described here provide further evidence that aggregating agents are of two distinct types. First, exogenous ADP, the effect of which is abolished by pyruvate kinase, but not by monofluoroacetate. Second, noradrenaline, thrombin and collagen, which are unaffected by pyruvate kinase, but cannot increase platelet mobility in the presence of monofluoroacetate. A further difference between the effect of ADP and noradrenaline on platelet surface charge is that dipyridamole abolishes the increase in mobility caused by noradrenaline, but has no effect on the increase produced by ADP.

It appears that when exogenous ADP is added to a platelet suspension, it is adsorbed on to the platelet surface; for this, both calcium[6] and thiol groups are necessary. Noradrenaline, thrombin and collagen, on the other hand, cause the release on to the platelet surface of endogenous ADP or some similar substance. Monofluoroacetate can prevent this release, but once the endogenous ADP is on the platelet surface it is unable to remove it. Thiol groups are, however, necessary if both exogenous and endogenous ADP are to remain on the platelet surface, the sulphydryl blockers being able to reverse the effect of noradrenaline and of ADP. It would appear that pyruvate kinase acts by removing exogenous ADP from the system before it can become adsorbed on to the platelet surface, but that the enzyme cannot remove adsorbed ADP or endogenous ADP.

We thank Sir George Pickering for advice and encouragement; Dr. Machlut of Karl Thomae *A.G.*, Biberach, Germany, for supplies of purified monofluorocitrate; and Dr. D. Middleton of Boehringer Ingelheim, Ltd., for supplies of dipyridamole.

NUMBER AND LOCATION OF ACETYLCHOLINESTERASE MOLECULES AT MOTOR ENDPLATES OF THE MOUSE

By DR. A. W. ROGERS*, DR. Z. DARŻYNKIEWICZ†, PROF. E. A. BARNARD and DR. M. M. SALPETER

Molecular Enzymology Unit, Department of Biochemical Pharmacology, State University of New York, Buffalo, New York, and Department of Engineering Physics, Cornell University, Ithaca, New York

THE mammalian motor endplate is a highly specialized structure, at which the terminal axonal twigs of the motor nerve come to lie in a series of shallow gutters in the surface of the striated muscle fibre. Numerous light and electron microscope studies have elaborated its detailed structure. This endplate is cholinergic, and the enzyme acetylcholinesterase (AChase) occurs there at relatively high concentrations. The occurrence of AChase at these endplates has been demonstrated by several classical histochemical studies with the light microscope and, more recently, by histochemical techniques modified for electron microscopy[1]. Up to the present time, however, no technique has been evolved to measure the amount of AChase in single endplates, or to describe its detailed distribution in quantitative terms.

It is possible to block the action of AChase with a number of organophosphorus compounds, such as diisopropylfluorophosphate (DFP), which form a covalent bond with the serine hydroxyl group at the active centre of the enzyme. This reaction has been proposed by Barnard and Ostrowski as a possible basis for the cytochemical demonstration of the enzyme[2]. Radioactive DFP would introduce labelled diisopropylphosphoryl (DP) groups at the active site of the enzyme, and the localization of the latter should be demonstrable autoradiographically, both with the light and electron microscope. Measurements of the radioactivity present could be used to indicate the number of enzyme molecules per motor endplate. DFP is not specific for AChase, but reacts with several other enzymes. Furthermore, since DFP is lipophilic, it is difficult to remove loosely bound DFP from treated tissues. Any measurement of AChase that uses labelled DFP as a reagent must, therefore, distinguish clearly between these two sources of unwanted radioactivity on the one hand, and the phosphorylation of AChase by DFP on the other.

Measurement of the Total DFP-reactive Sites per Endplate. The measurement of the total number of molecules of DFP bound per endplate was made in the present experiments with the technique of beta-track autoradiography. Levinthal and Thomas[3] have demonstrated the precision of this technique in quantitative studies, and Levi and Rogers[4] have investigated its technical requirements in detail. Small fragments of the sternomastoid muscle and diaphragm of male Swiss mice were dissected out, and the endplates lightly stained by brief (5–10 min) reaction in the Koelle acetylthiocholine method (ref. 5, p. 890). After fixation in cold formalin (*p*H 7·4), DFP, labelled with phosphorus-32 (Radiochemical Centre, Amersham, and New England Nuclear Corp., specific activity 40–80 mc./mmole), was applied at 10^{-4} M for 20 min at room temperature, in 0·02 M phosphate buffer (*p*H 7·4). Extensive washing followed, both in phosphate buffer and in unlabelled DFP (10^{-3} M). Individual lengths of muscle fibre were then obtained under the dissecting microscope, some bearing stained endplates, some without. These were pipetted on to a gelatinized slide, and coated with a 60-μ layer of Ilford '*G5*' nuclear research emulsion. After exposure periods of 15–16 h, development and fixation took place, following the procedures outlined by Levi and Rogers[4].

At the exposure times used, beta-tracks, numbering up to ten on each endplate, could be clearly seen entering the emulsion from the stained endplates (Fig. 1). In each experiment, the track density per unit surface area of the muscle fibres without endplates was determined, and the observed track count from each endplate corrected for this muscle background. Since the specific activity of the ^{32}P-DFP was known, a conversion of the observed track counts to the number of molecules of DFP bound to each endplate was possible after appropriate corrections for geometrical factors and for radioactive decay.

The value for the number of sites of phosphorylation per endplate was reasonably consistent from one experiment to another. It was not altered by incubation in ^{32}P-DFP for 30 min instead of 20 min, or in 10^{-3} M instead of 10^{-4} M ^{32}P-DFP, indicating that the reaction was complete in the conditions used routinely. Nor was this value significantly influenced by the formalin fixation, since material that was not fixed until after the labelling procedure was completed gave the same number of reactive sites per endplate. Prior treatment of the muscle with unlabelled DFP (10^{-4} M) for 20 min completely prevented the uptake of radioactivity at endplates.

With phosphorus-32, it is reasonable to ignore self-absorption within the tissue. Similarly, the failure of very low energy beta particles to give rise to recognizable tracks[4] is quite insignificant with this isotope. Latent image fading was excluded, on the basis of an investigation of the grain spacing in the beta-tracks. A chemographic artefact was consistently found, however, in material exposed for more than 24 h, resulting in the desensitization of the emulsion immediately adjacent to the tissue. Only

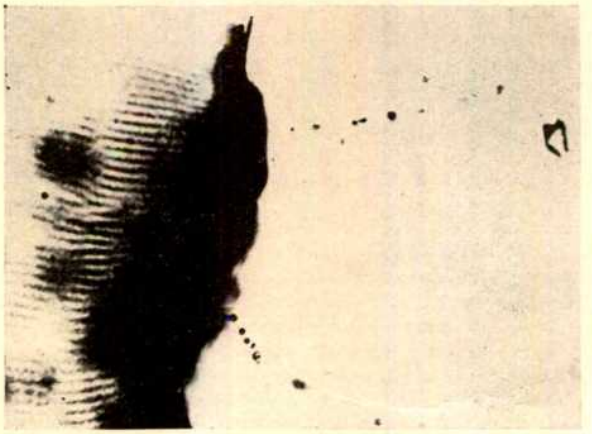

Fig. 1. Beta-track autoradiograph of a sternomastoid endplate treated with ^{32}P-DFP. The tracks of 2 beta particles can be seen entering the emulsion from the stained endplate. (× *c.* 556)

the data from autoradiographs exposed for less than 24 h were, therefore, used in the calculation of absolute values.

For the sternomastoid muscle, the observed number of phosphorylated sites per endplate decreased with increasing time of incubation in the acetylthiocholine-containing medium used to stain the endplates (Fig. 2). It has not proved possible to identify endplates satisfactorily on unstained material, nor to stain the endplates after reaction with DFP. From the data shown in Fig. 2, it seems reasonable to extrapolate to zero incubation time, and assume that the uptake of labelled DFP in unstained endplates would be $7{\cdot}0–10{\cdot}0 \times 10^7$ molecules/endplate in the sternomastoid, and (from similar data) $2{\cdot}5–3{\cdot}5 \times 10^7$ for the diaphragm.

The latter figure is in close agreement with the estimate, given in a recent note by Waser and Keller[6], of $2{\cdot}4 \times 10^7$ sites per diaphragm endplate, obtained by an independent autoradiographic technique. However, their claim that all these sites are AChase cannot be accepted in the light of the evidence on specificity presented in the following section.

After labelling muscle material with ^{3}H-DFP, sectioning, and preparation of grain density autoradiographs, a low, but significant, level of labelling was found over endplates. It is difficult to calculate the total number of DFP-reactive sites per complete endplate from such material, without accurate knowledge of the grain yield of the autoradiographs and the geometry of the endplates. However, the ratio of labelling between endplate and muscle fibre was compatible with that found in track autoradiographs, and the grain counts over endplates were within the range expected from the grain yield figures available in the literature[7].

Barnard, Ostrowski, *et al.*[8] previously applied ^{3}H-DFP to mouse diaphragm, and found heavily labelled areas which they deduced to be AChase at motor endplates. It will be shown in a subsequent publication that those results failed to distinguish endplates from mast cells; it is a matter of much interest, which will be explored elsewhere, that mast cells have a far higher concentration of DFP-reactive sites. In the present work, with ^{3}H-DFP at higher specific activities, endplates could always be clearly identified as the source of the radioactivity measured.

The Specificity of Phosphorylation with DFP. The proportion of this total number of DFP-reactive sites that is contributed by the active centres of AChase was found by two independent methods. In the first of these, pyridine-2-aldoxime methiodide (2-PAM) was used. This compound is a specific reactivator for the DP-AChase complex, removing the DP group and restoring activity to the enzyme. It has been shown to reactivate organophosphate-

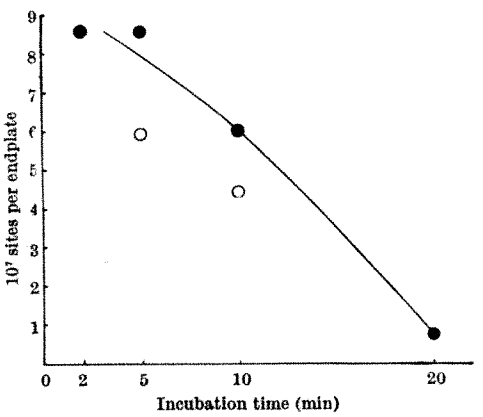

Fig. 2. Effect of the period of incubation in the Koelle acetylthiocholine medium on the number of sites subsequently phosphorylated by ^{32}P-DFP, in sternomastoid endplates. In each individual experiment, the mean value was derived using 12–48 endplates. The closed circles (and the curve) show a series of four experiments all using the muscle of one animal, reacted together. The open circles are the means of two (5 min) or five (10 min) experiments on other specimens

Table 1. CONTRIBUTION OF ACHASE TO THE TOTAL SITES PHOSPHORYLATED BY DFP IN ENDPLATES OF DIAPHRAGM AND STERNOMASTOID

Muscle	Specific agent	Autoradiographic technique	AChase as percentage of total DFP-reactive sites
Diaphragm	2-PAM	Beta-track	37
		Grain density	31
			36
			36
			46
	284C51	Beta-track	31
		Grain density	34
	Eserine	Grain density	34
Sternomastoid	2-PAM	Beta-track	33
			37
	284C51	Beta-track	51

Each value is the mean of a separate experiment involving groups of 12–48 endplates in beta-track autoradiographs and counts from fifty or one hundred sections of endplates in grain density measurements.

inhibited pseudocholinesterase (Chase) also, but at about 0·01 per cent of the rate for AChase[9]. After 20 min treatment with 2-PAM at 10^{-3} M (Table 1), 30–40 per cent of the radioactivity was removed from endplates previously labelled with DFP. There was no further loss of radioactivity after 30 or 60 min exposure to 2-PAM. The same decrease in this range was obtained from endplates of either sternomastoid or diaphragm muscles, whether labelled with ^{32}P-DFP and examined by beta-track autoradiography, or with ^{3}H-DFP and examined by grain density autoradiography. Using a complementary procedure, endplates were treated with unlabelled DFP, followed by 2-PAM, blocking all the reactive sites except those of AChase. In these circumstances, only one third of the total number of reactive sites could then be labelled with ^{3}H-DFP.

'Ageing' of the DP-AChase complex involves the loss of one isopropyl group: it has a half-time of about 12 h at room temperature, and is very much slower at 4° C (ref. 10). The 'aged' complex cannot be reactivated by 2-PAM. In the present material the time between DFP application and 2-PAM reactivation was 35 min at room temperature, and 2–3 h at 4° C. The effect of 'ageing' on these measurements is thus negligible, and they can be interpreted as showing that the active centres of AChase represent about one third of the total DFP-reactive sites.

In an alternative approach, the AChase was protected from radioactive DFP by the presence of tightly bound specific inhibitors, and the reduction in labelling was measured. The inhibitor '284C51' (Burroughs Wellcome) is highly specific for AChase when used at 3×10^{-5} M (ref. 11). This compound, when applied to the muscle fragments before, during, and after labelling with DFP, reduced DFP uptake by (on average) about one third (Table 1). Eserine, at 10^{-5} M, should protect both AChase and Chase. In a similar experiment using eserine, the reduction in labelling was again about one third, suggesting that little, if any, Chase is present at the endplate. Ethopropazine (Warner Chilcott Laboratories) at 3×10^{-5} M protects Chase alone[12]. In two experiments, values of 5 per cent and 15 per cent protection were obtained. Taken in conjunction with the eserine results, it is probably safe to deduce that less than 10 per cent of the DFP is reacting with Chase.

Direct Estimation of AChase Molecules per Endplate. Accepting that 30–40 per cent of the radioactivity at mouse sternomastoid and diaphragm endplates represents phosphorylation of AChase, the number of molecules of this enzyme at one endplate becomes $2{\cdot}1–4{\cdot}0 \times 10^7$ (sternomastoid) and $0{\cdot}8–1{\cdot}4 \times 10^7$ (diaphragm). The sternomastoid value has been checked directly by liquid scintillation counting, making use of exhaustive extraction by a 2-PAM solution.

First, the reduction in labelling with ^{3}H-DFP following staining by the Koelle technique was measured: after 10 min staining, the radioactivity eluted by 2-PAM (10^{-3} M) solution from small fragments of muscle rich in endplates was 55 per cent of that from similar but unstained material. This is in good agreement with the value obtained by extrapolation to zero staining time in Fig. 2.

Small unstained fragments of sternomastoid were labelled with ^{3}H-DFP and, after very extensive washing, the radioactivity that was eluted with 2-PAM was measured. The fragments were then treated by Koelle's technique to stain the endplates, which were counted. Similar treatment of fragments without endplates provided an estimate of the muscle background. In a further experimental design, stained, labelled endplates were obtained by microdissection, and the radioactivity eluted from these by 2-PAM was measured: the results were corrected for muscle background, and for the reduction in labelling known to result from the staining procedure.

Six experiments by the above techniques have given estimates ranging from $1{\cdot}2$ to $4{\cdot}4 \times 10^7$ molecules AChase per endplate, with a mean value of $2{\cdot}4 \times 10^7$, confirming the values obtained by beta-track autoradiography (Table 2).

Table 2. Number of Molecules of AChase per Endplate of Mouse Sternomastoid and Diaphragm, determined by Three Independent Techniques following Treatment with Radioactive DFP

Muscle	Technique	No. of molecules of AChase per endplate
Sternomastoid	Beta-track	$2{\cdot}1$–$4{\cdot}0 \times 10^7$
	Liquid scintillation counting	$1{\cdot}2$–$4{\cdot}4 \times 10^7$
	Electron microscope autoradiography	1–2×10^7
Diaphragm	Beta-track	$0{\cdot}8$–$1{\cdot}4 \times 10^7$

The figures are the ranges of all determinations.

The Detailed Distribution of AChase at Sternomastoid Endplates. For an evaluation of the distribution of AChase within the endplate with higher resolution than that available with the light microscope, the technique of electron microscope autoradiography was used following the methods described by Salpeter and Bachmann[13]. Fragments of sternomastoid rich in endplates were fixed in 1 per cent buffered glutaraldehyde (*p*H 7·4) at 4° C. AChase only was labelled in this material, using the sequence: unlabelled DFP, 2-PAM reactivation, labelling with ^{3}H-DFP, and the usual washing. Post-fixation in osmium tetroxide and embedding in 'Epon' followed.

The necessary conditions for the quantitative evaluation of electron microscope autoradiography, such as the control of the uniformity and thickness of the emulsion, have been described by Bachmann and Salpeter[14]. The level of radioactivity in the present material was so low that relatively thick sections (1000 Å) were used. For ease of scanning and grain counting, monolayers of Ilford '*L*4' emulsion (giving a purple interference colour) were developed with 'Microdol *X*'. The resolution thus obtained was about 1800 Å.

Control experiments with light microscope autoradiography indicated that glutaraldehyde fixation decreased the uptake of labelled DFP by about 10 per cent only.

Developed grains were counted from large areas of muscle and expressed as grains per unit volume of underlying tissue. This procedure showed a significant localization of radioactivity at the endplates, where the grain density was 25 times higher than over the muscle. The endplates were subdivided into three major compartments (Fig. 3): (i), the terminal axon, which forms 25–35 per cent of the total volume; (ii), the post-junctional zone, which is 40–50 per cent of the total volume (this includes the sarcolemmal folds and the primary cleft that separates them from the terminal axon); (iii), the teloglial cap, or overlying connective tissue with tongues of Schwann cell cytoplasm, which is 20–30 per cent of the total volume. Of more than 60 developed grains seen over endplates, 85 per cent lay over the junctional folds (Figs. 3 and 4), giving a grain density approximately 45 times that of the muscle background. 10 per cent of the grains occurred over the teloglial cap, a density ten times the muscle background. Only 5 per cent lay over the terminal axon.

In the conditions of autoradiography used, each developed grain represents approximately ten disintegrations within the section[15]. On this basis, the junctional fold region contains about 19,000 molecules AChase per μ^3: the connective tissue cap has about 4,000 per μ^3. Averaged over the whole endplate, the concentration of AChase is about 10,000 molecules per μ^3.

We have attempted to relate these figures to those obtained by beta-track autoradiography and liquid scintillation counting, by converting them to the number of molecules of AChase per complete endplate. To do this, we have estimated the mean volume of a sternomastoid endplate from combined light and electron microscope measurements. The estimates obtained in this way have a considerable element of uncertainty: the values range from 1,000 to 2,000 μ^3, depending on the precise assumptions made regarding the proportion of the stained endplate formed by synaptic gutters. On this basis, we get figures of 1–2×10^7 molecules AChase per sternomastoid endplate. In spite of the uncertainties of this conversion, this figure is in good agreement with those given by the other techniques (Table 2).

Autoradiographic cytochemistry, with labelled enzyme inhibitors as reagents, can clearly give precise information on the number and location of enzyme sites, in suitable circumstances. The quantitative agreement between beta-track counts, electron microscope autoradiography, and liquid scintillation counting is most encouraging.

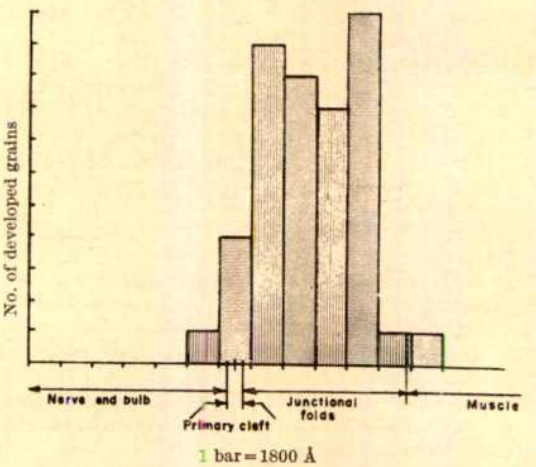

Fig. 3. Histogram based on the distribution of developed grains seen over fifty sections through sternomastoid endplates, labelled with ^{3}H-DFP and studied by electron microscope autoradiography

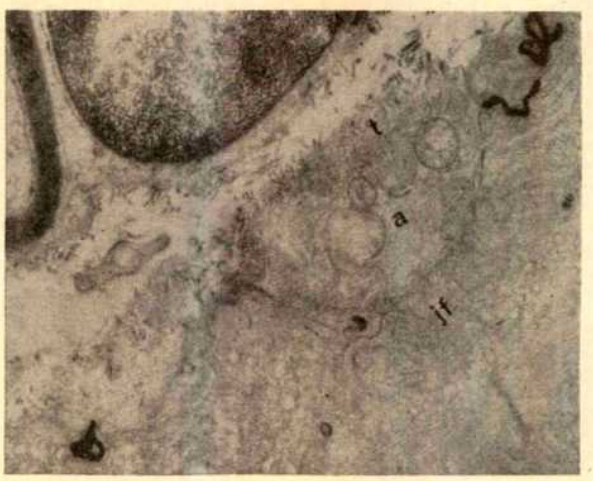

Fig. 4. Electron microscope autoradiograph of a motor endplate in the sternomastoid muscle of the mouse, after labelling the AChase (only) with ^{3}H-DFP (using a 2-PAM routine). Three developed grains lie over the post-synaptic junctional folds. *a*, Terminal axon; *jf*, junctional folds (× 12,000)

The results indicate that there are 7·0–10·0 × 10^7 and 2·5–3·5 × 10^7 sites that react with DFP in endplates of mouse sternomastoid and diaphragm respectively. About 35 per cent of these are active centres of AChase, and probably less than 10 per cent are Chase. Of the AChase molecules, approximately 85 per cent lie in the junctional fold region of the endplate, approximately 10 per cent in the overlying connective tissue and perhaps about 5 per cent in the terminal axon.

The nature of the remaining reactive sites, which form 50–60 per cent of the total, is under investigation. The consistent labelling of these sites, persisting through exchange with unlabelled DFP at high concentrations, and blocked by prior treatment with unlabelled DFP, suggests that these sites are enzymes phosphorylated by DFP. The presence of esterases other than AChase and Chase has been demonstrated histochemically at the endplate[5,15] (and confirmed similarly by us on the muscles investigated here), but the methods used do not permit any deductions to be made as to their relative amount. It may be possible to determine the nature and distribution of these sites, using extensions of the methods described here.

We thank Miss A. O'Connor, of Cornell University, for assistance with the electron microscope autoradiography, and Dr. K. Ostrowski of the Medical Academy, Warsaw, Poland for interest and advice. This work was supported by grants from the National Institutes of Health, U.S. Public Health Service.

REGIONAL DIFFERENCES IN THE RATE OF TURNOVER OF NOREPINEPHRINE IN THE RAT BRAIN

By DR. L. L. IVERSEN* and DR. J. GLOWINSKI†

Laboratory of Clinical Science, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland

NOREPINEPHRINE is present in different concentrations in specific areas of the mammalian brain[1,2] and recent histochemical findings have clearly demonstrated its precise localization in a complex system of neurones[3,4]. Norepinephrine, which acts as a neurotransmitter substance in the peripheral sympathetic nervous system[5], may also have a similar function in the central nervous system.

Although there have been many reports of changes in the level of norepinephrine in the brain in response to centrally acting drugs[1,6], little is known about the dynamic aspects of the metabolism of this catecholamine in the central nervous system. Measurements of the rate of turnover of brain norepinephrine have been hampered by the existence of a blood–brain barrier to catecholamines[7], which prevents the labelling of central stores by the systemic administration of radioactive norepinephrine. An alternative approach has been to use radioactive precursors of norepinephrine, such as tyrosine or 3-4-dihydroxyphenylalanine (DOPA), which more readily enter the brain[8,9].

After the introduction of labelled norepinephrine or its precursors into the brain, the rate of turnover of the endogenous amine can be measured by following the rate of decline of its specific activity.

The injection of very small amounts of ^{3}H-norepinephrine into the lateral ventricle of the rat brain by a stereotaxic technique[10,11] offers a convenient method for the labelling of brain norepinephrine stores.

Radioactive norepinephrine appears to be selectively taken up and retained in catecholamine-containing neurones, where it mixes with the endogenous stores of norepinephrine[12]. ^{3}H-norepinephrine disappears from the brain in a multiphasic fashion; the initial phase during the first 12 h after injection accounts for the disappearance of approximately 93 per cent of the accumulated amine[12]. The rate of disappearance of ^{3}H-norepinephrine from the whole brain during this major initial phase indicates a half-life of approximately 4 h, which is in good agreement with previous estimates of the rate of norepinephrine turnover in the brain[8,9]. ^{3}H-norepinephrine, however, distributes in more than one pool of endogenous norepinephrine and this has led to difficulties in the use of this technique for studies of norepinephrine turnover in peripheral tissues[13]. In order to test the validity of using the rate of disappearance of ^{3}H-norepinephrine as a measure of turnover in the brain, this method has been compared with two alternative experimental approaches.

α-Methyl-*p*-tyrosine has recently been shown to act as an effective inhibitor of norepinephrine synthesis *in vivo*[14]; this drug is thought to act by inhibiting the rate-limiting step in the biosynthetic pathway, the conversion of tyrosine to DOPA (ref. 15). The rate of disappearance of the endogenous norepinephrine stores from the brain after inhibition of synthesis with this drug can be used as an alternative measure of the rate of utilization of the catecholamine. Another approach has been to measure the rate of disappearance of ^{3}H-norepinephrine endogenously formed in the brain from ^{3}H-dopamine. In addition we have investigated the possibility that differences in the rate of norepinephrine turnover may exist between various anatomical regions of the rat brain.

Rat brains were rapidly dissected at 4° C into several regions: cerebellum, hypothalamus, medulla oblongata, striatum, mid brain, hippocampus and cerebral cortex, using a procedure which will be described in detail elsewhere[16]. The rate of turnover of norepinephrine in the various regions was measured by the following methods.

In method 1 a large dose of the synthesis inhibitor L-α-methyl-*p*-tyrosine (200 mg/kg) was administered intra-

* Harkness Fellow.

† Fellowship: Foundations' Fund for Research in Psychiatry.

peritoneally and the endogenous norepinephrine content of the various brain regions was measured at different times after this treatment. Norepinephrine was isolated from brain extracts by alumina adsorption[17] and was assayed fluorometrically[18].

In method 2 a small amount (1·5 μg) of ^{3}H-dopamine (1·5 c./mole, generally labelled, New England Nuclear Corp., Boston) was injected into the lateral ventricle of the rat brain, and the disappearance of the radioactive norepinephrine formed from the labelled precursor was measured. ^{3}H-norepinephrine was extracted from brain tissues and separated from labelled dopamine and other radioactive metabolites by a combination of alumina adsorption and ion-exchange chromatography[19].

For method 3 the disappearance of ^{3}H-norepinephrine from various brain regions was measured after the intraventricular injection of a small amount (0·15 μg) of DL-7-^{3}H-norepinephrine (5·0 c./mmole, New England Nuclear Corp.). ^{3}H-norepinephrine was assayed after isolation on alumina[20].

Table 1. RATE OF NOREPINEPHRINE (NE) TURNOVER IN RAT HYPOTHALAMUS
Results obtained by three experimental methods

Time (h)	Method 1 NE content (mμg/g)	Method 2 ^{3}H-NE content (mμg/g)	Method 3 ^{3}H-NE content (mμg/g)
0	1,790 ± 102 (8)	—	—
1	1,500 ± 232 (5)	—	—
2	1,020 ± 47 (3)	34·7 ± 2·6	42·9 ± 2·5
3	1,000 ± 93 (5)	—	—
4	710 ± 50 (3)	—	31·5 ± 2·7
6	520 ± 30 (8)	20·6 ± 0·8	23·5 ± 1·7
8	—	—	14·0 ± 1·1

Sample of experimental data obtained by three different methods for measuring rate of norepinephrine (NE) turnover in rat hypothalamus. In method 1 animals received a single intraperitoneal injection of L-α-methyl-p-tyrosine (200 mg/kg) and the norepinephrine content of hypothalamus was assayed at various times thereafter. Results are mean values ± standard errors of the mean; number of animals in each group is indicated in brackets. In method 2 the content of ^{3}H-norepinephrine was measured at various times after the intraventricular injection of ^{3}H-dopamine (1·5 μg). Values are means for five determinations; each sample was obtained by pooling tissue from two brains. For method 3 the ^{3}H-norepinephrine content was assayed at various times after the intraventricular injection of ^{3}H-NE (0·15 μg). Values are the means for four determinations ± standard errors of the mean.

An example of results obtained by the three methods is given in Table 1 for the hypothalamus. The data obtained by method 3 for this region, which has the highest norepinephrine concentration in the brain, are compared with results obtained by this method for the cerebellum, a region containing only small amounts of endogenous norepinephrine (Fig. 1). Results obtained by the three different methods for the hypothalamus and cerebellum are illustrated and compared in Fig. 2. The rates of disappearance of endogenous norepinephrine (method 1) and of ^{3}H-norepinephrine (methods 2 and 3) are expressed by slopes (Figs. 1 and 2) calculated by the method of least squares analysis. For each region the slopes obtained were compared by an analysis of variance[21]. It was concluded that for any given region of the brain the slopes or disappearance rates obtained by the three methods did not differ significantly.

Table 2. NOREPINEPHRINE (NE) TURNOVER RATES IN HYPOTHALAMUS AND CEREBELLUM OF RAT ESTIMATED BY THREE EXPERIMENTAL METHODS

	Method 1	Method 2	Method 3
Cerebellum	2·25	2·33	2·03
Hypothalamus	3·31	5·28	3·82

Summary of estimates of half-life of norepinephrine (NE) in rat cerebellum and hypothalamus by the three methods described in the text. Half-life was determined from the calculated slopes (Figs. 1 and 2) by the expression: half-life $= \frac{\log_{10}2}{\text{slope}}$.

Differences in slopes between regions were, however, apparent (Figs. 1 and 2). For example, the estimated half-life for norepinephrine in the cerebellum and hypothalamus by all three methods indicated a more rapid turnover in the cerebellum (Table 2). Estimates for the half-life of norepinephrine in other brain areas were intermediate between those for the hypothalamus and

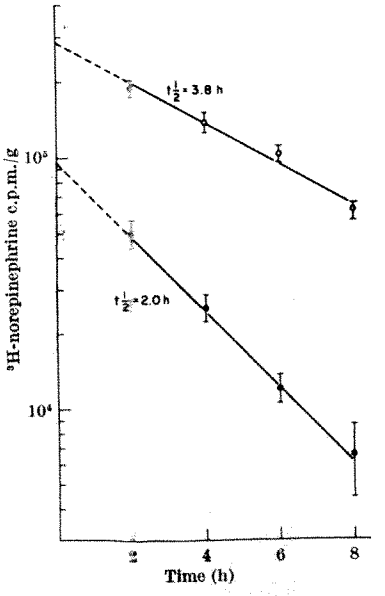

Fig. 1. ^{3}H-norepinephrine content of rat cerebellum (●) and hypothalamus (○) at various times after the intraventricular injection of 0·15 μg D,L-^{3}H-norepinephrine. Each point is the mean of four determinations ± standard error of the mean; slopes were calculated by least squares analysis

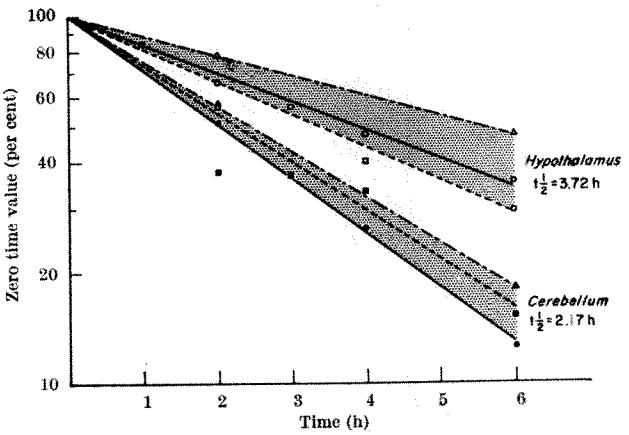

Fig. 2. A comparison of the results obtained for rat hypothalamus and cerebellum by the three experimental methods described in the text. Zero time values for each method for the two regions were adjusted to 100 per cent for purposes of illustration. Each point is the mean value for three to eight determinations (Table 1). Weighted mean values for half-life of norepinephrine in each region are shown in the figure. ——, Method 1; — · —, method 2; - - -, method 3

cerebellum. The estimated half-life for norepinephrine in the cerebellum by method 3 was significantly lower than that obtained for any other brain region. The rate of norepinephrine formation in any region can be estimated from the turnover rate and the size of the endogenous norepinephrine pool. Since the hypothalamus has a high endogenous norepinephrine content (1·79 μg/g) and the cerebellum a low content (0·17 μg/g), the rate of norepinephrine formation per gram of tissue is actually higher in the hypothalamus than in the cerebellum, although the rate of turnover is faster in the latter region. The estimated rates of norepinephrine formation in hypothalamus and cerebellum are 234 mμg/g/h and 42 mμg/g/h, respectively.

The close agreement among the estimates of norepinephrine turnover by the three different experimental procedures used in the present investigations supports the conclusion that the disposition of ^{3}H-norepinephrine after intraventricular injection is representative of the metabolism of the endogenous stores of norepinephrine in the brain. This simple and reliable procedure can therefore

be used to obtain valid estimates of the rate of norepinephrine turnover in the brain under various experimental conditions. With this technique it is possible to introduce considerable amounts of radioactivity into the brain without appreciably altering the size of the endogenous catecholamine pools (Table 1).

The present results demonstrate for the first time significant differences in norepinephrine turnover rates in specific areas of the brain. The cerebellum, containing only low concentrations of norepinephrine, has a rate of norepinephrine turnover almost twice that of the whole brain or hypothalamus. These results emphasize the importance of considering the dynamic aspects of catecholamine metabolism in the brain. Measurements of the changes in the levels of norepinephrine in the brain under various experimental conditions can only reflect gross changes in the complex disposition of this amine in the central nervous system and cannot yield precise information on the rates of formation and utilization of the catecholamine. Norepinephrine-containing neurones in various regions of the rat brain have different anatomical characteristics[4]. Our results also show variations in the rate of metabolism of norepinephrine in these neurones in different areas of the brain, which may reflect regional differences in their physiological activity.

We thank Dr. S. W. Greenhouse and Mrs. J. A. Menken for statistical analyses, and Dr. J. Axelrod for his advice and encouragement. We also thank D. C. Porter, of the Merck Institute for Therapeutic Research, for supplying L-α-methyl-*p*-tyrosine.

INHIBITION OF THE AGGREGATION OF DISSOCIATED EMBRYO-CHICK FIBROBLAST CELLS BY ADENOSINE TRIPHOSPHATE

By V. A. KNIGHT, PROF. B. M. JONES and DR. P. C. T. JONES
Department of Zoology, University College of Wales, Aberystwyth

IT has been shown that there exists in many types of cells a nucleotide triphosphatase (ATPase) which is capable of hydrolysing exogenous adenosine triphosphate (ATP)[1]. According to evidence provided by electron micrographs it also appears as if the plasma membrane is a site of ATPase activity[2].

The possibility of a contractile protein with ATPase activity existing at the cell surface was first raised in 1952 (ref. 3). The contractile protein was envisaged as being intimately linked with osmotic work. In view of the fact that contractile proteins are involved in the movement of cells, the suggestion that these proteins may be coupled with processes entailing the movement of cell surface elements was not unreasonable. However, only in 1951 was it first suggested that the mechanisms responsible for the motility of cells may resemble the contractile system of striated muscle[4]. In 1954 it was demonstrated that glycerol-extracted fibroblast cells exhibited active contraction in the presence of exogenous ATP[5]. In 1956 an actomyosin-like protein with ATPase activity was isolated from tumour cells[6], and recently a protein with the typical properties of an actomyosin-type was extracted from human platelets[7]. It has also been shown that the ATP disappearing from the platelets during viscous metamorphosis is mainly converted into ADP, which, after being secreted, induces platelet clumping[8]. Apparently the ATP which is being split is at the surface, which suggests that the actomyosin-like molecule with ATPase activity is likely to be located at the platelet surface. This possibility is supported by the report that an actomyosin-like protein has been obtained from the outer membrane of liver cells[9].

It seemed therefore suggestive to assume that a contractile protein with ATPase activity existing at the cell surface might be capable of utilizing exogenous ATP in the same way as an actomyosin-like system. Moreover, since actomyosin-like protein threads extracted from non-muscle cells are capable of contracting to 20 per cent of their original dimensions by the addition of ATP[5], there remained the possibility that contraction of an actomyosin-like protein situated at or near to the cell surface might affect its adhesive properties. On this assumption experiments were devised to test the effects of nucleotide phosphates on the adhesiveness of chick embryo fibroblast cells.

The cells were obtained from the muscle tissue of 10-day-old chick embryos. The tissues were washed in warm Hanks's solution and then treated with a 0·2 per cent trypsin (Difco 1 : 250) solution for 3–4 min at 37° C. The cells were afterwards washed and resuspended in Hanks's solution, *p*H 7·2.

The technique of reaggregation was first applied to embryonic cells in 1944 (ref. 10). When cells of a young chick or mouse embryo are chemically separated and subsequently rotated in suspension to make them collide, they will readily aggregate. In the present investigation reaggregation was quantitatively estimated by a turbidimetric method, which has previously been applied to platelets[11] and tissue cells[12]. The cell preparations were placed in siliconized 2-ml. test tubes. These were inserted in absorptiometers (*EEL* 'Quantitrator' with 'Unigalvo 20' attached), the suspensions being kept at 37° C, and stirred by a magnetically rotated rod covered with siliconized glass. An increase in aggregation within the suspension brings about a decrease in optical density. The changes in optical density were measured at 600 mμ. The density of single cells in the test preparations was adjusted to about 8 million cells/ml. by using a haemocytometer.

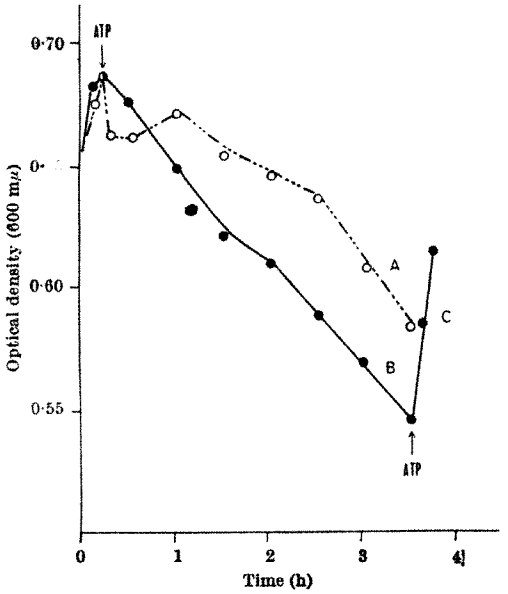

Fig. 1. Effect of exogenous ATP on the optical density of a suspension of chick-embryo fibroblast cells at 16×10^{-6} cells/ml. rotated in Hanks's solution at 37° C. The curves are related to the introduction of ATP into the medium. (*A*) 1×10^{-3} M ATP introduced after 15 min; (*B*) nil (control); (*C*) precipitous rise in control curve after the introduction of ATP at a final concentration of 1×10^{-3} M

In the control preparations the process of reaggregation was completed at the end of about 4 h. That the process is a cumulative one with the aggregates gradually increasing in size as single cells are added to them is reflected in the downward inflexion of the optical density curve of the untreated preparation in Fig. 1. It is not easy to explain the slight but significant initial increase in optical density in the first 30 min. But it may well be due to the cells recovering from the trypsin treatment and washings, and relaxing centripetally, thus reflecting more light. The fall in optical density which followed this initial rise ended when the process of aggregation came to a halt. This occurred after about 4 h under the conditions of the experiments.

When ATP was introduced into the suspension of cells in Hanks's solution by adding 0·02 ml. of ATP in Hanks's solution at 1×10^{-1} M to give a final concentration of 1×10^{-3} M, the process of reaggregation was inhibited. Fig. 1 shows that immediately after the ATP was introduced there was a slight fall and compensatory rise in optical density. The decrease in optical density which followed was significantly less than it was in the case of the control preparations. This is shown by the difference in steepness of the slopes of the optical density curves in Fig. 1. Examining and comparing samples taken from untreated and treated preparations also showed conclusively that at any given time in the first 2 h aggregation in the former was conspicuously less advanced (Fig. 2). After more than 2 h, the rate of decrease of optical density in the treated preparations compared favourably with that recorded for the controls (Fig. 1).

When ATP was added to a suspension of control cells containing newly formed aggregates, there was a release of cells from the aggregates, and a breaking up of the aggregates into smaller ones as well as a corresponding sharp rise in the optical density of the preparation (Fig. 1). This further indicates that the state of ATP-sensitive elements at or near the cell surface may be an important factor in adhesion.

Attention was next turned to plotting the extinction of exogenous ATP in the treated cell preparations against time. In the method adopted for estimating ATP, a sample of 0·25 ml. of the treated cell suspension was removed and cold perchloric acid at 0·6 M strength was added to prevent further hydrolysis. The sample was then centrifuged at 3,000 r.p.m. for 5 min and 0·2 ml. of the supernatant was added to a mixture of D-3-phosphoglyceric acid at 6×10^{-3} M and DPNH at $1{\cdot}2 \times 10^{-2}$ M in the presence of 0·1 M triethanolamine buffer.

$$3\text{-PG} + \text{ATP} \rightleftharpoons 1,3\text{-PG-P} + \text{ADP} \quad (1)$$

$$1,3\text{-PG-P} + \text{DPNH} + \text{H}^+ \rightleftharpoons \text{GAP} + \text{P} + \text{DPN}^+ \quad (2)$$

Phosphoglycerate kinase is added to mediate the first reaction, and glyceraldehyde phosphate dehydrogenase the second. DPNH is estimated by photometry at 340 mμ

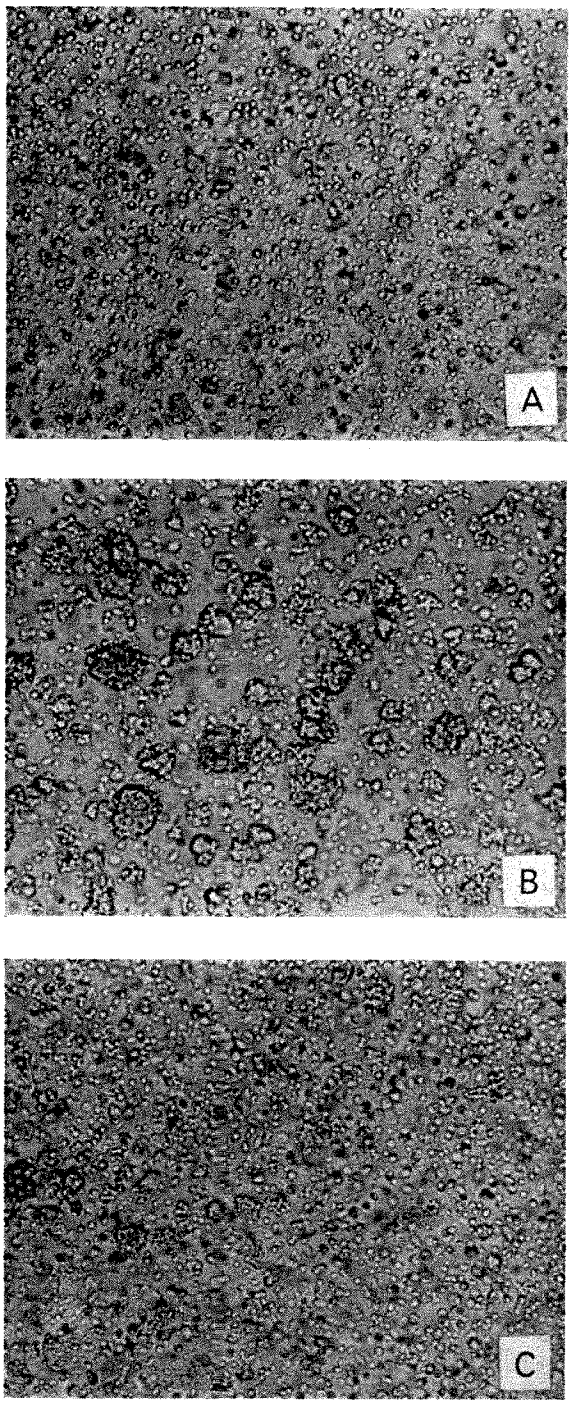

Fig. 2. Effect of exogenous ATP on the aggregation of chick-embryo fibroblast cells rotated in Hanks's solution. *A*, Cells in isolation at the beginning of the period of their rotation; *B*, aggregates of cells in Hanks's solution after being rotated for 2 h; *C*, state of aggregation of cells after 2 h in Hanks's solution which contained ATP at 1×10^{-3} M at the beginning of the 2-h period

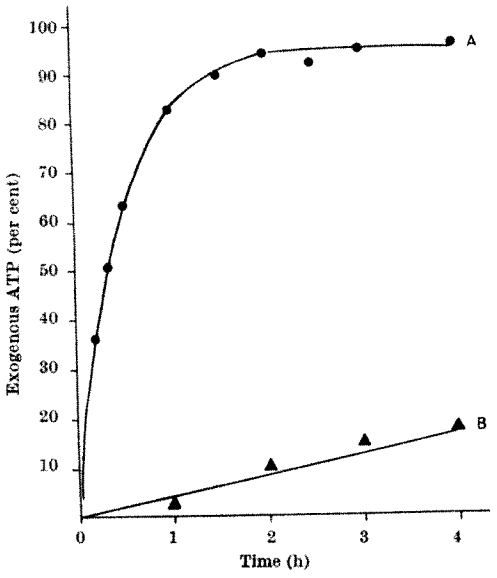

Fig. 3. Extinction of exogenous ATP at a concentration of 1×10^{-3} M in a rotated suspension of chick-embryo fibroblast cells at 16×10^{6} cells/ml. in Hanks's solution (curve *A*) and in cell-free Hanks's solution (curve B)

before and after the addition of the enzymes. The reactions proceed stoichiometrically and the difference in optical densities relative to the decrease in DPNH is proportional to the number of μmoles of ATP. Details of the method are in the ATP Test Combination obtainable from Boehringer and Sohn, Mannheim, Germany.

When ATP was introduced into Hanks's solution to give a final concentration of 1×10^{-3} M there was an estimated 15 per cent loss of ATP at the end of 3 h (Fig. 3). The extinction curve for ATP in the presence of cells at a density of 8 million cells/ml. shows that 85 per cent of the exogenous ATP had disappeared after 1 h, and 95 per cent after 2 h before reaching what appears to be a lower limiting level (Fig. 2). This relatively rapid break-down of ATP over the first 2 h coincided with the period when cell aggregation was inhibited (Figs. 1 and 2). These results strongly suggest that it was the presence of the exogenous ATP which inhibited aggregation, for by the time the ATP had reached its lower limiting level, aggregation entered a phase during which the rate was comparable with that observed in the control preparations.

Inosine triphosphate (ITP) was also shown to be capable of inhibiting aggregation, but it was slightly less effective than ATP. Adenosine diphosphate (ADP) neither enhanced nor inhibited aggregation.

It can be concluded that ATP inhibited aggregation, but it is less easy to explain the precise mechanism by which this compound produced the effect. One main reason for this is that our knowledge of the chemical organization of the cell surface is still very limited because of technical difficulties which hamper the characterization of the different components of the cell surface. An effect resulting from an interaction between a chemical substance and cells is usually explained in terms of the substance acting on the cell surface to alter its permeability allowing an influx of extracellular material which causes a disturbance of the intracellular ionic balance. Notwithstanding this kind of broad explanation, it is difficult to discard the one-sided possibility that the inhibitory effect on cell aggregation by exogenous ATP is due to ATP-splitting by an ATPase situated at the cell surface. Moreover, since ATP-splitting activity is a typical property of contractile proteins of the actomyosin-type[13] and since ATP induces contraction of this protein[5,13], the possibility of a mechanism of this kind lying directly under or at the cell surface influencing adhesion cannot obviously be dismissed.

However, the likelihood of the inhibitory effect of the exogenous ATP being due to the ATP chelating the calcium and magnesium ions has not been overlooked. But the amount of ATP introduced was certainly insufficient to chelate all the calcium and magnesium ions present. Furthermore, calcium-ATP is regarded as being ineffective as an energy source[14], which implies that in this state it is non-hydrolysable. Yet the results of the present work show that the exogenous ATP was broken down relatively rapidly in the presence of cells until it reached a lower limiting level (Fig. 3). Thereafter, the cells regained their ability to aggregate at a rate comparable with that of the 'control' cells (Fig. 1). This recovery would not have occurred if the ATP was acting as a chelating agent depriving the cells indefinitely of the calcium and magnesium ions they require for aggregation.

One of us (V. A. K.) during the course of the present work has succeeded in extracting an actomyosin-like protein with ATPase activity from embryo-chick fibroblast cells without disrupting them, and from the evidence so far it seems as if the protein in question is being removed from the peripheral region of the cell. This was achieved by immersing the cells for 3 min at 0–4° C in a 'Weber-Edsall' solution (buffered 0·6 M KCl). This is the conventional method used for extracting actomyosin-type protein[13]. The cells recovered from this treatment and remained viable. The amount of protein of the actomyosin-type removed in this way was relatively small, but it is of interest that the treated cells failed to aggregate under the conditions of the experiments described above. This suggests that it may not be too far-fetched to assume that there is a link between the actomyosin-like protein and adhesion. However, this aspect of the work is still in progress, and the results will be published in due course.

The several excellent reviews on the subject of cell contact and adhesion[15] make it abundantly clear that there is a multiplicity of factors capable of influencing both the adhesion and de-adhesion of cells. Yet, curiously enough, the search for basic cellular mechanisms capable of initiating changes in the adhesive properties of the cell surface has not so far alighted on contracting and relaxing systems involving contractile actomyosin-like proteins operating at or subjacent to the surface. It would seem, however, that the link between these proteins and cell motility[5], and their presence in many types of cells[16,17] particularly at the cell surface[9], together with the evidence from the present investigation, converge in support of our suggestion that the activity of proteins of the actomyosin-type accumulated at the cell surface may well have an important role in adhesion.

This work was aided by grants provided by the Science Research Council and the British Empire Cancer Campaign.

EFFECT OF VITAMIN A DEFICIENCY ON THE RETINA OF THE EXPERIMENTAL RABBIT

By PROF. ARNOLD SORSBY and DR. H. W. READING

Wernher Research Unit on Ophthalmological Genetics (Medical Research Council), Royal College of Surgeons of England, London

AND

J. BUNYAN

Walton Oaks Experimental Station, Tadworth, Surrey

TANSLEY[1,2] reported that severe vitamin A deficiency in the rat and in the dog produced characteristic histological damage in the rod and pigment layers of the retina. Confirmatory findings for the rat came from Johnson[3] and for the horse from Anderson and Hart[4]. No such damage was, however, observed by Mann, Pirie, Tansley and Wood[5] in a series of fifty vitamin A-deficient rabbits, although three animals showed localized changes which were interpreted as evidence of spontaneously occurring hereditary retinal degeneration such as is frequently seen in inbred rat colonies—a reading supported by the fact that two of three affected rabbits were littermates and that the same lesion was seen in another littermate which served as one of the ten controls in this experiment.

Johnson[6] and Wald[7] suggested that the structural retinal derangement described in the vitamin A-deficient rat might be responsible for the lasting or permanent effect of nightblindness which persists after the deficiency has been relieved. More recently Dowling and Wald[8,9], and in a series of communications summarized and listed in Dowling[10], have reported that, while vitamin A acid can replace vitamin A in maintaining rats in good health, such replacement is inadequate for the retina (as was originally suggested as a possibility by Moore[11]): they observed extensive degenerative changes in the rods and the pigment epithelium in vitamin A-deficient rats kept generally fit on supplements of vitamin A acid. The changes in the retina recall those seen in retinitis pigmentosa in man and in spontaneously occurring hereditary retinal degeneration in the rat. These findings are therefore of particular interest in that they may help to elucidate not only the role of vitamin A in the metabolism of the retina, but also the mechanism of retinitis pigmentosa in man—probably the commonest of the hereditary blinding affections.

These are fundamental issues. The present investigation of the significance of vitamin A aldehyde in the metabolism of the retina in the intact animal was undertaken in the rabbit partly because spontaneous retinal degeneration has not been definitely recorded in this animal and mainly because in the rabbit it is possible to watch any developing lesion by means of an ophthalmoscope.

Dutch rabbits were used throughout. Two separate experiments were carried out:

(1) In the first experiment of six young litter mates, two were used as controls—one being kept on a vitamin A-deficient diet without any supplement and the other on the deficient diet supplemented by vitamin A palmitate. The remaining four were kept on the same diet deficient in vitamin A but supplemented by vitamin A acid. Three of the four animals so treated were kept for 30 months and one for 22·5 months under the conditions to be described; the first of the two controls was destroyed at 12·5 months, and the second accidentally at 14·5 months.

(2) The second experiment began 5·5 months later; six baby rabbits from three litters were used. All the six animals, the weights of which ranged from 560 g to 640 g, were kept on a vitamin A-deficient diet until they ceased to gain weight, when their diet was supplemented by vitamin A acid. One was destroyed at 14·5 months and a second at 18·5 months, both for histological studies. The remaining four were kept for 24 months.

In both series, all animals were submitted to ocular examination, including ophthalmoscopy, at intervals, generally of 2 months. Electroretinography was carried out in six animals 4 months before they were destroyed for histological examination: three of the first batch at 26 months and three of the second batch at 20 months, with a repeat examination of one animal in each series at 30 months and 24 months, respectively.

Dietetic procedures

(*a*) *The vitamin A-deficient diet.* The composition of the vitamin A-deficient diet used is given in Table 1.

Table 1

Groundnut meal	17·5 g
Sugar-beet pulp	10 g
Oatmeal	27 g
Fine wheatfeed	13 g
Molasses	3 g
Linseed oil meal	23 g
Common salt	0·5 g
Dried brewer's yeast	4 g
Salt mixture†	2 g
D-α-tocopheryl acetate*	40 mg/rabbit/week
Vitamin D_3*	1,000 I.U./rabbit/week

* In oil by mouth until 13 months when these vitamins were incorporated in the diet (vitamin D in protected form).

† The salt mixture supplied consisted of (g/kg diet): sodium chloride, 1·1; $CaH_4(PO_4)_2{\cdot}2H_2O$, 8·7; ferric citrate, 0·8; sodium dihydrogen phosphate, 2·3; $MgSO_4{\cdot}7H_2O$, 1·7; potassium chloride, 5·4; potassium iodide, 0·02; sodium fluoride, 0·0009; $MnSO_4{\cdot}4H_2O$, 0·0044.

This diet is similar to that used by Lamming, Woollam and Millen[12]. Chemical analysis showed it to contain less than 0·07 I.U. true vitamin A/g, together with β-carotene equivalent to 0·08 I.U. provitamin A/g and a xanthophyll fraction estimated as 1·1 μg/g. From the seventeenth month of the first experiment (12·5 months of the second experiment) each batch of basal diet was tested for absence of vitamin A before being used.

(*b*) *Supplements used.* When vitamin A acid was given the dose was 15 mg/kg of diet. Vitamin A palmitate (for control rabbit *B*) was given in a dose of 2·5 mg/kg of the vitamin A-deficient diet. After 7 months, vitamin A palmitate was omitted from the diet and given to the rabbit by mouth, at the rate of 40 mg/week for 2 months followed by 0·8 mg/week until the end of the observations at 14·5 months.

(*c*) *Nutritional history*

The first series: The six litter mates—whose mother was put on a vitamin A-deficient diet 12 days after their birth—were kept on a vitamin A-deficient diet from the age of 12–25 days, and on this diet with the acid supplement for the next 10 days. Thereafter, rabbits Nos. 1–4 were continued on this supplemented diet, while control rabbit *B* had vitamin A palmitate as the supplement instead of vitamin A acid, and control rabbit *A* had the vitamin A-deficient diet without any supplement.

All the rabbits grew well except control rabbit *A* which showed a decline in weight and necessitated giving it

vitamin A acid supplement at the age of 4·5 months. It finally developed a flaccid paralysis 8 months later and was destroyed.

The second series: The six rabbits were all maintained on a vitamin A-deficient diet for a preliminary depletion period of up to 5·5 months of age before giving them the vitamin A acid supplement. They had all reached a weight plateau at this time and they showed weight gain on receiving the supplement.

Change of diet after the onset of the retinal lesion. Five and a half months before the end of the experiment in both series, when the retinal lesion was fully established, rabbits Nos. 1, 4, 7, 8 and 9 were given modified diets to determine whether the lesion could be reversed. Rabbit No. 1 was given a normal diet (diet *S.G.*1 (Rank)) and the remaining rabbits (Nos. 4, 7, 8 and 9) were given the vitamin A-deficient diet and an oral dose of 6 mg vitamin A palmitate/rabbit/week. These modifications were continued until the end of the experiment (at 30 months in the first series and at 24 months in the second).

Accidental administration of vitamin A palmitate. On one occasion, at 13 months and 7·5 months in the two series respectively, all survivors receiving vitamin A acid supplement were accidentally given 0·6 mg vitamin A (instead of an intended dose of vitamin D). These animals were later put back on a vitamin A-deficient diet without any supplement for 5 weeks and then returned to their diet containing vitamin A acid supplement.

(*d*) *Estimation of vitamin A and vitamin A aldehyde.* At the end of the experiment estimation of the concentration of vitamin A and vitamin A aldehyde was carried out for several tissues. The procedures used were:

Vitamin A. This was estimated in liver and brain by the method of Ames, Risley and Harris[13]. Very concentrated extracts of tissues believed to be deficient in vitamin A were prepared and tested, giving a lower limit of sensitivity of about 2–3 I.U./g tissue (that is, about 1 μg/g).

Vitamin A aldehyde. This was measured by the thiobarbituric acid method of Futterman and Saslaw[14]. The eyes were preserved at −10° overnight, allowed to thaw, and then dark-adapted. Each eye was dissected under a dim red light, and the cornea, lens and vitreous were removed. The remainder of the eye was extracted with alcohol in an M.S.E. top-drive steel-bladed homogenizer, using the 10-ml.-sized goblet. The amounts of retinene in a single rabbit retina proved too small to be detected by this procedure. (At the time these estimations were carried out, it was not realized that storage of the eyes *post mortem* destroyed the vitamin A aldehyde content and the capacity for its regeneration. Subsequent estimations have shown that it is necessary to carry out the estimations as soon as possible after enucleation.)

RESULTS

The salient ocular findings and the conditions under which they were observed have been set out in Table 2. Rabbit *A*, kept on a vitamin A-deficient diet without any supplement, was in a poor state by 4·5 months and had to be put on vitamin A acid supplement for the rest of the experiment. It had developed typical xerosis of the conjunctiva and cornea at 7·5 months and at 9·5 months it showed white dots at the fundus similar to the lesions observed at the same time in rabbits Nos. 2 and 4 which were thriving on the same deficient diet supplemented by vitamin A acid from the beginning. The same fundus lesion was observed 6 weeks later in the two remaining treated animals of the first experiment (Nos. 1 and 3), but at no time during the 14·5 months' observation was a fundus lesion seen in control rabbit *B*, which received the vitamin A-deficient diet supplemented by vitamin A palmitate. The five rabbits on a vitamin A-deficient diet supplemented by vitamin A acid therefore all showed a fundus lesion at about 10 months.

It will also be seen from Table 2 that all six rabbits in the second experiment—all kept on a vitamin A-deficient diet supplemented by vitamin A acid—developed fundus lesions, first clearly seen at 13·5 months.

The fundus lesions were not the only ocular changes. As can be seen from Table 2, xerosis of the cornea was present in one of the four treated animals in the first series (in addition to the expected corneal lesions seen in the control animal *A*) and in four of the six animals in the second series. It is possible that this complication (which interfered with opthalmoscopic examination) was partly

Table 2. (i) OBSERVATIONS ON SIX LITTER MATES BORN ON OCTOBER 19, 1961

No. of animal	Diet	Period of observation (months)	Xerosis of cornea at (months)	Fundus lesion first observed at (months)	Severity of lesion towards the end of the second year	Modification of diet for the last 5·5 months (after lesion fully established)	Effect on lesion
A	Vitamin A deficient	12·5	7·5	9·5	(General condition very poor at 4·5 months; given vitamin A acid from then on; destroyed at 12·5 months because of flaccid paralysis)		
B	Vitamin A deficient + vitamin A palmitate	14·5	—	—			
1	Vitamin A deficient + vitamin A acid	30	—	11	+ +	Normal diet	No regression

In this experiment the vitamin A acid supplement was only given after 5·5 months when the animals ceased to gain weight on the vitamin A-deficient diet.

responsible for the delay in establishing the presence of fundus lesions in the second series.

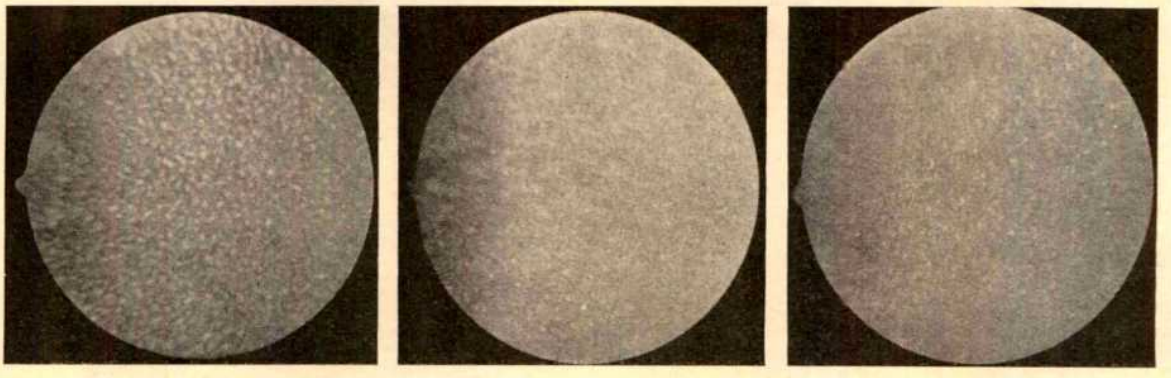
The Fundus Lesion

(i) *Ophthalmoscopic appearances.* The fundus lesion in all these animals was highly characteristic. The first changes were inconclusive and consisted of an indefinite breaking up of the reddish background, suggestive of a geographical map. Within some 6–8 weeks these changes had become more defined by the appearance of white dots in the lower half of the fundus, beginning at about 1 disk distance below the disk, and extending downwards. These white dots first appeared at the periphery, the central area below the disk becoming affected last. That the lesion was definitely pathological, and not a physiological variant of the rather wide range of the normal appearances of the rabbit fundus, was not beyond question until about 9 months from the beginning of the observations.

Once the white dots appeared in the fundus they progressed steadily and sometimes rapidly, so that the indicated in Table 2, two of the four treated animals in severity of the lesions varied in the different animals. As the first series were regarded as severe (Nos. 3 and 4), the remaining two being moderately affected. Likewise, only two of the second series (Nos. 5 and 6) were severe; the rest, except for No. 7 which showed a mild lesion, were moderately affected. The range of ophthalmoscopic appearances is shown by Figs. 1*a*, *b* and *c*.

The fundus lesion proved irreversible. Three of the rabbits in the first series had survived at 24 months, and four of the second series at 18 months. Four of these seven animals were given intensive vitamin A therapy (6 mg vitamin A palmitate/week) and one was kept on a normal rabbit diet; none of these five animals showed any regression of their lesion during the 6 months of observation.

(ii) *Electroretinography.* Rabbits Nos. 1, 3 and 4 had electroretinographic examination at 26 months, and rabbit No. 1 a repeated test at 30 months. Rabbits Nos. 6, 8 and 9 had such an examination at 20 months with a repeat test for rabbit No. 6 at 24 months. These tests showed a consistent pattern. In all animals the *b* wave was most affected, being small or absent; the amplitude was not influenced by dark adaptation. Lesser and indefinite anomalies were seen in the *c* wave. The photoptic components of the electroretinogram were normal. In contrast to the normal rabbit, which shows a predominantly rod type of electroretinogram, these rabbits showed a cone type of tracing.



(iii) *Histological appearances.* All animals were destroyed by the injection of air into the vein of the ear except control rabbit *B* and rabbit No. 5, both of which died from an overdose of anaesthesia, the first while having an abscess of the upper jaw treated, and the second while undergoing an electroretinographic test. In all animals the eyes were excised immediately after death and those destined for histological study were fixed in acid Zenker solution. Paraffin sections were stained with haemalum and eosin. Both eyes were used for histology in rabbits Nos. 2, 5 and 10 and in the control rabbits; in the animals destroyed at the end of the experiment (Nos. 1, 3, 4, 6, 7, 8 and 9) one eye was kept for biochemical tests. Of the eleven animals kept on a vitamin A-deficient diet supplemented by vitamin A acid (ten from the beginning and one after 4·5 months) sections for histological study were obtained in only nine.

Pathological changes were recognized in all the sections. They were most prominent in the area centralis, but extended into the mid-peripheral area as well. Debris appeared between the outer rod segments and the pigmented epithelium. It consisted partly of foamy, lightly eosinophilic material coating the pigmented epithelium and of local aggregations of circular masses staining much more deeply with eosin (Fig. 2*a*). In addition, a few large macrophage-like cells were observed (Fig. 2*b*). Occasionally, these contained pigment granules or small masses of material resembling the eosinophilic debris. The pigmented epithelium itself in the area centralis had a ragged appearance and there was patchy loss of pigment. In places the macrophage-like cells were seen adhering to normal-looking pigmented epithelial cells. Elsewhere the latter appeared in process of rounding up as though they were transforming into macrophage-like cells (Fig. 2*c*).

Changes in the retina proper were slight. Local thinning of the outer nuclear layer was seen, often in association with aggregates of debris. The visual cells which remained appeared largely intact, though some of the deeply staining eosinophilic debris may have been derived from degenerated rod outer segments.

Biochemical Control

The following observations were made as to the vitamin A concentration in the liver: (1) Control rabbit *A* on a vitamin A-deficient diet, destroyed at 12·5 months. The liver contained no vitamin A. (2) Control rabbit *B*, on the same diet supplemented by vitamin A palmitate, accidentally killed at 14·5 months. The liver showed 70 mg of vitamin A. (3) Treated rabbits on vitamin A-deficient diet and vitamin A acid supplement. No. 10 destroyed at 14·5 months, No. 6 destroyed at 24 months, and No. 3 destroyed at 30 months. The liver contained no vitamin A. (4) Treated rabbits on vitamin A-deficient diet supplemented by vitamin A acid, and given a normal diet (No. 1) or vitamin A palmitate supplement subsequent to the development of the retinal lesion (rabbits Nos. 4, 7, 8 and 9). Vitamin A was present in the liver in the

The coating of foamy debris can also be seen. (Haemalum and eosin × 600)

following quantities: 5 mg, 25 mg, 27 mg, 32 mg and 41 mg, respectively.

In addition, the brains of rabbits Nos. 3, 4, 6, 7, 8 and 9 were examined for vitamin A with negative results. The retinae of these animals were tested for vitamin A aldehyde also with negative result by the method used.

DISCUSSION

(1) *Vitamin A aldehyde in the visual purple cycle.* In the mammal, visual pigment consists of a molecular compound between retinene (vitamin A aldehyde) and the protein opsin. Vitamin A alcohol, the precursor of retinene, is oxidized in the eye to its aldehyde (retinene) under the action of an enzyme, alcohol dehydrogenase—the same enzyme system being responsible for the reduction of retinene to vitamin A following the bleaching action of light. A further degree of biological specificity is found in the visual cycle in that a particular geometrical configuration of retinene is obligatory for the synthesis of visual pigment. Vitamin A and retinene exist in a variety of *cis-trans* isomeric forms, and, in the visual pigment, retinene is in the 11-*cis* configuration. Isomerization of vitamin A and/or retinene occurs in the eye under the action of a specific enzyme, retinene isomerase[15]. The primary action of light on the visual pigment is to convert the 11-*cis* retinene into its all-*trans* isomer, and then to break apart the molecular bond between retinene and the protein opsin. A cyclic series of reactions involving synthesis and bleaching of visual pigment is therefore continuously occurring in the retina under the influence of light stimulation and dark adaptation.

In this mechanism vitamin A acid has no place. It is itself the oxidation product of retinene and so far, within the body, no system has been demonstrated which is capable of reversing the process.

(2) *The histological findings in the present investigation.* The following observations are relevant: (i) It is highly probable that the white dots seen with the ophthalmoscope are aggregates of eosinophilic debris. (ii) The macrophage-like cells might be modified pigmented epithelial cells. They also resemble the 'interstitial cells' described in normal mouse retina[15a]. (iii) The aggregates of eosinophilic debris recall the bundles of extracellular lamellae described by Dowling and Sidman[16] in rats with inherited retinal dystrophy. (iv) The pathological changes differ from those seen in known retinopathies induced by various chemical agents. (v) These changes also differ from those described by Dowling and Wald[17] in vitamin A deficiency in the rat in which changes appear first in the rod outer segment, there is fairly rapid diminution in the number of visual cells, and the pigmented epithelium remains normal.

(3) *The fundus lesion observed in the present investigation as the counterpart of retinitis albi punctatus.* The outstanding feature of the observations in the present investigation on vitamin A aldehyde deficiency in the rabbit is the lack of any substantial effect on the rods. The striking fundus lesion seen ophthalmoscopically has a surprisingly slight histological basis: only the pigment epithelium shows any substantial changes, and even these are relatively mild. The electroretinographic tracings are consistent with disturbed dark adaptation and, though they do not exclude damage to the rod system, they do not support such an assumption either.

The lesion in the rabbit is in fact reminiscent of the features seen in vitamin A deficiency in man and in retinitis albi punctatus. In both these affections, night-blindness is an outstanding feature, and in both white dots on the fundus are the characteristic ophthalmoscopic appearances.

The white dots which can be seen using the ophthalmoscope in vitamin A deficiency are not a feature widely known. It is not seen by ophthalmologists practising in affluent countries, but in the Far East, with its massive nutritional problems, it seems to be well recognized since it was first described by Uyemura in 1928 (ref. 18) (Fig. 3). (The literature is reviewed by McLaren[19].) It is likely that in man the associated—and possibly earlier—corneal

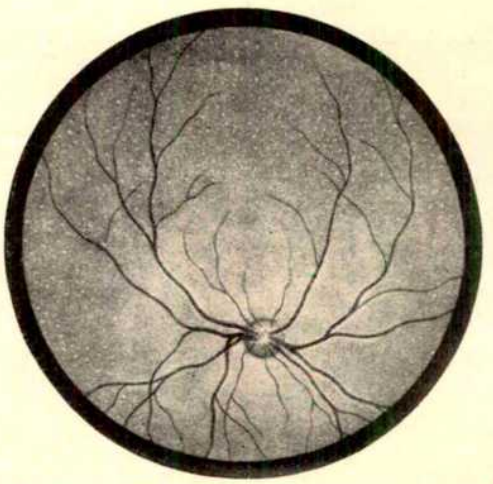

Fig. 3. Fundus appearances in vitamin A deficiency. (After Uyemura (ref. 18))

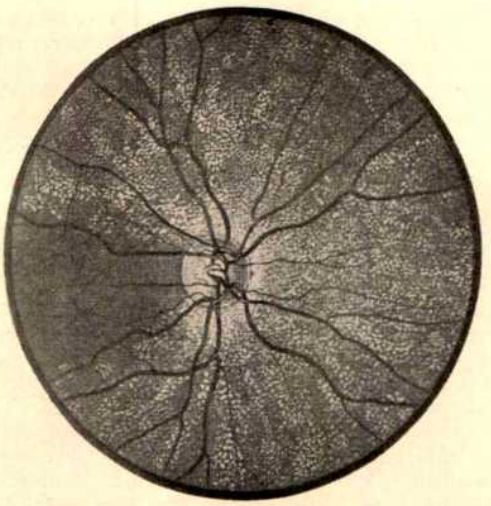

Fig. 4. Fundus albi punctatus. (After François (ref. 21))

xerosis makes the recognition of this fundus lesion difficult in many cases, and it is perhaps significant that, in such of the rabbits as developed corneal xerosis in the present experiment, the corneal lesion preceded a recognizable fundus lesion.

Retinitis albi punctatus has the same ophthalmoscopically visible white dots (Fig. 4) and nightblindness. It is a well-established, though rare, genetic affection, described by Lauber in 1910 (ref. 20), and shows a recessive mode of inheritance. Its clinical importance lies in the fact that, unlike retinitis pigmentosa, it is a stationary affection. It is apparently congenital; it does not lead to pigmentary disturbances, shrinking fields of vision and ultimately total or sub-total blindness. Its mild course excludes any possible involvement of the rods, and the nightblindness and the white dots are presumably the result of an anomaly in the pigment layer—as they appear to be in the rabbit. Though histological evidence is lacking in retinitis albi punctatus, and inconclusive in vitamin A deficiency in man, it is not unreasonable to assume that the experimental lesion in the rabbit is a closely allied disturbance—possibly their counterpart.

These findings in the rabbit fully substantiate those of Wald and Dowling in the rat as to the adequacy of vitamin A acid for the body as a whole, and the dependence of the pigment epithelium (and the visual pigment) on vitamin A aldehyde. They differ, however, in limiting the dependence to this tissue and this cycle: the integrity of the rods is apparently not dependent on vitamin A aldehyde. In the rabbit, in any event, the deprivation of vitamin A aldehyde does not give a picture similar to retinitis pigmentosa, but a considerably less serious disturbance, and it is possible that the pigment epithelium is the major and perhaps the exclusive site of conversion of vitamin A into the specific chromophore for the visual pigment.

Further investigations on both the rat and the rabbit are needed to assess this discrepancy in the findings and its bearing on the fundamental problem whether vitamin A deficiency is an aspect of retinitis pigmentosa with its affection of the rods.

We thank the directors of Vitamins, Ltd., for providing facilities for the animal experiments at their Walton Oaks Experimental Station, and Messrs. Roche Products, Ltd., and their medical adviser, Dr. A. L. Morrison, for generous supplies of vitamin A acid. Dr. Hisako Ikeda of the Institute of Ophthalmology and Mr. A. I. Friedmann of the Royal College of Surgeons and the Royal Eye Hospital carried out and interpreted the electroretinographic tests, while Dr. David Lucas of the Radiobiological Research Unit, Harwell, was responsible for part of the histological study of the retinae. We also thank Miss E. G. Nairne, Miss E. J. Castle and Mr. R. Harding for technical help.

CELL WALL SURFACE OF THE HIGHER PLANTS

By PROF. FLORA MURRAY SCOTT
Department of Botany and Plant Biochemistry, University of California, Los Angeles

RECENT work with the electron microscope considerably clarifies earlier observations on the surface of the cell wall in shoot and in root. The present article deals with the surface of the cell wall in the growing regions of the higher plant: (1) external surface of the outer epidermal wall; (2) lining of intercellular space system; (3) intracellular lining.

The External Surface

Shoot-cutin. The outer wall of epidermal cells in the shoot is covered with a cuticle which appears at an early stage of development in the seed. In certain species an additional coating of wax is more or less conspicuous, while, in others, mineral substances such as silica or calcium carbonate may encrust or partially impregnate the cell wall.

The precursors of cutin and other surface substances elaborated within the living protoplast pass to the surface along plasmodesmata through pits in the outer epidermal wall. A pit is defined here, as in previous publications, as a collection of pores in the structural cellulose wall. In the epidermal wall of the rind of the fruit of *Citrus*, and also in the *Citrus* leaf, pits are visible under the light microscope[1,2]. Ultrasonic fragmentation is an excellent method for tearing or peeling the cuticle of any tissue. In the leaf of *Bergenia* the larger pits are demonstrable under the light microscope when stained with ruthenium red and Sudan 3. In the same material and in the onion under the electron microscope minute pits and innumerable pores are clearly defined[3]. They resemble in structure the pits ubiquitous in the internal cell walls[4]. Plasmodesmata are still present in the pits and in the pores unless

they have been removed by ultrasonic treatment. In texture the isolated cuticle resembles a very fine artificial rubber sponge.

The plasmodesmata appear to be anchored in the cuticle of the outer wall of all epidermal cells. The sensitive contractility of slender protoplasmic strands is familiar to all observers of living cells. The disturbance inevitable during the preparation of material for examination may cause the retraction of the plasmodesmata into the cellulose layer of the wall. At the same time the elastic cuticle, stretched by the turgor of the cell, shrinks instantly and no visible plasmodesmatal cuticular pores remain. However, the thinner areas which are obvious in cuticular electron micrographs may mark the former location of the plasmodesmatal endings.

Shoot-wax. The characteristic 'bloom' on leaves such as *Eucalyptus*, onion and cabbage, and on fruits such as grapes, is due to the presence of wax. About 100 years ago De Bary described and illustrated various types of wax rodlets and postulated the presence of wax canals[5]. Under the light microscope, wax canals are visible in the epidermis of the orange rind, in the onion leaf and in the seed of *Cercidium*[6]. The close distribution of rodlets in the onion leaf is evident under the electron microscope[3]. In the leaf of beet, rodlets are present in the youngest leaves and eventually fuse into rugose plaques[7].

Root. The epidermis of the root, like that of the shoot, is covered with a cuticle which is defined at an early stage of embryonic development. In fresh material of soil-grown seedlings, and in the feeder roots of older plants, a cuticle covers the entire surface of the growing primary region of the root including the root hairs. All roots are also coated with a more or less conspicuous layer of mucilage[8].

In the roots of certain azaleas, mucilage occurs as a conspicuous sheath[9]. In the smoke tree, a desert xerophyte, the mucilage of the extremely long tap root of the one-year seedlings dries out during the rainless season, except occasionally for a sheath near the tip when the surrounding soil still retains some trace of hygroscopic moisture[10].

Pits occur in the outer epidermal wall of all soil-grown roots examined. The larger pits are visible under the light microscope and the smaller may be faintly indicated in the root hairs of certain gymnosperms. Under the electron-microscope the smaller pits and pores are clearly defined[11,12].

Lining of the Intercellular Space

Apical meristems. The ideal shape of isodiametric cells is tetrakaidekahedral[13], but this ideal changes constantly during cell division and growth The polyhedral cells are closely packed and interconnected by plasmodesmata through pits which are ubiquitous on all cell faces. As the cells expand and divide, the cell corners round off and minute intercellular spaces arise within about 20μ, or two cells distant from the apical surface of stem or root[14]. The breaking of the plasmodesmata is virtually a wounding of the living protoplast. The intercellular system, the respiratory system of Haberlandt[15], develops in general as an air-filled continuum as seen in fresh material and also clearly defined in the meticulous slides of Schuepp[16]. The wall surface of the intercellular continuum is lined with a non-cellulosic lipid layer, tenuous in younger tissue but clearly defined during later growth. In microchemical reactions it resembles cutin and suberin, but, as its chemical composition is not yet known, it is termed a 'lipid' layer.

Leaf. The cells of the leaf primordia, like those of the apical meristems, are polyhedral and closely packed. In the mature leaf the volume of intercellular space and the internal surface vary with the species[17]. In the spongy mesophyll the cells are lobed or branched. The larger cells in the middle of the leaf areole as a rule remain in contact with eight surrounding cells, while the smaller, nearer to the veinlets, are in plasmodesmatal contact with six others. The ellipsoidal palisade cells also vary in size, in diameter and length. In general, the larger are in contact laterally with about eight cells, the smaller with six. The entire surface of the intercellular space is lipid lined. In the region of abscission 'internal suberization' is conspicuous and the walls of the abscizing leaves are impregnated with suberin, and resistant to the action of 80 per cent sulphuric acid[18].

Endodermis and stele. Intercellular space occurs in cortical and also in stelar parenchyma as seen clearly in *Ricinus* and other species. Suberin deposition on the Casparian strip of the endodermis begins at the outer and inner edges of the radial wall which are nearest to the cortical and stelar intercellular spaces. Pits occur on all faces of the endodermal cells. As seen under the electron microscope, some become occluded by microfibrils during later growth[12].

In *Ricinus* in fresh material, clearly defined intercellular spaces around the spiral vessels are visible under the light microscope. These spaces, like all others, are lined with lipid. Structural details are visible under the electron microscope[19].

Flower. The presence of intercellular space in all parts of the flower including the petals is well known. In flowers which last for a few hours, or at most a day, such as the primulas, the intercellular lining is tenuous as in the meristematic region. In contrast, in long-lasting flowers, such as orchids and camellias, the lipid lining resembles in thickness that of a xerophytic leaf[20].

Fruit. The lining of intercellular space is notable during the development of the outer integument of the seed of *Cercidium*[6]. In the same seed the inner integument differs from other tissues examined. At no time during development is air observed in the extensive intercellular space which surrounds the long-armed parenchymatous cells. This space is filled continuously with amorphous mucilage. Nevertheless, in this mucilaginous mass, a lipid layer appears about 1–2μ from the cellulosic parenchymatous walls. This layer is visible under light and electron microscopes and is similar in microchemical reactions to cutin and suberin. It is suggested that the differentiation of this layer may indicate the existence of an oxygen gradient in the mucilaginous mass. The mucilage elaborated within the protoplast is extruded through pits which are present in the arms and body of the integumentary cells.

Intracellular Lining of Xylem Vessels

The protoplasts of the spiral vessels of *Ricinus* are interconnected through pits by plasmodesmata with contiguous vessels and with surrounding xylem parenchyma cells. The pits are visible under light and electron microscopes[19]. In the differentiating vessels a lipid-like lining is seen in living cells under the light microscope. After the death of the protoplast the empty vessels are lined with a suberin-like layer, which, as seen under the electron microscope, resembles in texture the isolated external cuticle and the intercellular lipid lining.

Discussion

Fatty substances, lipids, essential components of protoplasm, furnish the precursors of cell wall surface materials. In all living cells examined the chloroplasts are surrounded by coronae of lipid droplets visible under light and phase microscopes and which can be immediately stained with sudan black. The same is true of leucoplasts and elaioplasts. It is probable that these droplets are concerned in the formation of surface material precursors[21].

In a recent review, Napp-Zinn[22] pointed out that pits in the outer epidermal wall of higher plants were described in *Elymus arenaria* and in *Cycas revoluta* by Hugo Von Mohl in 1842. In the following hundred years they were

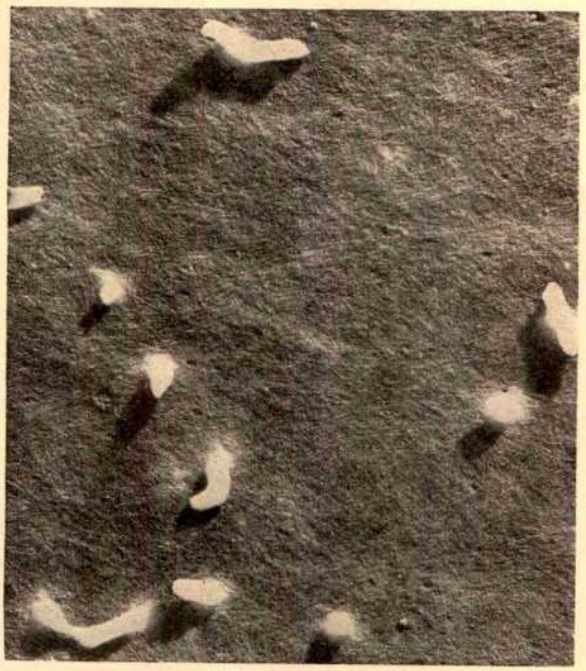

Fig. 1. Rhizoplane of mustard (*Brassica nigra*) root from garden soil; electron micrograph (*c.* × 19,200). Part of outer epidermal wall of non-piliferous cell showing microfibrillar network with clearly defined pits and bacteria *in situ*. The thin coating of mucilage has been removed during ultrasonic treatment. Bacteria may be attached in or near pits (ref. 12)

reported by many other observers, but were apparently ignored in text-books. To-day, as seen under the electron microscope, epidermal pits are similar in structure to those of internal cell walls.

The nature of the strands in epidermal pits, plasmodesmata or ectodesmata, is at present a topic of lively discussion[23]. Whatever the result of the present-day controversy, the strands presumably furnish the principal path for the transport of the precursors of surface materials, cutin and wax in the shoot and cutin and mucilage in the growing root.

Haberlandt noted that the wounding of living tissues in air stimulates the formation of traumatic acid and the deposition of a film of suberin on the wounded surface[15]. Priestley demonstrated experimentally that suberin deposition depends on the presence of oxygen[24]. The breaking of plasmodesmatal strands during the formation of intercellular space is virtually a wounding of the protoplast. The deposition of the lipid lining of intercellular space already evident in the meristem may, therefore, be considered a wound reaction.

The deposition of a lipid layer in the inner integument of the seed of *Cercidium* has been noted. It is suggested that this deposition may depend on the presence of an oxygen gradient in the mucilaginous mass. An investigation of other mucilaginous tissues in which at no time during development is air observed in intercellular space should prove interesting.

Thus, in conclusion, in all plants which have been examined, pits are present in the epidermis of all shoots and roots, including the root hairs. Retraction of plasmodesmata into the cellulosic layer of the cell wall probably results from the shock inevitable during the preparation of material for examination. In the isolated shrunken elastic cuticle, cuticular pores do not remain visible but their previous location may be indicated by the ubiquitous thinner areas evident in electron micrographs. Formation of intercellular space entails the breaking of the plasmodesmata and is therefore a wounding of the protoplast. Lipid deposition on the surface of intercellular space is the first visible reaction to wounding. Deposition of lipid in the mucilaginous mass in the inner integument of *Cercidium* may depend on the presence of an oxygen gradient.

The occurrence of pits in the outer wall of the growing root may indicate the preferred points of entrance for bacterial plant pathogens as seen in the electron micrograph (Fig. 1).

INSULIN-LIKE EFFECTS OF ADENOSINE-3′,5′-MONOPHOSPHATE ON RAT STRIATED MUSCLE

By DR. P. M. EDELMAN, DR. J. C. EDELMAN and PROF. I. L. SCHWARTZ

Departments of Physiology and Medicine, University of Cincinnati College of Medicine, Cincinnati, Ohio; The Medical Research Center, Brookhaven National Laboratory, Upton, Long Island, New York; and The Mount Sinai Medical and Graduate Schools, New York

RECENT investigations[1–5] suggest that adenosine-3′,5′-monophosphate (cyclic AMP) acts as a cellular mediator involved in the tissue response to a number of hormones, including catecholamines, glucagon, adrenocorticotrophic hormone and vasopressin. It is clear that cyclic AMP may produce alterations in the activity of intracellular enzyme systems[1,6,7], but the steps correlating intracellular accumulation of the nucleotide with the cellular response to the hormone are not known.

This article describes two insulin-like effects of cyclic AMP on striated muscle: increased glucose uptake and decreased extracellular space. These effects are discussed in terms of ultrastructural alterations recently observed to occur under various physiological conditions.

Glucose-uptake experiments. Diaphragms from 230–250-g female Sprague–Dawley rats were rapidly removed and dissected in halves. One member of the pair of hemidiaphragms served as control for the other. The hemi-

diaphragms were placed in 20-ml. conical flasks containing 1 ml. of freshly gassed (oxygen–carbon dioxide, 95 per cent : 5 per cent) bicarbonate-buffered media[8] containing glucose 2·5 mg/ml., 1 unit insulin/ml., 10^{-3} M cyclic AMP (final concentration), 10^{-3} M 5′ AMP, or an equal volume of buffered media (volume of addition, < 10 per cent of initial volume); the flasks gassed again, stoppered, and shaken in a water bath (T = 37° C, 144 c/m). After 1 h the tissues were removed, blotted and weighed. Glucose determinations on the incubation bath before and after incubation were obtained by the glucose oxidase method[9].

Extracellular space determinations. Rat femoral musculature (intact limbs with skin and surface connective tissue removed; approximate weight, 10 g) was placed in 14 ml. of gassed incubation media (*vide supra*) containing 1 μc./ml. carboxyl-^{14}C-inulin (New England Nuclear Corporation: specific activity = 3·57 μc./mg). The limbs were gassed and shaken continuously for 1 h at 37° C in media containing 1·5 mg/ml. of glucose but otherwise identical with that used in the glucose-uptake experiments. Cyclic AMP was added to the bath containing one of the limbs to a final concentration of either 10^{-3} M or 2×10^{-3} M. The bath containing the paired limb received a volume of buffered media equal to that of the cyclic AMP solution but was otherwise untreated and therefore served as a control. Following incubation, the tissues were dipped three times in three 14-ml. solutions of incubating media free of labelled inulin, dissected free of fat, connective tissue and bone, and then the muscle was thoroughly minced. The mince was weighed and made to a 10 per cent (w/v) mixture with 0·25 M sucrose and homogenized in glass tubes with loose- and then tight-fitting pestles. Portions (0·01–0·05 ml.) of bath or tissue homogenate were placed in glass scintillation vials containing 14 ml. of scintillation fluid and counted (efficiency approximately 80 per cent) in a liquid scintillation counter. (The scintillation fluid consisted of: 8·25 g 2,5-diphenyloxazole, 0·103 g 1,4-*bis*-2-(5-phenyloxazolyl)-benzene, 113 g naphthalene, 320 ml. toluene, 40 g 'Cab-O-Sil', all made to one litre with 'spectroquality' *p*-dioxane. The chemicals listed were purchased from the Packard Instrument Co., La Grange, Illinois, with the exception of the *p*-dioxane which was purchased from the Matheson, Coleman and Bell Co., Cincinnati, Ohio.) The extracellular volume was calculated as the ratio of the inulin concentration in the homogenate to the final concentration of inulin in the bath.

Rat hemidiaphragms exposed to 10^{-3} M or 2×10^{-3} M cyclic AMP *in vitro* take up significantly ($P < 0{\cdot}001$) more glucose from a glucose-containing medium (initial concentration 250 mg per cent) than do paired untreated (control) hemidiaphragms. On the other hand, adenosine-5′-monophosphate (5′-AMP) does not appear to increase significantly ($P = 0{\cdot}3$) the uptake of glucose by the rat hemidiaphragm. Similar experiments conducted with insulin (medium concentration 1 U./ml.) show that the glucose uptake of the insulin-treated hemidiaphragms is significantly ($P = 0{\cdot}05$) greater than the glucose uptake of the cyclic AMP-treated hemidiaphragms (Table 1, Figs. 1 and 2). Although further increase in the concentration of cyclic AMP in the experimental medium failed to increase glucose uptake, the possibility remains that the quantitative difference between the effect of insulin and that of cyclic AMP may be due in part to the relatively low permeability of tissues to cyclic AMP (refs. 1 and 10).

Table 1. EFFECT OF INSULIN AND CYCLIC AMP ON GLUCOSE UPTAKE IN RAT DIAPHRAGM: GLUCOSE UPTAKE IN MG/G/H ± STANDARD ERROR

Control	Insulin	C-AMP	5′-AMP
3·40 ± 0·1 (22)*	5·20 ± 0·33 (9) Insulin versus control $P < 0{\cdot}001$	4·51 ± 0·15 (9) C-AMP versus control $P < 0{\cdot}001$	3·82 ± 0·22 (4) 5′-AMP versus control $P = 0{\cdot}3$
		Insulin versus C-AMP $P = 0{\cdot}05$	

* Numbers in parentheses represent the number of hemidiaphragms tested.

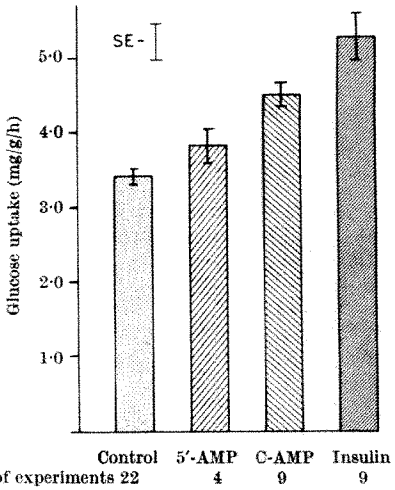

Fig. 1

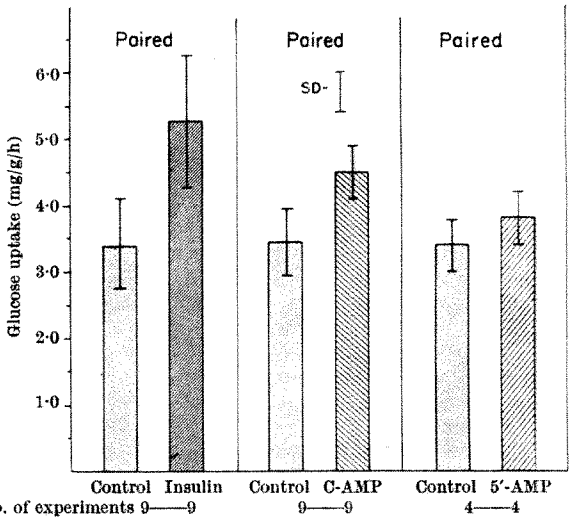

Fig. 2

The inulin space of rat femoral muscles treated with cyclic AMP was less than that of paired control femoral muscles (Table 2). The wide variation in the diminution of the extracellular space observed with cyclic AMP may be due in part to differences in the ratio of surface to volume of muscle mass which would affect the extent of penetration of cyclic AMP into the muscle. Creese and Northover[11], Fritz and Knobil[12], and Randle and Smith[13] have shown previously that insulin decreases the inulin space in the rat diaphragm and that this effect may be correlated with other parameters of insulin action.

Cellular ultrastructural components thought to be involved in extra-to-intracellular translocation of substances have recently been under intensive study. Electron microscopic investigations of striated muscle reveal the transverse tubule (central element of the triad) as an invagination of the sarcolemma[14,15]; the lumen of this tubule, therefore, is continuous with the extracellular space[16,17]. There is evidence that the transverse tubule of the triad functions as a direct channel for the internal passage of electrolytes, metabolites and depolarizing currents[18–20]. This transverse tubular system, which appears to be similar to the 'special region' of Hodgkin

and Horowitz[22] and the 'intermediary space' of Adrian and Freygang[23], possesses the faculty of altering its capacity by dilation[24–26].

It has been shown that the transverse tubules swell when the muscle cell membrane is hyperpolarized by chloride ion withdrawal procedures or by electrical stimulation[24–26]. If swelling of the transverse tubules is thus generally associated with hyperpolarization, the demonstration by Zierler[27,28] that insulin hyperpolarizes the muscle cell membrane raises the possibility that the action of insulin on cell membrane transport involves not only the sarcolemma but also its extensions into the triadic system (transverse tubules and terminal cysternae of the sarcoplasmic reticulum). This speculation is an extension of that raised by Krahl[29], who suggested that insulin may act on the cytoskeleton of Peters[30], and by Hechter[31], who suggested that both insulin and ACTH may act on the endoplasmic reticulum of their target cells.

The finding that both cyclic AMP and insulin diminish the inulin space of muscle without changing the total water content of the tissue would be expected if the triadic system and the muscle cell were swelling at the expense of the extracellular space. The evidence for almost exclusive localization of labelled insulin at the sarcolemmae and in the soluble fraction of the muscle cell[32,33] is in accord with the idea that the hormone may be acting on the transverse tubular invaginations of the sarcolemmae.

In considering the possibility that the insulin-induced glucose transport in muscle involves the mediation of cyclic AMP it must be emphasized that, before cyclic AMP can be established as a mediator of insulin action, effects on other known parameters of insulin action must be tested, the relationship of epinephrine and cyclic AMP in muscle must be clarified, and direct tissue analyses for cyclic AMP must be carried out.

In summary, cyclic AMP has been found to increase the glucose uptake of the rat diaphragm and decrease the extracellular space of striated muscle, but its effects on other parameters of insulin action have not yet been investigated. The possibility has been raised that insulin may attach and act on the transverse tubular extensions of the sarcolemmal membrane, swelling the transverse tubular system and cell and diminishing the interstitial space—effects which would stretch the sarcolemma and expand pathways by which water, glucose and amino-acids could enter the cell. A hormonally sensitive, possibly contractile, system of this type involving the membrane systems of the cell as a whole could also account at least in part for the known effects of insulin on protein synthesis by facilitating translocations of substrates within the cell.

Crystalline insulin, Lot 795372, was a generous gift of Dr. O. K. Behrens of the Eli Lilly Co., Indianapolis, Indiana. 3′,5′-Cyclic adenosine monophosphate (cyclic AMP) and 5′-adenosine monophosphate (5-AMP) used as the sodium salts were obtained from the Sigma Chemical Co., St. Louis, Missouri.

This work was supported by a U.S. Public Health Service grant of the National Institute of Arthritis and Metabolic Diseases and by the U.S. Atomic Energy Commission.

AN APPROACH TO THE ORGANIZATION AND CLASSIFICATION OF VERTEBRATE VIRUSES

By Dr. YECHIEL BECKER
Department of Virology, Hebrew University-Hadassah Medical School, Jerusalem, Israel

RECENTLY, Lwoff *et al.*[1] attempted to arrange viruses into an orderly system using as a basis the definition that a virus is a biological entity which exhibits in its life-cycle an infectious particle containing only one type of nucleic acid. In order to classify all viruses which replicate in vertebrates, insects, plants and bacteria, two characteristic features of virions were used: (1) the chemical constitution of the genetic material DNA or RNA; (2) the architecture of the viral capsids. These authors also suggested that other properties of the viral nucleic acids and proteins could be used for further subdivisions.

In contrast to the system of Lwoff *et al.*[1], a more recent attempt at virus classification by the Provisional Committee for Nomenclature of Viruses[2] makes use of the Linnaean system. However, the basic approach to virus characterization is similar to that of Lwoff *et al.*, in so far as the viruses are divided into two sub-phyla according to whether they contain DNA or RNA and then further sub-divided into classes and orders according to the nature and characteristics of the viral coats.

The importance of the viral genetic material as the carrier of the genetic information has already been stressed by Crick and Watson[3]. It is the nucleic acid which controls, during the replicative cycle of the virus in the host cell, the structure of the proteins of the viral coat, which provides a protective shell for the viral nucleic acid. In addition, conditions have been developed for the use of naked viral nucleic acid molecules as infectious material[4]. The existence of a virus as a naked nucleic acid[5] defective in regard to its ability to produce coat protein emphasizes the inadequacy of the use of

virus morphology for the purpose of classification. Moreover, the viral coat contains only a few of those proteins coded by the viral genomes, and in several virus groups components specific to the host cell are incorporated into the viral coats and determine their morphology. In addition, the coating of the viral nucleic acid molecules, which is the last step in virus maturation, is not always an efficient process[6].

In contrast to the use of coat architecture, the physical properties of the viral nucleic acids may provide a better tool for classification. The two types of nucleic acids, DNA or RNA, which appear in viruses could be further characterized according to the nature of their polynucleotide chain, either double stranded or single stranded which can attain a linear or circular form. The viral genome contains all the information necessary for its replication and determines the fate of the host cell. With the aid of cellular mechanisms, the viral genomes transcribe their genetic information. The viral nucleic acids are generally stable, except for mutational changes, and retain their full complement of genetic material through many cycles of replication. The amount of information encoded in the virus genome is related to the molecular size of the viral nucleic acid[7].

The present approach to the organization and classification of vertebrate viruses uses the viral nucleic acids as the most characteristic component of the virus which controls all other phenotypic viral properties. As shown in Table 1, the viruses are divided into two major groups, as already suggested[1]: (1) DNA viruses; (2) RNA viruses. The next step in the organization is the division of each of the major groups into two sub-groups according to the physical properties of the viral nucleic acids: (*a*) double-stranded molecules; (*b*) single-stranded molecules. Each is further sub-divided into: (i) linear; (ii) circular forms. The further division is according to the molecular weight of the specific nucleic acid.

It should be stated that the use of the molecular shape of the nucleic acids (linearity or circularity of the double-stranded DNA or RNA molecules) is based on analytical and morphological properties of molecules which are sensitive to shearing after extraction from the virions. The development of more accurate techniques for the preservation of the extracted molecules will make possible a reconsideration of the physical characteristics of viral nucleic acids.

As indicated in Table 2, further characterization and definition of the different vertebrate virus groups are based on: (1) The phenotypic expressions of the viral genomes, (*a*) the structure and the shape of the viral coats, and (*b*) the general morphology of the virions as viewed in the electron microscope. (2) It is also suggested that the cellular site of viral nucleic acid replication be included as a criterion of the different virus groups. The site of virus replication might indicate the nature of the cellular mechanisms utilized by the viruses for replication and maturation. The nomenclature of the different virus groups is the same as that used by Andrewes[8] and as recently reviewed[7,9–11].

A further division of each group into sub-groups and species can be effected on the basis of: (1) the differences in the molecular weights of the nucleic acids of different virus strains; (2) the guanosine + cytosine content in the viral nucleic acids; and (3) differences in the chemical compositions o viral protein coats and envelopes.

The advantages of the proposed scheme are: (1) the group of vertebrate viruses at present known can be distinguished from each other by the nature of their nucleic acids; (2) it will be possible to classify viruses which lack distinct coats; (3) the characteristics will be indicated of viruses not yet known to replicate in vertebrates but known to exist in other cellular systems, for example,

EFFECTS OF 6-DAY MATERNAL DEPRIVATION ON RHESUS MONKEY INFANTS

By R. A. HINDE, Y. SPENCER-BOOTH and M. BRUCE

Sub-Department of Animal Behaviour, University of Cambridge

BOWLBY[1] concluded that if a young child is deprived of maternal care for a prolonged period, there may be far-reaching effects on his future development. His views, based in part on earlier work[2–4], have given rise to much research and some controversy. While his basic thesis is well supported[5], it opens up many problems, such as measuring the extent of the effects produced by maternal deprivation, assessing their irreversibility, and understanding the mechanisms involved.

Research on the effects of temporary maternal deprivation has depended largely on retrospective studies of individuals who have had a separation experience in the past[6], and on studies of the immediate consequences of maternal deprivation[7–9]. For ethical reasons, experimental studies of maternal deprivation in human subjects are out of the question, although a few workers have taken advantage of an already existing condition to provide experimental alleviation[10,11]. Control of the deprivation circumstances, or of the post-deprivation conditions, has thus nearly always been impossible, and retrospective investigations are sometimes open to the criticism of possible bias (genetic or otherwise) in sample selection.

Can the symptoms of maternal deprivation seen in man be studied experimentally in animals? Monkeys are an obvious possibility, since adult behaviour is known to be markedly affected by the social conditions of rearing[12], and immediately following brief periods of separation the pattern of mother–infant interaction is disturbed[13,14]. Although gross species comparisons can be misleading, whether or not maternal deprivation produces similar consequences in monkeys and men is an empirical question.

Accordingly an attempt has been made to study the effects of a period of maternal deprivation on the subsequent behaviour and mother–infant interaction of rhesus macaques. In the present experiment the age at separation was 30–32 weeks, and the period of separation 6 days. Four infants were used, special care being taken to assess their individual pre-separation characteristics, and to study their behaviour not only immediately the mother was returned, but for several months afterwards.

The animals concerned lived in groups each consisting of a male, two or three females and their young. Each group was housed in an outdoor cage 18 ft. × 8 ft. × 8 ft. communicating with an inside room 7·5 ft. × 6 ft. × 4·5 ft. (ref. 15). Each infant was watched for 6 h a week (birth to 8 weeks) or a fortnight (weeks 9/10–30) to compare mother–infant relations with those of eight control infants studied previously which had no separation experience. On the three pre-separation days each mother–infant pair was watched from 1000 h G.M.T. until the infant had been off the mother for 2 h, or until 1430 h, whichever was the earlier. Just before 1000 h on day 4 the mother was caught and placed out of sight of the infant in a room about 60 yd. away. Further watches were made immediately the mother was removed (day 4, or first day of separation) and on days 5, 7 and 9, when the mother was returned on day 10, and on days 11, 12, 14, 16, 23, 30 and 37. Routine watches were also made for 6 h a month for the rest of the first year.

The method of observation was similar to that already described[16]. In addition, during the pre-separation, separation and post-separation periods (that is, days 1–37) a second observer recorded the amount of locomotor activity (that is, the number of sectors of the cage entered in each half-minute period), and the type of activity shown, while the infant was off its mother. Only certain parameters of the infants' behaviour which indicate the more obvious consequences of the deprivation experience will be considered here: a more detailed analysis is in preparation.

During the pre-experimental period, the behaviour of these four infants was generally similar to that of the control subjects living under similar conditions previously studied: if anything, they spent on average rather

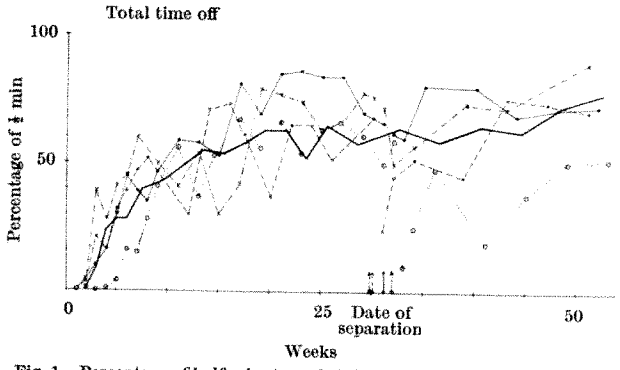

Fig. 1. Percentage of half-minute periods in which infants were recorded off their mothers. Thick line—median for eight control animals which had no separation experience. Linda, —·—×; Doris, ——●; Hilary, ——○; Tim, ····○

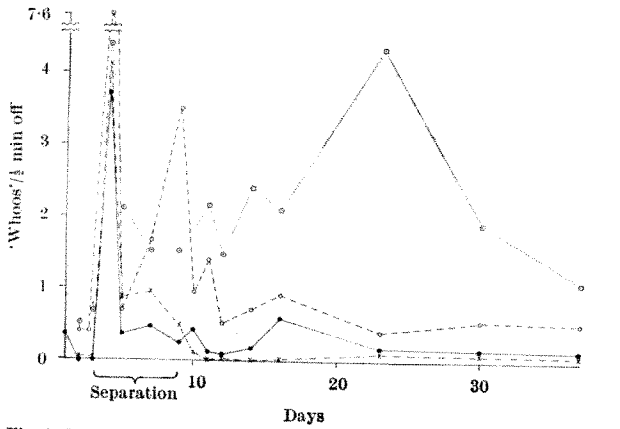

Fig. 2. Frequency of 'whoo' calls while off mother during pre-separation, separation and post-separation periods. Conventions as in Fig. 1

more time off their mothers (Fig. 1), and a higher proportion of that time at a distance from their mothers, than the median for the controls. During the pre-separation watches the inter-individual differences between the four subjects can be summarized as follows. Ranking the individuals with respect to one another, the amount of time spent off the mother decreased in order from Linda, Doris, Hilary to Tim: this was due to the behaviour of the infants rather than to restrictiveness by the mothers. Linda was an active infant who spent frequent short periods away from her mother, during which she did not spend long at a distance from her. The others spent less time at a distance from their mothers in the order Doris, Hilary, Tim: all had higher scores in this respect than Linda, but showed (in the same order) increasing scores of social and manipulative play and locomotor activity.

During the separation period, the infants directed some of the behaviour which they had previously directed towards their mothers towards other adults in the group, but they received much less care from these than they had previously from their mothers. For example, before separation they were recorded on their mothers in 41–53 per cent of half-minute observation periods, and on other adults for less than 1 per cent, but during the separation they were on other adults for only 0–24 per cent (mean 17 per cent).

When the mother was removed there was an immediate increase in 'whoo' calls—a call characteristically given by an infant separated from its mother[17]. The rate of calling fell off somewhat during the rest of the separation period, but in all four subjects was still higher than the pre-separation mean 4 weeks after the mothers' return (Fig. 2).

During the mother's absence, the behaviour of the infants can be described as 'depressed'. They usually sat in a characteristic hunched posture, and crept about on their hind legs. Almost immediately after the mothers' removal they became less active than they had been previously when off their mothers (Fig. 3). During the course of the separation period all four infants became active for more of the time (that is, they sat still less), but they became progressively less active when not sitting still. Three of the four infants returned to the pre-separation level of activity within a week of the return of their mothers, but Tim showed less activity on every watch up to 4 weeks afterwards. The amount of social and manipulative play shown changed in a manner generally similar to that of general locomotor behaviour.

On the first day of the return of their mothers, all four infants spent a high proportion of their time on her (Fig. 4). The more they had been off the mother before separation, the less clinging were they on her return, and the more quickly did they return to behaviour similar to that seen before separation. Thus Linda spent only a little more time on her mother than before separation, but Tim scarcely left his mother on the first day of her return. Similarly, while Linda and Doris were leaving their mothers almost as much as before separation within a week of the return of their mothers, in Hilary and Tim the effects persisted for a month or longer. When Tim was a year old he was still off his mother less than he had been before separation, although the median for the control animals was increasing during this time (Fig. 1).

In all four infants the amount of time spent off the mother recovered in the first few days after the mothers' return, but then regressed for a while, the permanent recovery occurring more slowly (Fig. 4). The reason for this is not apparent: although the proportion of attempts by the infant to gain the nipple which were rejected by

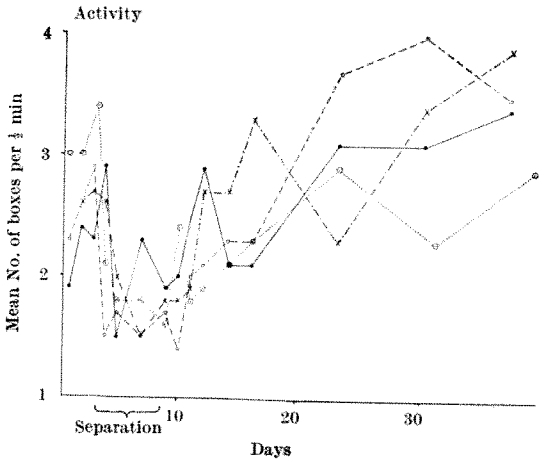

Fig. 3. Activity changes during the pre-separation, separation and post-separation periods. The cage was divided into sixteen 'boxes', and activity measured by the number of boxes entered per half minute while off the mother. Conventions as in Fig. 1

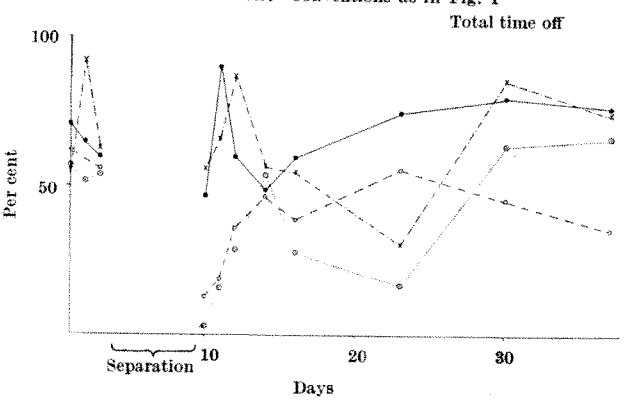

Fig. 4. Percentage of half-minute periods in which infants were recorded off mothers during pre-separation, separation and post-separation periods. Conventions as in Fig. 1

the mother varied directly with the amount of time spent off the mother both during the pre-separation period and later in the post-separation period, it did not do so during the period in which this initial recovery and subsequent temporary regression occurred.

Not only did the infants leave their mothers less often during the post-separation period, but they went less far from her when they were off her. On this measure, all four infants recovered to their pre-separation levels about a fortnight after the return of their mothers.

These data show that some rhesus infants of this age are adversely affected by a 6-day removal of their mothers, that the severity of the effects varies with the nature of the pre-separation mother–infant relationship and that they may persist for at least some weeks after the return of the mother. The consistency between individuals is adequate for conclusions of some generality to be drawn, but the individual differences are also revealing. The symptoms shown by the infants parallel in many ways those of human infants undergoing a similar experience, with the exception that none of the monkeys showed a phase of detachment from the mother on her return, similar to that described in children[8,18].

ESTIMATION OF THE TOTAL HYDROGEN CONTENT OF THE HUMAN BODY

By Dr. J. RUNDO and L. J. BUNCE

Atomic Energy Research Establishment, Harwell, Berkshire

METHODS are now available for the estimation of several important body constituents by non-destructive testing which can be applied to the living subject. Total-body water can be determined by the method of isotopic dilution using deuterium oxide or tritium oxide as the tracer. Estimates of the 'exchangeable' fractions of total sodium and potassium can also be obtained by this method using radioactive tracers, and determination of the total potassium content by measurement of the γ-radiation from the naturally radioactive isotope potassium-40 is a well-established technique, the applications of which are increasing. Recently the application was described of body radioactivity measurement to the estimation of total-body sodium, chlorine and even calcium following neutron activation *in vivo*[1]. This article describes a method of estimation of the total hydrogen content of the body. The method is based on the emission of 2·23 MeV γ-rays when hydrogen atoms capture thermal neutrons; the γ-rays are measured by scintillation spectrometry with thallium-activated sodium iodide. We have investigated the possibility of using cosmic radiation as a source of fast neutrons which are first moderated by, and then captured in, the body. The use of lead for the low-background shield for the measurement of the capture γ-rays increases the number of neutrons available, as evaporation neutrons are produced in the lead.

The γ-ray spectra in Fig. 1 illustrate the method. Curve 1 is the background spectrum (0·04–3·34 MeV) of the spectrometer, which uses four crystals of thallium-activated sodium iodide, each 6 in. in diameter by 3·5 in. thick. Curve 2 is the background spectrum when a 66-kg phantom was placed on the stretcher to simulate a human. The phantom[2] consisted of right circular and elliptical cylinders of polythene filled with 54 kg of distilled water, and it contained 7·8 kg of hydrogen. The two curves are very similar between channel numbers 17 and 130 (corresponding to approximate γ-ray energies of 210 keV and 1·7 MeV), but below channel 17 there is a marked increase in the counting-rate due to γ-rays which have been scattered and degraded by the phantom. Between channels 130 and 190 there is another increase with a well-defined peak at channel 170 (2·23 MeV). We have

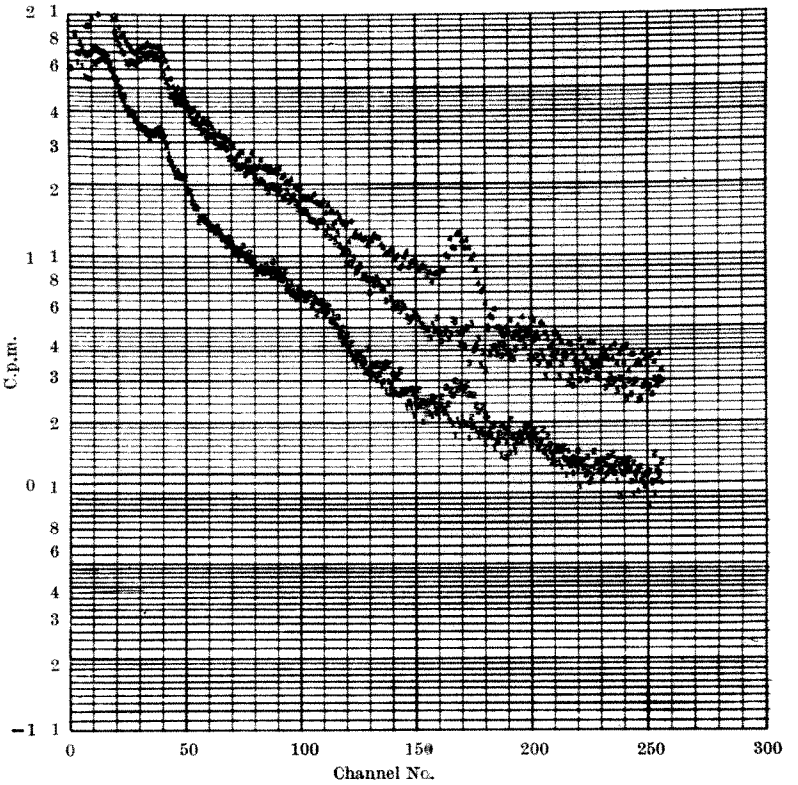

Fig. 1. Computer-produced plot of γ-ray spectra showing the effects on the spectrometer background (curve 1) of placing the polythene and water phantom on the stretcher (curve 2) and of a heavily-shielded 2-mc. radium-beryllium neutron source 6 ft. from the mid-point of the stretcher, without (curve 3) and with (curve 4) the phantom. The numbers −1, 0, 1 and 2 to the left of the vertical scale identify the powers of ten at the respective scale points

proved that this is due to neutrons (*a*) by investigating variations in the counting-rate in the peak at different barometric pressures and (*b*) by measuring the background spectrum with a 'phantom' composed of 63 kg polytetrafluoroethylene (PTFE) which contains no hydrogen. The results of (*a*) showed that the counting-rate in the 2·23-MeV peak varied from about 14 c.p.m. at a pressure of 716 mm mercury to 8·5 c.p.m. at 765 mm mercury. The coefficient was approximately −10 per cent per cm of mercury, in agreement with the coefficient for the neutron and neutron-producing components of cosmic rays[3]. The results of experiment (*b*) showed that while the PTFE phantom produced an increase in counting-rate at low energies (below channel 17) there was no increase at higher energies and no trace of a peak at 2·23 MeV. The results of both experiments showed that the peak was due to cosmic-ray neutrons reacting with the hydrogen in the polythene and water phantom, and not to some unidentified long-lived radioactive contaminant in the phantom.

Gamma-ray spectra taken with humans on the stretcher of the equipment also showed the peak at 2·23 MeV, and we have attempted to estimate the total-body hydrogen content. Because the intensity of the neutrons varied markedly with barometric pressure, two measurements of background were made each day, one with and one without the polythene and water phantom. The second of these was used as the counter background for the measurements of the areas of the peaks in the spectra from the subjects and from the phantom. In effect the latter was used as a measurement of the 'source strength'.

Calibration. The equipment was calibrated roughly to take account of the effects of variations in body size, which affect both the moderation of the fast neutrons and the number of capture γ-rays produced, as well as their self-absorption in the body and the geometrical efficiency for their detection by the scintillation counters. In order to increase the counting-rate for the calibration measurements a 2 mc. radium-beryllium fast neutron source was placed about 6 ft. from the centre of the stretcher, outside the 4-in. lead shield and with an additional 6 in. of lead shielding around it. The effect of this source on the background γ-ray spectrum (an increase by a factor of 2–2·5) is shown by curve 3 of Fig. 1, while the increased counting-rate when the phantom was placed on the stretcher is shown in curve 4. The area under the 2·23-MeV peak was increased ten-fold by the additional neutron source. Measurements were made of the peak area (c.p.m.) for a number of phantom sizes and shapes, with various configurations of the component parts of two phantoms (total weights 66 kg and 84 kg). The counting-rates per kg of hydrogen were plotted as a function of phantom weight, with the counting-rate from the 66 kg phantom normalized to that due to cosmic-rays alone at an average barometric pressure of 755 mm mercury. The calibration factor (c.p.m. per kg of hydrogen) varied from 1·53 to 1·07 for phantom weights in the range 40 to 84 kg.

Calculation of body hydrogen. After subtraction of the counter background the counting-rate in the energy range 2·08–2·35 MeV (channels 161–181) from each subject's γ-ray spectrum was corrected to correspond to a barometric pressure of 755 mm mercury. The hydrogen content was then calculated from the appropriate calibration factor for the subject's weight. Table 1 shows typical counting-rates with their statistical standard errors for counting times of 2^{11} sec (about 34 min) for the subject and 2^{13} sec (~ 136 min) for the background.

From the last two entries in Table 1, the hydrogen content is 6·7 ± 1·1 kg (9·5 ± 1·6 per cent of the body-weight). The hydrogen contents of twenty-seven adult males and of ten adult females were calculated in this way and the average concentrations were 9·47 per cent of body-weight for the men and 8·65 per cent of body-weight for the women. These values are similar to, although a little lower than, the value of 10 per cent quoted by Hawk *et al.*[4] and adopted by the International Commission on Radiological Protection[5]. However, there is evidence that there may be a systematic error on our estimates of body hydrogen. Thus, the 63 kg PTFE phantom reduced the background in the 2·23-MeV peak region by about 1 c.p.m., while above the peak there was a decrease of 4 c.p.m. in the energy range 2·51–3·34 MeV. These effects were presumably due to absorption of cosmic radiation or γ-rays produced by cosmic rays. On the other hand, the polythene and water phantom increased the background (79·6 c.p.m.) above the 2·23-MeV peak by 2·4 c.p.m. The difference between these two effects on the counting-rate may be explained, at least in part, by the fact that the neutrons produce an increase in the background when the polythene and water phantom is present. This effect is well demonstrated by curves 3 and 4 of Fig. 1; with the neutron source present the counting-rate in the energy range 2·51–3·34 MeV increased from 210 c.p.m. to 261 c.p.m. when the phantom was placed on the stretcher, presumably due to γ-rays produced as a result of inelastic scattering of the neutrons by oxygen atoms, as well as some produced by capture. Thus the true background in the region of the 2·23-MeV peak may be indeterminate because the neutron-produced increase (other than that due to hydrogen capture γ-rays) is masked by the decrease due to absorption of electromagnetic radiation.

From a careful investigation of our data, we conclude that there might be a systematic error, probably not exceeding 1 c.p.m. in the background counting-rate at 2·23 MeV, which would correspond to about 1 kg of hydrogen.

At present, knowledge of the hydrogen content of the human body appears to have no major application, although it is of interest that it can be estimated by body 'radioactivity' measurement without administration of radioactivity or exposure of the subject to extra radiation. Should it be considered important to determine body hydrogen with some precision, this could be done by increasing the neutron flux inside the shielded room as we did for our calibration measurements. This increased the counting-rate in the 2·23-MeV peak by a factor of about ten, while only increasing the background by a factor of 2·3. A dose-rate of 19 μrem/h was measured with a rem counter[6] on the stretcher, with the 2 mc. radium-beryllium source outside the shield. Thus it should be possible to measure the hydrogen content of a subject with a statistical error of less than 5 per cent, with a radiation dose of about 10 μrem of fast neutrons which should be quite acceptable. At the same time the potassium content of the subject could be measured with similar or better precision; from the lean body mass (which may be calculated from the equation[7]:

$$L.B.M. = 0{\cdot}0119\,K + 6{\cdot}04\,SA$$

where K is the potassium content in milliequivalents and SA is the surface area in m^2) the associated hydrogen content can be calculated. The difference from the total-body hydrogen might be useful in some applications, provided it has not too large an uncertainty.

Table 1

	C.p.m. in 2·23 MeV peak
Background	37·0 ± 0·5
Subject plus background (764 mm mercury)	43·7 ± 1·1
Response due to subject	6·7 ± 1·25
Correction for pressure	+0·9
Corrected response	7·6 ± 1·3
Calibration factor (70 kg)	1·14

OBSERVATIONS ON CAESIUM ENRICHMENT AND THE POTASSIUM/RUBIDIUM/CAESIUM RELATIONSHIP IN ECLOGITES FROM THE ROBERTS VICTOR MINE, SOUTH AFRICA

By J. J. GURNEY, G. W. BERG and Prof. L. H. AHRENS
Department of Geochemistry, University of Capetown, Rondebosch, South Africa

THE possibility of either eclogite or peridotite as a constituent of the upper mantle has often been suggested. Quantitative data, particularly on trace elements, are, however, either lacking or often unsatisfactory. We are accordingly undertaking a systematic study of the composition of eclogites and peridotites, with particular reference to their trace-element content. Most samples are from the kimberlite pipes of Southern Africa. Whereas peridotites are a widespread occurrence, the majority of eclogites being studied come from the pipe of the Roberts Victor Mine, Orange Free State.

Considerations of heat flow and the chondritic earth model both indicated that the alkalis would be an interesting group of elements for study. Preliminary investigations made it immediately apparent that the eclogites from the Roberts Victor Mine were enriched in caesium relative to potassium and rubidium, as compared with common igneous rocks. The caesium content of eclogites and peridotites from other localities did not show the same anomalous behaviour. In the light of this discovery the potassium, rubidium and caesium contents of a suite of seventeen eclogites from the Roberts Victor Mine have been determined. Two eclogites from the Jagersfontein Mine, Cape Province, South Africa, and two from the Dodoma Mine, Tanganyika, have been included for purposes of comparison. Five kimberlites from Roberts Victor have also been studied.

Previous accurate work on the alkali content of eclogites from the Roberts Victor Mine is limited to Heier[1], who reports the potassium content of seven specimens. Three of these, together with one sample from Jagersfontein and one sample from Tanganyika, form part of the present collection. Faure and Hurley[2] have reported a single rubidium value of 6·90 p.p.m. for a Roberts Victor eclogite.

Williams[3] suggested that the eclogites had undergone considerable secondary alteration; this conclusion was also reached by Heier[1]. These points are to be borne in mind when discussing the results reported here.

These results have been obtained as follows:

Rock type and locality	Potassium (%)	Rubidium (p.p.m.)	Caesium (p.p.m.)
Roberts Victor eclogite (ref. 17)	Flame	Emission	Emission spectrograph
Eclogite from other localities (ref. 4)	Photometer	Spectrograph	—
Roberts Victor kimberlite (ref. 6)		X-ray fluorescence	Emission spectrograph

Emission Spectrography

The comparatively wide range in concentration of rubidium, caesium and the internal standard potassium, coupled with differences in sensitivity of the analysis lines (potassium 6939 Å; rubidium 7947 Å and 7800 Å; caesium 8521 Å) and the problem of self-absorption, meant that it was not possible to obtain results for all the samples under identical conditions. However, only two sets of conditions were necessary. Synthetic standards were used. *W*–1 was treated as an unknown sample and five of the eclogites were used to correlate the two procedures. All standards and *W*–1 were arced in triplicate, all samples in duplicate. The average values obtained for *W*–1 were 23 p.p.m. for rubidium and 0·79 p.p.m. for caesium, both of which are close to previously reported values. The correlation between the results obtained by the two different sets of conditions was good. The relative deviations obtained using the formula:

$$C = \sqrt{\frac{\Sigma d^2 \text{ as } \%}{2N}}$$

(where C is the relative deviation, d^2 as % is the $\frac{\text{difference between two duplicates} \times 100}{\text{average}}$ and N is the number of samples) were:

Line Å		Run No. 1 (%)	Run No. 2 (%)
Rubidium	7947		
	7800	5·6	5·3
Caesium	8521	8·2	5·3

These figures refer to the eclogites only.

Full details of the spectrographic technique will be given at a later date.

The results of the present work given in Table 1 can be summarized as follows:

(1) *Potassium and rubidium abundance.* (*a*) *Eclogite:* The potassium and rubidium concentrations in the Roberts Victor samples would seem to be greater than the level of concentration in the Jagersfontein and Tanganyikan eclogites. (*b*) *Kimberlite from Roberts Victor:* The potassium and rubidium concentration here is of the order of ten times the level found in the eclogites from the same locality.

(2) *Caesium abundance.* (*a*) *Eclogites:* The caesium concentration of the Roberts Victor eclogites is extremely high (the average is 5·9 p.p.m.). It may be significant that the average caesium content of the kimberlite from the same area is also ~6 p.p.m. The caesium content of the Jagersfontein and Tanganyikan eclogites has not specifically been sought. Indications are, however, that the concentration is less than 0·3 p.p.m., and that the potassium/caesium ratios are greater than 5,000. One further point of interest is the wide range reported in the Roberts Victor eclogites from 0·59 p.p.m. in a sample with a potassium/caesium ratio of 7,320, to 16·4 p.p.m. in a sample with a potassium/caesium ratio of 158. (*b*) *Kimberlite from Roberts Victor:* Owing to the erratic behaviour of kimberlites in the d.c. arc and the possibility of a matrix effect, the caesium values quoted in this article must be taken as indications only. (It should be noted that the quoted relative deviation does not refer to the results obtained for kimberlites.)

(3) *Potassium and rubidium correlation.* A strong correlation is apparent between potassium and rubidium in all the samples analysed (Fig. 1). However, with the data now available, it is not possible to establish whether the relationship is linear (that is, whether a uniform potassium/rubidium ratio holds over the whole range of potassium and rubidium content, or whether there is a slight tendency for rubidium to concentrate relative to potassium. In the latter case, the potassium/rubidium ratio may approach that of the kimberlite, as indicated by the dashed line (Fig. 1). The average potassium/rubidium ratio of the Roberts Victor eclogites (367) is distinctly greater than the average for the kimberlites (246) which is close to the estimated crustal average of 230 (ref. 4).

(4) *Potassium and caesium correlation.* (*a*) *Roberts Victor eclogites:* No correlation is apparent between

potassium and caesium, nor between rubidium and caesium (Fig. 2). Indeed, *RV* 374, *RV* 377 and *KRV* 3 with a caesium content of 1 p.p.m. or less have among the highest potassium and rubidium contents of all the Roberts Victor eclogites. Ahrens *et al.*[5] and Ahrens and Edge[6] have reported average potassium/caesium values of 7,500 for gabbroic and basaltic rocks. On this evidence, and also on the reported potassium/caesium ratios for many different rock types the average potassium/caesium ratio of 1,800 for Roberts Victor eclogites can only be regarded as extraordinarily low. It is, in fact, lower than that found in shales[4] where an enrichment of caesium is to be expected. Taken individually, the ratios are even more unusual, with five potassium/caesium ratios less than 500, and thirteen of the seventeen results less than the average value. (*b*) *Roberts Victor kimberlite:* Bearing in mind the limitations previously mentioned, the only conclusion which can be drawn from the five reported potassium/caesium ratios is that they are the same magnitude as the estimated crustal average[4]. They show that, relative to potassium, caesium is enriched in eclogites compared with the kimberlite in which these inclusions occur.

Caesium in Roberts Victor Eclogite

Finally, it must be emphasized that the caesium concentrations reported here are high even on an absolute scale, the average caesium content being greater than the recommended maximum crustal average of Heier and Adams (4·2 p.p.m.)[4]. Coupled with the ultrabasic nature of the samples and their relatively low potassium and rubidium content a concentration of caesium of this order is impossible to explain, except by invoking some second-

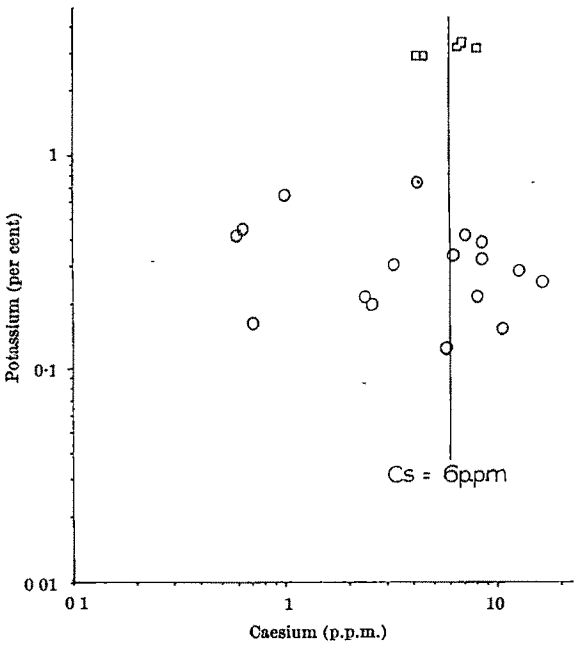

Fig. 2. Plot of potassium (per cent) versus caesium (p.p.m) in eclogite (○) and kimberlite (□) from Roberts Victor Mine

ary process or processes which differentiate between potassium and rubidium on the one hand and caesium on the other.

For one eclogite, *RV* 372, the secondary mineral containing the caesium has been separated and found to have an analcite-type structure. The crystalochemical properties of analcite appear to explain the unusual trends in alkali ratios reported here. Further details of this aspect will be given later.

We thank Prof. E. S. W. Simpson, head of the Department of Geology, University of Capetown, and the Anglo-American Corporation for making samples available. We also thank A. J. Erlank, J. P. Willis and H. W. Fesq for advice and helpful discussions and also the C.S.I.R. (Pretoria) for financial assistance.

CONTINENTAL DRIFT AND OCEANIC HEAT-FLOW

By Dr. R. D. SCHUILING
Department of Geology, Princeton University, Princeton, New Jersey

THE fact that oceanic heat-flow tends to be approximately equal to the heat-flow observed on the continents has been used as an argument against the possibility of continental drift[1]. This argument, in its most simple form, runs as follows. A comparison of the radioactive heat-production of a typical continental and a typical oceanic section shows that the continental heat-flow should exceed the oceanic heat-flow by a factor of 2–3 (ref. 2), provided that the mantle under the oceans and the mantle under the continents have the same content of radioactive elements. As in fact the average oceanic and continental heat-flow are nearly equal (1·43 μcal/cm² sec for continents, 1·37 μcal/cm² sec for oceans, if values above 4 are omitted[3]), some authors have concluded that in a continental section the radioactive elements, together with the light elements, have segregated and accumulated into a continent, whereas under the oceans this segregation has not occurred. Here the radioactive elements would still be distributed through the mantle. This explanation has become a basis for many geochemical calculations[4]. It seems impossible to reconcile the idea of chemical differences characteristic of oceanic or continental areas, extending to depths of several hundred kilometres, with continental drift, which would conceivably bring continents on top of undifferentiated 'sub-oceanic' mantle, and create oceans on top of depleted 'sub-continental' mantle. The general effect would be a significantly higher heat-flow from the continents than under the oceans.

The idea of large-scale chemical differentiation occurring in some sectors of the mantle, and not at all in other sectors, seems a rather unattractive proposition, even without moving the continents. One would expect to see a whole series of transitional areas with some crust developed. As such transitions are virtually absent, and as continental drift is supported by a large amount of evidence, it was decided to see whether an unsteady state of affairs caused by the relatively young age of the oceanic basins would cause the rough equality of oceanic and continental heat-flow. A series of cooling curves were therefore computed for a model in which at time $t = t_0$ a continent was suddenly removed, and the newly formed oceanic section of the mantle was allowed to come to its new thermal equilibrium. As a second boundary condition we chose that the temperature T at the plane of separation was 800° C and that the thermal gradient in the upper mantle was 2°/km (probably a minimum, see ref. 5). This choice does not greatly influence the outcome. The temperature at the new surface will be held at 0° C. The computer programme was run twice, for values of thermal diffusivity $\varkappa = 0{\cdot}01$ cm²/sec (decidedly too low) and 0·03 (probably a maximum). The formula for the model situation outlined above is given by Carslaw and Jaeger[6] as follows:

$$v = V \operatorname{erf} \frac{x}{2\sqrt{\varkappa t}} + kx$$

in which v is the temperature at time t; V, the temperature at time t_0; t the time; $\varkappa$ the thermal diffusivity; x the depth and k the thermal gradient at time $t = 0$, chosen as 2×10^{-5} °C/cm. The cooling curves thus obtained (see Fig. 1) give us direct information on the heat-flow at the surface after different time intervals. As can be seen from these computed heat-flows (Fig. 2), the contribution of the unsteady state cooling (labelled 'excess heat-flow' in Fig. 2) is still of the same order of magnitude as the average continental heat-flow in a steady-state situation even after several hundred million years.

The assumption of 'sudden removal' of a continent, though mathematically attractive, causes very high heat-flows during the first 50 million years or so. In

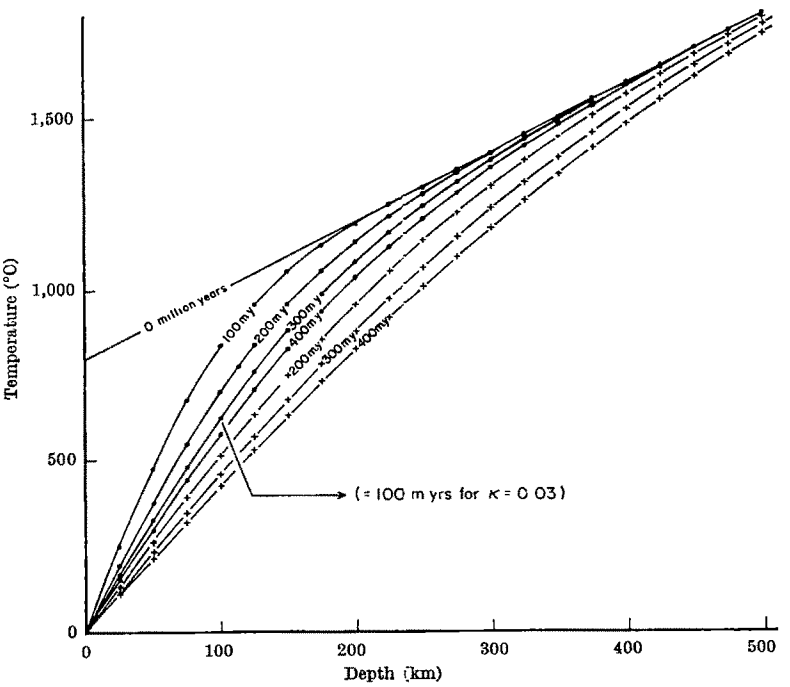

Fig. 1. Cooling curves for unsteady state model. +, $\varkappa = 0{\cdot}03$; ●, $\varkappa = 0{\cdot}01$

order to eliminate this effect, which is solely due to the introduction of a temperature discontinuity by the assumption of 'sudden removal', we recalculated the heat-flow for the case that the temperature at the plane of separation decreases exponentially with time, with a half-life of 20 million years. The resulting heat-flow curves are indicated with dotted lines in Fig. 2. This corresponds roughly to a situation in which a wedge-shaped continental edge is gradually removed.

One could try to incorporate more details in the model, but I feel that it would be unrealistic to try to be more realistic. Therefore heat-contributions from radioactivity in the mantle, or from exothermic reactions which would proceed on cooling, have not been taken into account. Heat contributions from a horizontally spreading layer of hot material, brought up by a convection current, have also not been taken into account. It can easily be seen that their effect would be to counteract cooling, and so maintain a higher heat-flow than expected from the model used. The effect of an increase of the thermal diffusivity with depth, as radiative heat-transport becomes more effective with increasing temperature[7], is more difficult to assess. All these possible refinements of the calculation do not change my basic conclusion, that continental drift itself may be the explanation of the approximate equality of oceanic and continental heat-flow. Once a continent which acted as an 'electric blanket' is displaced by convection currents, the new ocean floor is able to maintain an essentially normal heat-flow for geologically long periods of time.

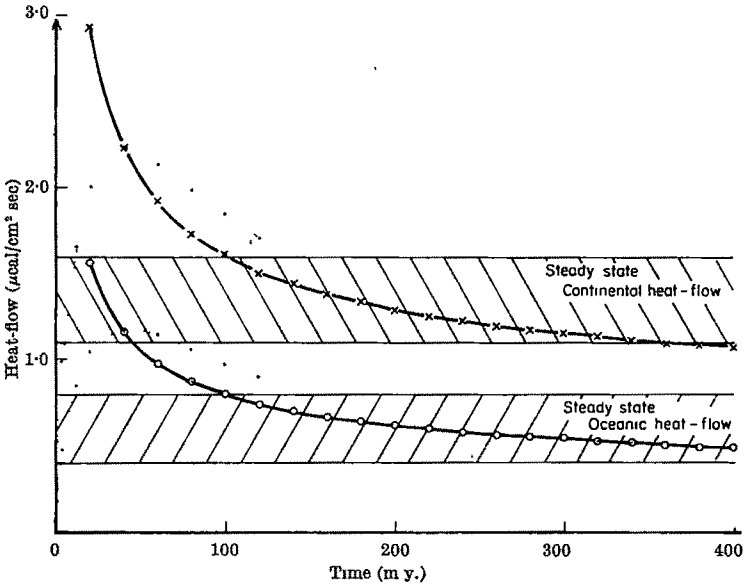

Fig. 2. Excess heat-flow curves from unsteady state model, compared with the heat-flow to be expected from radioactivities of typical continental and typical oceanic sections in a steady state situation. Any heat contribution from other sources than unsteady state cooling must be added to these excess heat-flow curves in order to obtain the true heat-flow. Dotted lines indicate heat-flow for a model in which gradual, rather than sudden, removal of a continent is assumed. ×, Excess heat-flow for $\varkappa = 0{\cdot}03$; ○, Excess heat-flow for $\varkappa = 0{\cdot}01$

I conclude that the approximate equality of oceanic and continental heat-flows cannot be used as an argument against continental drift having occurred in the past few hundred million years, and that there is no valid reason to suppose that continents sit on top of differentiated mantle and oceans on top of undifferentiated mantle.

I would like to point out some of the repercussions of the model outlined here. If there exist very old, undisturbed parts of oceans, these will be characterized by a lower than average heat-flow. It may be expected that near the trailing edge of a drifting continent the heat-flow values are slightly above normal. If it is accepted that the mid-oceanic ridges are the loci of upwelling convection currents, accompanied by volcanism and serpentinization[8] and thus characterized by high heat-flow, an ideal heat-flow profile should show a shallow minimum between the oceanic ridges and the continental slope. As a further consequence of the unsteady-state model it is possible that a layer of low viscosity in which horizontal movement is presumably concentrated is not to be found everywhere at the same depth.

The theory outlined here offers a general explanation of the unexpectedly high average level of oceanic heat-flows, and it removes one of the strongest objections against continental drift. In areas more restricted geographically, especially near the ridges, heat contributions by volcanism, serpentinization and upwelling convection currents will be more important than unsteady state cooling.

I thank Dr. W. S. Morgan for setting up the computer programme, and Prof. H. H. Hess, Prof. W. M. Elsasser, Prof. H. J. Greenwood and Dr. Morgan for their stimulating discussions.

RADIOCHEMICAL DATA CORRELATIONS FOR SEA-WATER AND CORAL-SURFACE BURSTS

By G. R. CROCKER
U.S. Naval Radiological Defense Laboratory, San Francisco, California

A SYSTEMATIC investigation and correlation of all available radiochemical data from field test operations is an essential step toward an understanding of the phenomenon of fractionation in fall-out formation. The first step in this direction was an examination by Freiling[1] of the data from high-yield coral-surface and sea-water bursts of Operation Redwing. A subsequent publication[2] by the same author presented the results of correlations of some air-burst data.

This report is based on radiochemical data from three high-yield bursts from Operation Hardtack—one on a coral surface, one on the surface of deep water, and one on the surface of shallow water over a coral bottom. The conditions are similar to those of some of the Redwing events dealt with in ref. 1. Since a slightly different method of making correlations has been used in the present investigation, the Redwing data have been recalculated in accordance with it, so that direct comparisons can be made.

It has been shown[1] that certain relationships between the fractionation behaviour of fission-product radionuclides can be established by a method of logarithmic

plotting. The application of the method is most straightforward if the analytical data on the radionuclides are first expressed as "equivalent fissions of the device" at the time of detonation (rather than disintegrations per minute, or number of atoms present at time of detonation, or the more complicated ratios of nuclides found in the sample normalized to the ratios observed in unfractionated uranium-235 thermal-neutron fission products).

The term 'equivalent fissions' means the number of atoms of material in the device which must have undergone fission in order to produce the amount of a particular radionuclide observed in the sample. In order to express radiochemical results in terms of equivalent fissions of the device, the yields of the nuclides for the device must be known. Then, if the sample contains a_n atoms of nuclide n (at the time of detonation) and if the fractional yield of nuclide n for the device was y_n, the number of equivalent fissions, f_n, is:

$$f_n = \frac{a_n}{y_n}$$

For the purpose of investigating fractionation, it is convenient to form ratios of equivalent fissions of two nuclides, i and j:

$$r_{i,j} = \frac{f_i}{f_j}$$

If nuclides i and j have not fractionated from each other in the sample under consideration, the value of $r_{i,j}$ will be unity (or reasonably near it). Pairs of nuclides of the group zirconium-95, molybdenum-99, cerium-144 and neodymium-147 usually behave this way in land-surface bursts. However, if i fractionates from j, the value of $r_{i,j}$ may be either much less or much greater than unity. For example, strontium-89 generally fractionates from zirconium-95 in land-surface bursts, and both high and low values of the ratio $r_{89,95}$ are commonly observed.

It should be clear that such terms as 'fractionate', 'fractionating', 'fractionation', etc., are meaningful strictly only in so far as they express or imply 'fractionates from some reference substance', etc. A looser usage has become commonplace, however, which categorizes mass chains with volatile members as fractionating and mass chains with all refractory members as non-fractionating. An alternative terminology refers to the two kinds of chains as 'volatile' and 'refractory', respectively. In fact, these latter terms are also commonly applied (through abbreviation of speech) to the nuclides themselves. Thus, strontium-89 is referred to as volatile, although the volatility is characteristic of the bromine, krypton and rubidium in the mass-89 chain and not of the strontium.

Since the mass-89 chain and the mass-95 chain are subject to severe fractionation from each other, the ratio $r_{89,95}$ (equivalent fissions of strontium-89 to equivalent fissions of zirconium-95) is a useful indicator of the degree of fractionation of a sample. The fractionation of any other nuclide i from zirconium-95 can then be related to $r_{89,95}$ in a simple way by making log–log plots. Values of $r_{89,95}$ for a set of samples are used as abscissae and corresponding values of $r_{i,95}$ are used as ordinates. The points can usually be fitted with a fair degree of confidence to the line:

$$\log r_{i,95} = a_i + b_i \log r_{89,95} \qquad (1)$$

Values of a_i and b_i can be determined by linear regression, together with coefficients of correlation and limits of confidence.

In Freiling's study of fractionation data[1], a slightly different method of correlation was presented, in which $r_{95,89}$ was used as abscissa and $r_{i,89}$ as ordinate. This earlier method regards the mass-95 chain and mass-i chain as fractionating from mass 89. The present method regards mass 89 and mass i as fractionating from mass 95. This latter point of view seems preferable as the mass-95 chain (having no volatile members) is usually regarded as non-fractionating.

If data are fitted to equation 1, the resulting slope, b_i, will indicate the degree to which the nuclide i fractionates from zirconium-95 relative to the fractionation of strontium-89 from zirconium-95. If i does not fractionate at all, the slope will be near zero; if i fractionates like strontium-89, the slope will be near one; intermediate fractionation yields slopes between zero and one, while degrees of fractionation greater than that of strontium-89 will give slopes greater than one. The quantity b_i is thus a measure of the volatility of the behaviour of the mass-i chain.

The significance of the intercepts, a_i, is less clear cut. If all the correlation lines pass through the point ($r_{89,95} = 1$, $r_{i,95} = 1$), then some part of the debris may exist that has the same relative proportions of radionuclides as the unfractionated fission-product mixture. Interpretation of the significance of the intercept values is complicated by the fact that they may be strongly affected by calibration errors in the determinations, as well as by errors in the nuclide yield estimates for the device.

Experience gained so far in making correlations of this kind indicates that strontium-89 and zirconium-95 are most satisfactory choices for reference fractionating and non-fractionating nuclides. However, in the case of the Hardtack data, zirconium-95 was not determined, and it was necessary to choose cerium-144 instead. The results seem satisfactory. For silicate-surface bursts it seems that the choice of molybdenum-99 would serve equally well. If necessary, one might choose caesium-137 instead of strontium-89, since these two nuclides show similar fractionation behaviour.

The data used in this article pertain to samples collected from three events of Operation Hardtack in 1958. The three events were all high-yield detonations. The first was a land-surface burst on a coral island; the second was a water-surface burst fired on a barge in deep water; and the third was a water–land-surface burst fired on a "Landing Craft Utility" (LCU) in 15 ft. of water over a coral reef.

The data for all particulate samples from these events were utilized in this investigation. All samples were collected by aircraft, except for one rocket-collected sample from the water-surface event. Some of the samples are from low altitude (1,000 ft.), the others from high altitudes (39,000–60,000 ft.). Some of the latter were separated into 'coarse' and 'fine' fractions.

Figs. 1 and 2 are examples of the log–log plots of the data. Fig. 1, the plot for strontium-90, illustrates the case of a nuclide that fractionates from cerium-144 almost as strongly as strontium-89, while Fig. 2, for molybdenum-99, illustrates a case of little or no fractionation from cerium-144. Data from all three events are included on each of the figures, and the correlation behaviour seems to be slightly different from one event to the other. In Fig. 1, for example, most of the data points for the land-

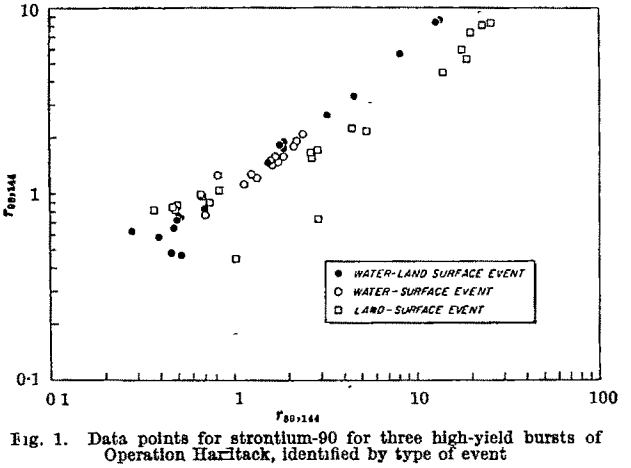

Fig. 1. Data points for strontium-90 for three high-yield bursts of Operation Hardtack, identified by type of event

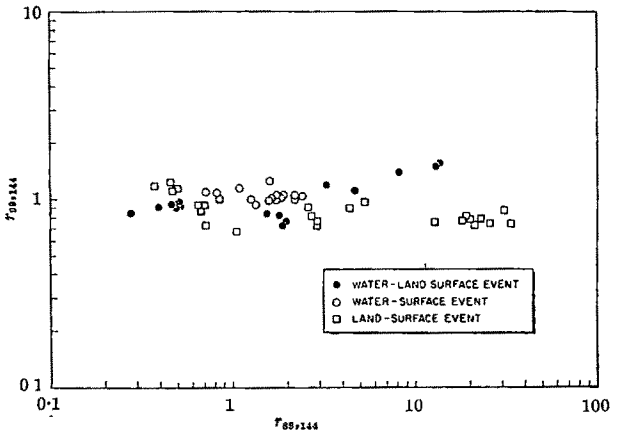

Fig. 2. Data points for molybdenum-99 for three high-yield bursts of Operation Hardtack, identified by type of event

surface event seem to lie on a line somewhat displaced from the line on which lie the data points for the other two events. In Fig. 2, the points for the water–land surface event suggest a slight positive correlation, while those for the land-surface event suggest a slight negative correlation. In view of these apparent differences, the data for the three events were correlated separately.

The points in Figs. 1 and 2 illustrate the wide range of fractionation observed in these samples. The values of $r_{89,144}$ vary by a factor greater than 100. However, for the water-surface event data point the range of this value is compressed to a factor of 3·4.

Figs. 3 and 4 show the same data points used in Figs. 1 and 2, but in this case the plotting symbols indicate the type of sample rather than the event. It is noteworthy that the data points for the low-altitude samples are contained in a relatively narrow range, the $r_{89,144}$ values being usually less than one. The samples collected at high altitudes, on the other hand, show nearly the complete range of $r_{89,144}$ values.

It is tempting to speculate that the narrow range of fractionation observed in the water-surface event, as compared with the other two events, was caused by some differences in the burst conditions. However, there is no assurance that the sampling of the cloud was sufficiently extensive to display the complete range of fractionation that actually existed, so that the absence of extremely fractionated samples in the water-surface case may be fortuitous.

The samples which were separated into fine and coarse fractions give some indication of the effect of particle size on the radionuclide fractionation. In all cases the $r_{89,144}$ value was lower for the coarse fraction than for the corresponding fine fraction. However, the r-values for fine fractions or coarse fractions, each considered as a class, do not fall into any well-defined range; on the contrary, they show wide variation.

The parameters for fitting the following line to the data:

$$\log r_{i,144} = c_i + m_i \log r_{89,144} \qquad (2)$$

are presented for the three Hardtack events in Tables 1, 2 and 3: the 95 per cent confidence limits are given as estimates of error. A positive value of the slope (with a coefficient of correlation sufficiently large to indicate that the data follow the equation reasonably well) means that nuclide i fractionated from cerium-144 in the same qualitative way that strontium-89 fractionated from cerium-144. The magnitude of the slope indicates the relative extent of the fractionation of nuclide i and strontium-89. A negative value of the slope, with a reasonably large negative coefficient of correlation, indicates fractionation in a reverse sense, that is, cerium-144 fractionated from i in the same way that strontium-89 fractionated from cerium-144. If nuclide i did not fractionate from cerium-144, both slope and coefficient of correlation should have small absolute values. Intermediate values of the coefficient of correlation (usually associated with relatively large confidence limits) indicate that the fit of the equation to the data is not sufficiently good to justify the drawing of conclusions.

Tables 1, 2 and 3 include values of the parameters for equation (1) as recalculated to fit the data from Operation Redwing. The Redwing burst referred to in Table 1 is described by Freiling[1] as a burst of megaton range at the surface of a coral atoll; the burst identified by *DWB* 1 in Table 2 was a sub-megaton burst at the surface of deep water, while *DWB* 2 was a burst of megaton range at the surface of deep water; and the burst in Table 3 was a burst of megaton range at the surface of shallow water.

Linear correlations of the Hardtack data were also made, by fitting the data to the following equation:

$$r_{i,144} = k_i + j_i r_{89,144} \qquad (3)$$

The data appear to fit equation (2) and equation (3) about equally well. The two kinds of correlation give the same indications as to the fractionation behaviour of the nuclides. For reasons discussed by Freiling[1], the logarithmic correlation is preferred, and the parameters of the linear fit are not presented in this article.

The land-surface burst of Operation Hardtack should compare with the coral-surface burst of Operation Redwing. The correlations for the latter, shown in Table 1, are based on zirconium-95 as reference nuclide, while those of the former are referred to cerium-144. As can be seen from the table, the Redwing data show the possibility of slight fractionation of cerium-144 from zirconium-95. Nevertheless, the slopes for the other nuclides agree for the two events within the 95 per cent

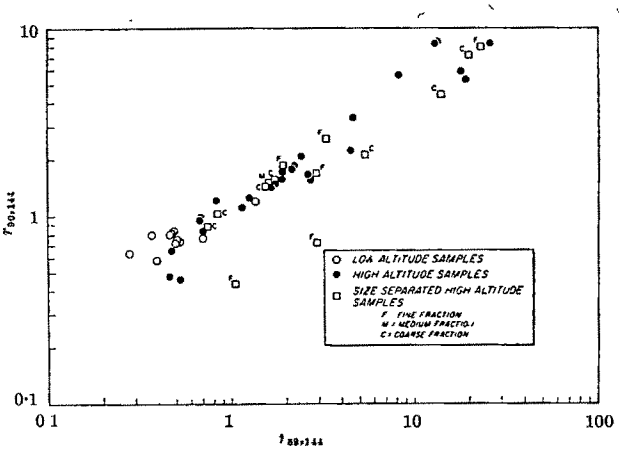

Fig. 3. Data points for strontium-90 for three high-yield bursts of Operation Hardtack, identified by type of sample

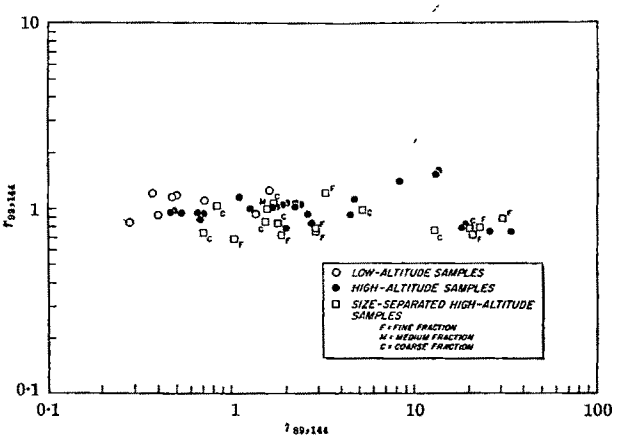

Fig. 4. Data points for molybdenum-99 for three high-yield bursts of Operation Hardtack, identified by type of sample

confidence limits. The fairly clear indication (based on the coefficient of correlation) of slight negative fractionation of uranium from cerium-144 in the Hardtack burst, as compared with the inconclusive case for negative fractionation of uranium from zirconium-95 in the Redwing burst, may also reflect a small degree of positive fractionation of cerium-144 from zirconium-95. The difference in behaviour is small relative to the other uncertainties in the data, and the Hardtack and Redwing correlations may be regarded as essentially in agreement.

Comparison of the parameters for the two water-surface bursts in Table 2 tends to support the observation that cerium-144 is slightly less refractory than zirconium-95. The Redwing burst shows positive fractionation of molybdenum-99 and uranium from zirconium-95 (for the *DWB* 2 event), but there is no conclusive evidence of fractionation of these nuclides from cerium-144 in the Hardtack burst.

Table 1. LEAST-SQUARE PARAMETERS FOR FITTING EQUATION 2 TO LAND-SURFACE EVENT DATA

Strontium-90	0·72 ± 0·12	1·0 ± 0·14	0·99	6
Molybdenum-99	−0·32 ± 0·33	0·76 ± 0·42	−0·74	7
Caesium-137	1·1 ± 0·74	0·64 ± 0·85	0·91	6
Cerium-144	−0·05 ± 0·18	0·76 ± 0·23	−0·32	7
Uranium-237	−0·15 ± 0·22	0·75 ± 0·28	−0·60	7
Uranium-239 (Neptunium-239)	−0·16 ± 0·25	0·78 ± 0·31	−0·60	7

The data on the two water–land-surface bursts in Table 3 do not support the foregoing interpretation. The cerium data from the Redwing burst do not show definite evidence of fractionation from zirconium. Furthermore, the definite positive fractionation of molybdenum-99 from cerium in the Hardtack burst and its failure to fractionate positively from zirconium in the Redwing burst suggest that cerium was slightly more refractory than zirconium in these bursts. There is no apparent reason why water–land-surface bursts should show this difference in behaviour, as compared with land-surface or water-surface bursts.

In all three Hardtack events, caesium-137 fractionated to about the same extent as strontium-89. These observations are in good agreement with the Redwing correlations. The Hardtack correlations of the yttrium-91 data show positive fractionation in all three events. There is indication that this fractionation of yttrium-91 was considerably more extensive in the water–land-surface burst than in the land-surface burst. The slope from the yttrium-91 correlations for the water-surface burst is intermediate to the other two. However, the limits of confidence are rather large, and the possibility of agreement with one of the other two bursts cannot be excluded.

The molybdenum-99 and caesium-136 data indicate that fractionation in the water–land-surface burst was not intermediate to that in the land burst and water burst. Molybdenum showed slight negative fractionation in the land event, no fractionation in the water event, and positive fractionation in the water–land-surface event. Similarly, caesium-136 fractionation increased in the order: land surface < water surface < water–land surface.

The calcium data for the land-surface burst show evidence of slight negative fractionation from the reference nuclide. The calcium data for the water-surface burst are few and inconclusive. In the case of the water–land burst, the data are contradictory because the calcium-45 correlation definitely indicates fractionation, while that for macroscopic calcium does not. The unreliability of these data (as well as of the calcium data on the water-surface burst) is suggested by the large confidence limits.

No firm conclusions can be drawn from the sodium data. The high coefficient of correlation, associated with large 95 per cent confidence limits, in the land-surface case may be due to the scarcity of data points. In the water–land surface case the coefficient is inconclusive and the limits still large, although there are a large number of datum points. In the water-surface case the correlation is clearly insignificant, but the very wide 95 per cent confidence limit for the slope suggests that the data are erratic.

The uranium data suggest negative fractionation in the land-surface burst but no significant fractionation in the water–land-surface burst. For both europium and uranium, in the case of the water-surface burst, the data are inconclusive.

It is noteworthy that, in all seven cases reported here, the uranium-237 data agree with the molybdenum-99 data. This may indicate that these nuclides do not fractionate from each other in the situations under discussion, although Freiling and Kay have shown[2] that they fractionate considerably from each other in air-burst debris.

In summary, the correlations presented in this article from the Hardtack data compare well with the correlations of similar data presented by Freiling[1]. Although the Hardtack data are more extensive, they are not sufficient in scope and precision to give much insight into such questions as the relative fractionation behaviour of zirconium-95 and cerium-144.

LETTERS TO THE EDITOR

GEOPHYSICS

Semi-annual Variation in Upper-atmosphere Density

A SEMI-ANNUAL variation in upper-atmosphere density, with maxima in April and October, and minima in January and July, was discovered in 1960 and has been generally accepted as a feature of the upper atmosphere at heights of 250–600 km. In a recent article, Anderson[1] suggested that the variation is a disguised effect of latitude. Anderson's hypothesis can be tested by analysing the orbit of a satellite of a near-circular polar orbit which samples all latitudes in a nearly equal degree. If the semi-annual variation is recognizable in the orbit of such a satellite, it cannot be due to changes in latitude.

Samos 2 (1961 α 1) is a suitable satellite, having an orbital inclination of 97°, a mean height near 500 km and a mean eccentricity of about 0·005. The motion of *Samos* 2 during 1961 and 1962 has been analysed using orbital data given in *Spacetrack Bulletins* and orbits recently determined at the Royal Aircraft Establishment[2].

Fig. 1 shows the monthly change Δa in the semi-major axis of the *Samos* 2 orbit, expressed as a fraction of the Earth's equatorial radius R. Small corrections have been made to allow for the effects of an oblate atmosphere with day-to-night variation in air density[3,4], the small variation in eccentricity due to the odd harmonics in the Earth's gravitational potential, and the decline in solar activity between 1961 and 1962. The change in semi-major axis is an indication of the average (over all latitudes) of the air density at heights near 500 km. The last four points in 1962 are likely to be the least accurate, because the orbital data are not so complete at these times. Satisfactory values are not available for February in either year.

The mean of the values for 1961 and 1962, shown by the solid line, reveals a semi-annual variation, the maximum values of $10^6\ \Delta a/R$ being 73 in April and 89 in October, and the minimum values being 44 in July and January. Thus at 500 km height in 1961–62, there is a clear semi-annual variation, independent of latitude, with the maximum density exceeding the minimum by a factor of 2·0.

Ionospheric Storms and Small Pressure Fluctuations at Ground Level

IN the past a number of attempts have been made to establish relationships between events occurring in the troposphere and in the ionosphere[1–3]. However, none of them has as yet been decisive. Recent work[4,5] has shown that it may be possible to link the two regions by the passage of gravity waves from one region to the other. Infrasonic waves, recorded at ground level near polar regions[6], indicate a possible relationship between aurora and these infrasonic waves. Earlier[7], infrasonic waves had been recorded at Washington, D.C., at times of magnetic activity travelling at speeds somewhat higher than the local speed of sound. Maeda and Watanabe[8] and, more recently, Iyengar[9] have discussed the possibility of pressure waves being generated at auroral heights. Also, Maeda and Young[10] have discussed the periods of pressure waves from aurorae. Bowman[11] has suggested that pressure waves generated near polar regions may be responsible for ionospheric storms at the times of magnetic storms. This report gives some results of possible troposphere–ionosphere relations from the analysis of microbarograph records, which have been made at Brisbane since July 1963. The type of microbarograph used is described by Jones and Forbes[12].

At about 0310 h on August 19, 1963, the microbarograph record at Brisbane begins a period of increased intensity, for the short-period oscillations (period less than 1 min),

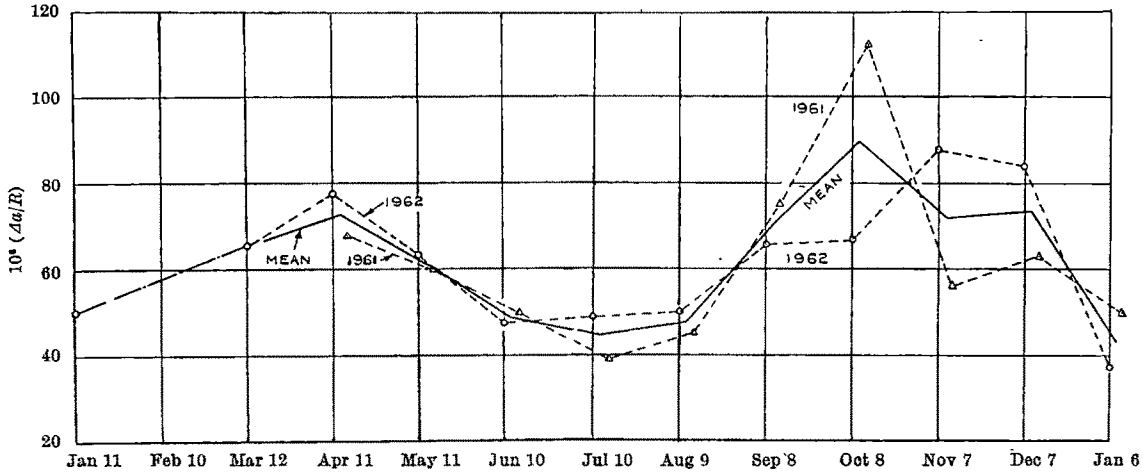

Fig. 1. Monthly change Δa in the semi-major axis of the *Samos* 2 satellite during 1961–1962, after correction for solar activity, etc.

which lasts for about 20 min. For the rest of the night this short-period activity is low. Several hours of the activity during the night can be seen from Fig. 1*A*, where the reported increased activity is also shown. Fig. 2 shows tracings of ionograms taken at Brisbane around this period. At 0310 h there is a dramatic F_2-layer height rise characteristic of ionospheric-storm behaviour, and after about 30 min the layer becomes stable again. Around these times the tracings of ionograms from Townsville (Fig. 2) also show the passage of a well-defined disturbance. Tracings of Canberra ionograms for the period are also shown in Fig. 2. Although the disturbance is not so well defined at Canberra as at the other stations, it is nevertheless well identifiable. There is a sudden height rise in the F_2-layer between 0150 and 0200 h of about 40 km and a burst of intense sporadic-*E* occurrence around these times.

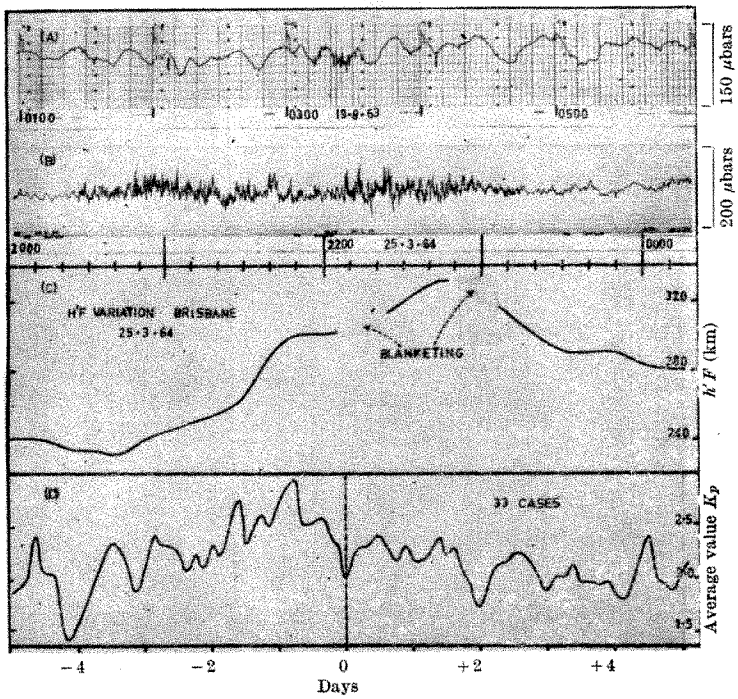

Fig. 1. (*A*) Microbarograph record on 19.8.63; (*B*) microbarograph record on 25.3.64; (*C*) *h'F*, variation at Brisbane on 25.3.64; (*D*) average K_p values for 5 days before and 5 days after selected tropospheric ionospheric events

This type of sporadic-*E* event often accompanies ionospheric disturbances. Inspection of the second- and third-multiple traces shows the height rise more clearly. Using times when it was thought the disturbance could first be detected, 0200 h for Canberra, 0250 h for Brisbane and 0300 h for Townsville, a calculation was made of the velocity of the disturbance, assuming that it advanced with a straight front. All times used are Eastern Australian Standard Time. The velocity of travel so calculated was about 300 m sec^{-1}, in a direction approximately north-east. Allowing for the fact that at Townsville and Canberra the ionograms were taken at 15-min intervals and at Brisbane at 10-min intervals, the calculated velocity is comparable with that found by Bowman[11] for ionospheric storms. Although a sudden commencement does not precede these events, there is an increase in the K_p value from 4− to 6+ about 6 h previous to these events.

During July 1, 1963, to December 31, 1964, some thirty-three cases have been found in which changes on the microbarograph record at the times of ionospheric height rises suggest a possible tropospheric–ionospheric association. Fig 1*B* shows an especially clear-cut example where the period of increased microbarograph activity coincides with the movement of the F_2-layer to greater heights (Fig. 1*C*). For the thirty-three cases the average value of the K_p index has been obtained at 3-h intervals for 5 days on either side of the events, using a superimposed epoch method. The high values of average K_p which occur prior to the zero time, reaching a peak about 18 h before, suggest that the ionospheric height rises are those produced by ionospheric storms. Fig. 1*D* shows the plot of average K_p values.

An analysis of ionograms at Brisbane for the 18-month period (July 1963–December 1964) revealed 123 occasions in which a height rise (F_2 layer) of 50 km or more occurred, or in which there was a drop in critical frequency of the F_2 layer greater than 0·5 Mc/s. On forty-nine occasions there was definitely no corresponding series of microbarograph oscillations, while on forty-one occasions the presence or absence of the microbarograph oscillations could not be decided owing to general confusion ('noise') on the records. For the thirty-three cases mentioned above, seventeen appeared

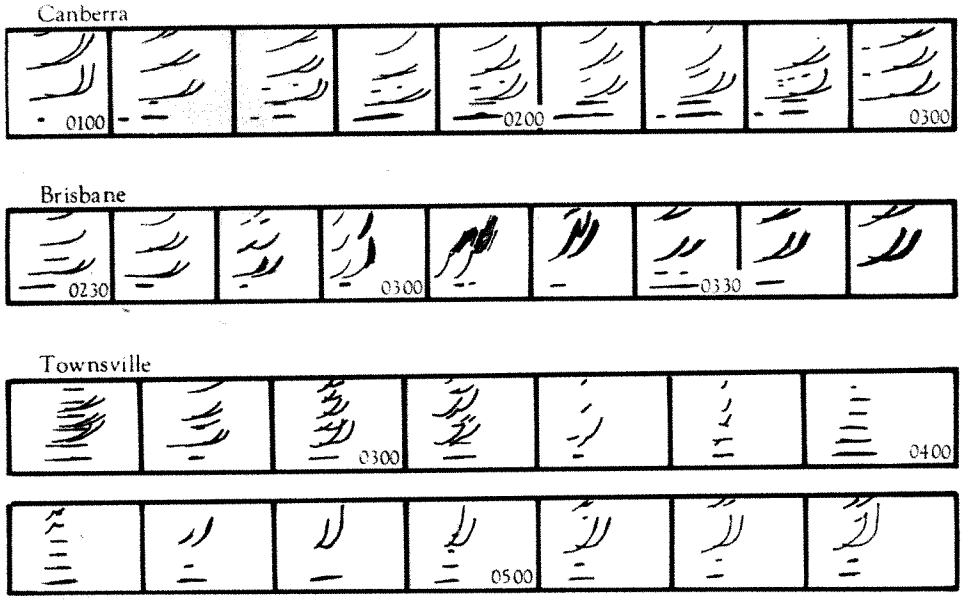

Fig. 2. Ionograms from Canberra, Brisbane and Townsville at selected times on 19.8.63 showing the progression of an ionospheric disturbance

as short-period oscillations (less than 1 min) sometimes resembling noise (Fig. 1*B*). For six of these cases, the period was greater than 1 min but less than 3 min. The remaining ten cases had periods greater than 3 min.

The results presented here appear to support Bowman's suggestion[11] that ionospheric storms are associated with pressure waves travelling from polar regions in the sound channel at an altitude of about 80 km, provided it is permissible to assume that coupling between this channel and the troposphere can occur in some cases (around 40 per cent) but not in others.

We thank Prof. H. C. Webster for his help, and the Ionospheric Prediction Service for making the ionograms available. This work forms part of the research programme of the Radio Research Board of C.S.I.R.O., Australia.

PHYSICS

Isotope Shifts in the Near Infra-red Bands of Diatomic Sulphur

STUDIES of the near infra-red bands of diatomic sulphur (S_2) showed[1,2] that they form two systems of bands involving (*a*) $^3\Pi_g$—$^3\Delta_u$ and (*b*) $^3\Pi_g$—$^3\Sigma_u^+$ transitions with $^3\Pi_g$ being the common initial level for both the systems. Bands of the isotopic molecules, $^{32}S\ ^{34}S$ and $^{34}S_2$ (in addition to $^{32}S_2$), have now been obtained. Vibrational and rotational analyses of these bands confirm the observations of earlier studies[2] and show that the emitter of the near infra-red bands is the diatomic sulphur molecule. Further, the isotope shifts provide a correct vibrational assignment of the bands in both the systems. The results of these investigations are presented in this communication.

The near infra-red bands are excited by a micro-wave discharge of 2,450 mc/sec through trace quantities of sulphur enriched with 37·2 per cent of sulphur-34 and 2–3 mm of helium. The spectra are photographed in the first order of a 6·6 m concave grating spectrograph at a dispersion of 1·1 Å/mm and shown in Fig. 1. The bands in (*a*) are due to $^{32}S\ ^{34}S$, $^{32}S_2$, and $^{34}S_2$, with their intensities decreasing in that order. In juxtaposition are the bands of $^{32}S_2$ in (*b*) obtained in discharges through natural sulphur[2].

The sub-bands at 6983·8 Å and 7069·6 Å belonging to $^3\Pi_g$—$^3\Delta_u$ transitions and those at 7506·8 Å and 7433·6 Å of $^3\Pi_g$—$^3\Sigma_u^+$ transitions show no significant isotope shifts (Fig. 1). This clearly indicates that the bands involve 0–0 transitions. The 0–1, 0–2, 0–3 bands, due to $^{32}S\ ^{34}S$ and $^{34}S_2$, show progressively larger shifts towards the shorter wave-length side of $^{32}S_2$ bands.

Isotope shifts of the bands due to $^{32}S\ ^{34}S$ and $^{34}S_2$ are calculated from the relation:

$$\nu_0 - \nu_0^i = (1-\rho)\{\omega_e'(v'+\tfrac{1}{2}) - \omega_e''(v''+\tfrac{1}{2})\} - (1-\rho^2)\{\omega_e'\chi_e'(v'+\tfrac{1}{2})^2 - \omega_e''\chi_e''(v''+\tfrac{1}{2})^2\}$$

where $\rho = \sqrt{\mu/\mu^i}$, μ and μ^i are the reduced masses of $^{32}S_2$ and $^{32}S\ ^{34}S$ (or $^{34}S_2$).

The lower-state vibrational frequencies and their successive differences are known from the observed bands. However, the vibrational constants of the common upper state $^3\Pi_g$ are not known, since vibrational levels with $v' \geqslant 1$ are predissociated. An anharmonicity equal to that of the lower state is assumed in calculating the isotope shifts. A value of 500 cm^{-1} for ω_e' gives a reasonable fit of the observed isotope shifts for the bands of $^{32}S\ ^{34}S$ and $^{34}S_2$ molecules, as can be seen from Table 1.

0–2	12,501·9$_7$		−14·2*	−13·7		
		12,368·2*	−14·6*	−13·7	−29·3*	−27·7

ν_0 refers to $^{32}S_2$ and ν_0^i to the isotopic molecule $^{32}S\ ^{34}S$ or $^{34}S_2$.
* Values from band head data.

Previous studies of the $^3\Pi_g$—$^3\Delta_u$ bands of $^{32}S_2$ showed that in the $v'=0$ level predissociation occurs at $J'=34$ in the $^3\Pi_{2g}$ state and at $J'=16$ in the $^3\Pi_{1g}$ state. Present studies of the rotational structure of the $^{32}S\ ^{34}S$ bands show that these predissociations occur at $J'=35$ and $J'=17$ levels of the $^3\Pi_2$ and $^3\Pi_1$ states respectively. Further, in the case of the $^{32}S\ ^{34}S$ molecule, the distinction between the symmetric and antisymmetric rotational levels that exists in $^{32}S_2$ or $^{34}S_2$ disappears as a result of which no alternate lines are missing. It is indeed found that the

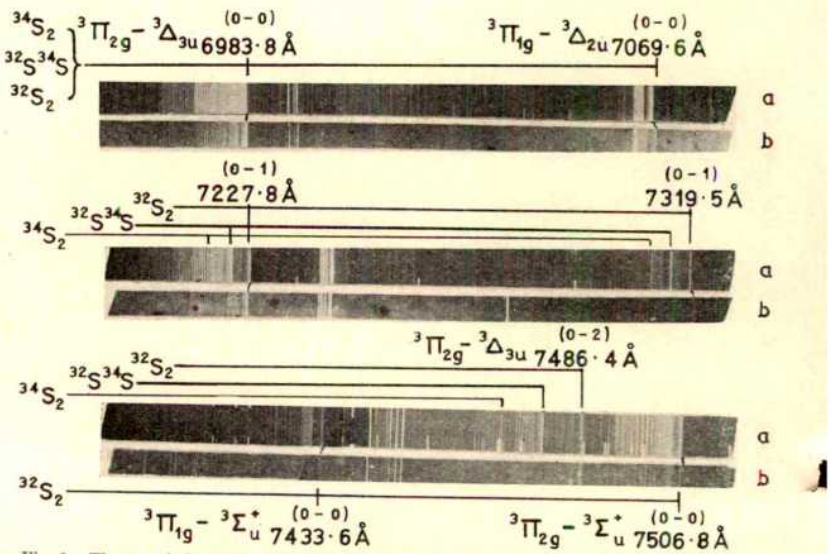

Fig. 1. The near infra-red bands of diatomic sulphur taken at a dispersion of 1·1 Å/mm. Bands in (*a*) are due to $^{32}S\ ^{34}S$, $^{32}S_2$ and $^{34}S_2$ while those in (*b*) are of $^{32}S_2$ obtained in discharges through natural sulphur. Because of a slight difference in the dispersion, the $^{32}S_2$ bands in (*a*) do not coincide exactly with those in (*b*)

even as well as odd rotational lines are present in the $^3\Pi_g$—$^3\Sigma_u^+$ transition.

Precursor Shock produced by 0·25-g Chemical Explosions

J. M. DEWEY, in a letter[1] written some months ago, described precursor shocks produced by a 500-ton hemispherical charge of 2,4,6-trinitrotoluene (TNT) fired on the ground. He suggested that the precursor shocks were probably formed by ground waves feeding energy into the air ahead of the air shock.

We have fired 0·25-g spherical charges of penta-erythritol tetranitrate (PETN) on a steel plate and photographed the air shock-pattern using the schlieren technique. These photographs have shown a precursor shock and in some firings a portion of the precursor was downward-facing (similar to Dewey's description). To investigate his explanation of precursor formation we positioned a soft plasticene wall close to the charge, the object of this being to separate the direct air shocks from any ground-induced waves on one side of the charge. A photograph of the wave pattern from one of the firings is shown in Fig. 1; before the final exposure was made, 60 μsec after charge detonation, two separate exposures were taken to superimpose (i) a 5-cm grid and (ii) the charge position on the photographic plate. The steel-driven air shocks are visible on the right of the picture, and are similar to those observed by Boys[2]. Waves transmitted through the plasticene wall are also visible. On the left-hand side the precursor is seen leading the main air shock. A series of photographs has shown that the precursor is eventually overtaken by the main air shock which it then lags behind, becoming progressively weaker. A firing on a wooden plate showed that the precursor was less advanced of the main air shock at 60 μsec, and its intersection with the main air shock occurred at a reduced height above the surface.

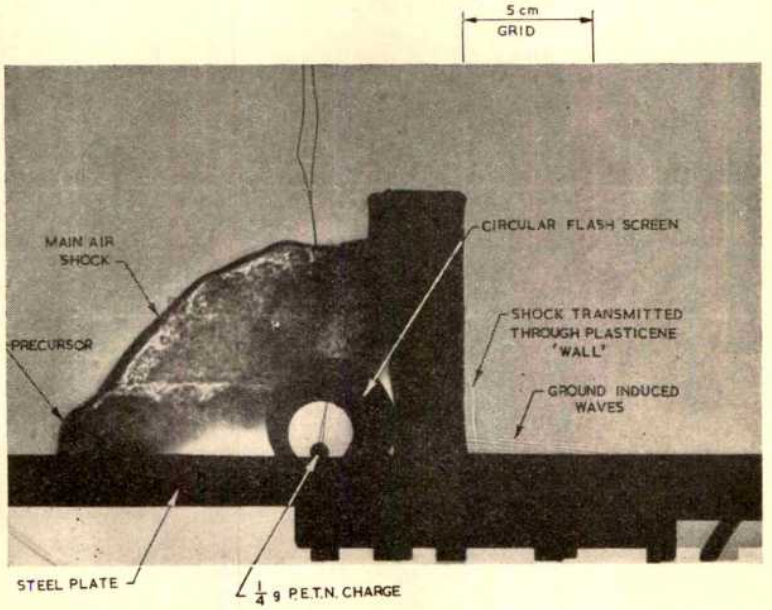

Fig. 1. Photograph of wave pattern from 0·25 g charge fired on a steel plate

These results suggest that, under certain conditions, precursors may be produced by the feedback of energy into the air from strong ground waves interacting with the main air shock.

Adsorption of Oxygen on Ultra-thin Titanium Films

A COMMON preparatory method used in the investigation of thin films is evaporation of a metal on to a non-metallic substrate. The actual formation of the film on the substrate is an intriguing process, for a collection of independently nucleated islands must grow together to form a continuous, two-dimensional body. This process has been examined with an electron microscope by Bassett *et al.*[1] and they have documented the case of gold on sodium chloride.

During the period in which the metal film is composed of discontinuous islands, electronic conduction through the film is difficult to explain by any mechanism other than tunnelling. Neugebauer and Webb[2,3] have considered this problem in association with the fact that such films have a negative temperature coefficient of resistance. Their conclusions are embodied in a conduction mechanism in which an electron must first be activated before it can tunnel across the gap separating the islands. The basic parameters which must be considered in this mechanism are related by the following equation*:

$$\sigma = \frac{A\,de^2\sqrt{2m\varphi}}{rh^2}\exp\left[-\frac{\varepsilon}{kT}\right]\exp\left[-\frac{4\pi d\sqrt{2m\varphi}}{h}\right] \qquad (1)$$

* Symbols are: σ, film conductivity; A, constant; d, inter-island distance; r, island radius; e, electronic charge; m, electronic mass; ε, activation energy; T, temperature; φ, metal work function; h, Planck's constant; k, Boltzman constant.

The dependence of equation (1) on the island radius, film temperature, and change in inter-island distance caused by thermal expansion of the substrate has been confirmed[2,3], but the tunnelling parameters, that is, metal work function and change in inter-island spacing caused by oxidation of the metal islands, have not been examined experimentally.

In the present investigation, the adsorption of oxygen on ultra-thin titanium films has been used to test the effect of a change in work function and inter-island distance on film conductivity. During the chemisorption of a monolayer of oxygen, the change in film conductivity caused by a change in work function can be determined. If the change in work function is known from other measurements, a value for the inter-island distance can be calculated from equation (1).

The reaction of oxygen with titanium does not stop with the adsorption of a monolayer of gas. Even at room temperature, an oxide layer continues to form. The oxide growth serves to increase the tunnelling distance between the metal islands if the assumption is made that tunnelling takes place from the surface of the metal and not from that of the oxide.

Equation (1) can be modified to include the empirical rate equation for the room-temperature oxidation of titanium[4].

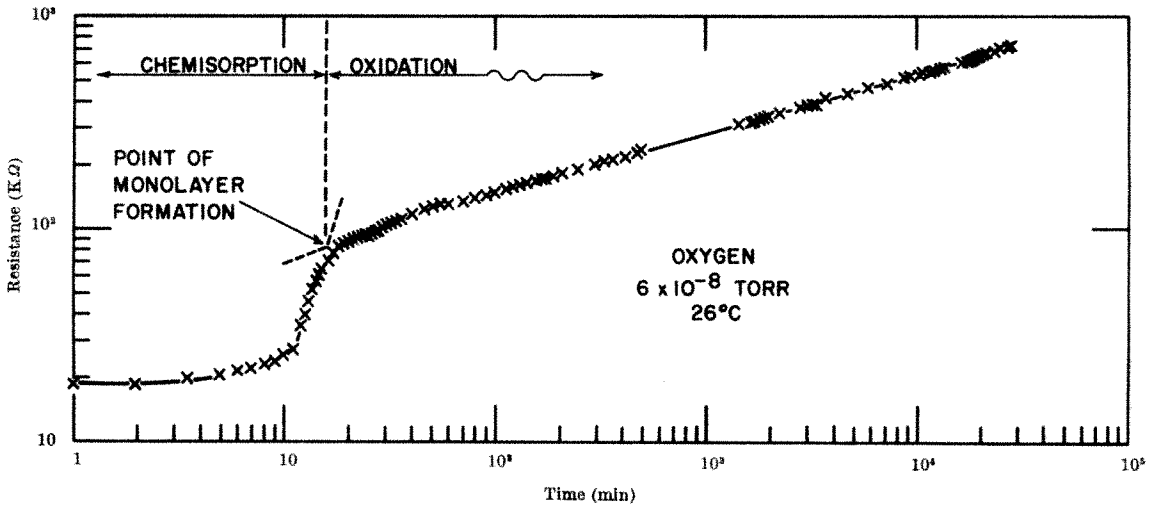

Fig. 1. Change in titanium film resistance

$$s = K \log (at + t_0) \qquad (2)$$

where s is the oxide thickness, t, the time, and K, a, and t_0 are constants. (t_0 may be disregarded when t is large.)

The tunnelling distance, d, is related to the oxide thickness, s, by the fact that d increases twice as fast as s. This increase may be related to a change in film conductivity, σ, by differentiating equation (1) with respect to d. Since s is a function of time (equation 2), and d is related to s, σ may be expressed as a function of time as follows:

$$\frac{\Delta \log \sigma}{\Delta \log t} = \frac{0{\cdot}87K}{d_0}\left[1 - 9{\cdot}26 \times 10^7\ \varphi^{1/2}\ d_0\right] \qquad (3)$$

where d_0 is the inter-island distance before oxidation has begun and K is the oxidation rate constant. Using the value of d_0 calculated from chemisorption data and the slope of the log–log plot of conductivity versus time, a value for the room-temperature oxidation rate constant of titanium can be found.

An ultra-high vacuum system has been used in examining the effect of adsorbed oxygen on the resistance of discontinuous titanium films. A base pressure of 1×10^{-9} torr and a substrate temperature range of $+250°$ to $-196°$ C were available. The gas inlet system was used to maintain a dynamic oxygen pressure between 1×10^{-8} and 1×10^{-6} torr. Titanium was evaporated on to glass slides at a rate of 10 Å/min and at a pressure no greater than 2×10^{-8} torr. The film thickness was controlled by halting the evaporation at a prescribed value of resistance. Immediately after evaporation, the titanium was exposed to oxygen and the film resistance was monitored as a function of time. Oxygen pressure was kept constant throughout the run.

Titanium films with a resistance in the neighbourhood of 20 kΩ (≈5 Å thick) were shown to be discontinuous by the fact that the temperature coefficient of resistance was negative[2]. Alternating current resistance as a function of frequency and electron diffraction also supported this conclusion.

The results of oxygen adsorption at room temperature on a 20-kΩ titanium film are shown in Fig. 1. The induction period was found to increase with a decrease in pressure but proved to be independent of temperature. These properties fit an explanation based on chemisorption. Hence equation (1) could be applied to the data and a value of d_0 calculated. Values of the work function and conductivity for the initial titanium film and the film covered with an oxygen monolayer were substituted into equation (1) expressed in log form. The resulting pair of equations was solved simultaneously and a value of d_0 equal to 5 Å was found for the 20-kΩ titanium film.

The break in the log resistance versus log time curve indicated the formation of a complete monolayer of oxygen. It was at this point that the reaction between titanium and oxygen slowed down, as shown by a rise in the vacuum system pressure. The continued reaction of oxygen with titanium beyond the point of monolayer formation produced the log–log linear plot. This could be attributed to oxidation, for it showed a small dependence on temperature but proved to be independent of pressure.

Using the value of d_0 obtained above and the slope of the linear portion of Fig. 1, a rate constant for the room temperature oxidation of titanium was calculated to be approximately 2×10^{-9} cm. This number agrees with the extrapolated results of Andreeva and Alekseeva[5] ($K = 1{\cdot}6 \times 10^{-9}$ cm).

The results of this study confirm the tunnelling explanation for conduction in discontinuous metal films. The dependencies of σ on φ and d, as stated by the equation of Neugebauer and Webb, allow the calculation of an inter-island distance and an oxidation rate constant which agrees with published data.

Effect of an Electron-scavenging Solute on the Radiolysis of *Cyclo*hexane

ALTHOUGH a considerable body of evidence exists indicating that solutes of a radical scavenging nature depress the yields of the principal products (hydrogen, *cyclo*hexene, di*cyclo*hexyl) from the gamma radiolysis of *cyclo*hexane[1], the effect of electron scavenging solutes is less well characterized. Scholes and Simic[2] have shown that in the presence of nitrous oxide, a powerful electron but feeble hydrogen atom scavenger, the hydrogen yield is decreased by a factor of two ($G(H_2) = 2{\cdot}78$ at $[N_2O] = 100$ mM), $G(N_2)$ being 3·75 at the same concentration. In the course of similar investigations on carefully de-aerated *cyclo*hexane we have observed a marked increase in the gamma radiolysis yield of di*cyclo*hexyl (see Table 1). The measured yields are independent of dose rate in the range 0·2–2·5 M rads/h and independent of nitrous oxide concentration in the range 15–130 mM. Impoverishment of nitrous oxide in the liquid phase was avoided by the use of low total doses (< 0·5 M rad) and by performing

irradiations on samples in which gas–liquid equilibration was facilitated by a high surface to volume ratio of the liquid.

The radiolysis yields obtained in the presence of iodine, a very effective *cyclo*hexyl radical scavenger, are also given in Table 1. It will be seen that there is no change in the residual di*cyclo*hexyl yield ($G(R_2) = 0{\cdot}3$) whether or not nitrous oxide is present, and that iodine disappears to an increased extent in the presence of nitrous oxide, the increase being independent of initial iodine concentration. At initial concentrations less than 0·9 mM, iodine is consumed almost entirely as a result of reaction with *cyclo*hexyl radicals[3]. The enhanced yield of *cyclo*hexyl radicals responsible for the disappearance of solute, $\Delta G(R\cdot)$, may therefore be equated with $\Delta G(-I)$, that is, 1·75. The enhanced di*cyclo*hexyl yield, $\Delta G(R_2) = 0{\cdot}85$, in the presence of nitrous oxide but in the absence of iodine, is equivalent to $\Delta G(R\cdot) = 2\Delta G(R_2) = 1{\cdot}70$ if it is assumed that the additional *cyclo*hexyl radicals react only by dimerization. It is well established, however, that radical disproportionation to *cyclo*hexane and *cyclo*hexene also occurs and we must therefore assume that a part of the additional di*cyclo*hexyl yield is due to processes not involving radicals.

The formation of di*cyclo*hexyl and other radiolysis products has been explained both in terms of reactions involving radicals and ions. *Cyclo*hexyl radicals may be produced either from direct excitation of *cyclo*hexane, or from the excited state produced by ion recombination:

$$RH \rightsquigarrow RH^+ + e \quad (1)$$

$$RH^+ + e \longrightarrow RH^* \quad (2)$$

$$RH^* \longrightarrow R\cdot + H\cdot \quad (3a)$$

$$\longrightarrow C_6H_{12} + H_2 \quad (3b)$$

If β and $(1-\beta)$ designate the probabilities that the excited state formed by ion recombination will decay by reactions (3*a*) and (3*b*) then, for each electron scavenged, there is a loss of not less than β *cyclo*hexyl radicals. Further *cyclo*hexyl radicals may, however, be produced by abstraction:

$$H\cdot + RH \longrightarrow H_2 + R\cdot \quad (4)$$

and the total loss of radicals per scavenged electron therefore lies between β and 2β, the exact value depending on the extent of hydrogen atom abstraction. Because nitrous oxide undergoes dissociative electron capture, we may postulate the following additional steps which result in two *cyclo*hexyl radicals:

$$N_2O + e \longrightarrow N_2O^- \longrightarrow N_2 + O^- \quad (5)$$

$$O^- + RH \longrightarrow R\cdot + OH^- \quad (6)$$

$$RH^+ + OH^- \longrightarrow R\cdot + H_2O \quad (7)$$

It is therefore evident that there will be an overall increase of between $(2-\beta)$ and $2(1-\beta)$ *cyclo*hexyl radicals per scavenged electron. Retention of excitation energy by the water molecule (reaction 7) may also result in the formation of further *cyclo*hexyl radicals.

Although a detailed mechanism cannot be proposed until a complete analysis of product yields has been made, the foregoing sequence is able to explain, at least qualitatively, the main features of our experiments. In addition, the postulated mechanism is able to account satisfactorily for the reported decrease in hydrogen yield in *cyclo*hexane[2] and polyethylene[4], and for the production of water and nitrogen in stoichiometric equivalence to the disappearance of nitrous oxide in polyethylene[4]. While it is possible to account for most of our observations in terms of enhanced *cyclo*hexyl radical production, it is also probable that electron scavenging will enhance ion-molecule reactions of the type discussed by Libby[5].

CHEMISTRY

Electron Spin Resonance Spectra associated with Nitrogen in Diamonds

MANY diamonds show an electron spin resonance spectrum which has been attributed to the presence of single nitrogen atoms substituted for carbon at a diamond lattice site. Smith *et al.*[1] found four types of nitrogen donors, equally abundant and differing only in their hyperfine axes, these being the four C–N bond directions. They measured the hyperfine coupling constants for $^{14}N(I=1)$, and for $^{13}C(I=\frac{1}{2})$ in the nearest neighbour positions (denoted centre I). Loubser and du Preez[2] found additional lines in the spectrum, which they attributed to interaction of the unpaired electron with carbon-13 at other lattice sites (centres II, III and IV). The hyperfine coupling constants are recorded in Table 1, together with the orbital populations. These populations were obtained using values of $|\psi_{2s}(0)|^2$ and $\langle r^{-3}\rangle_{2p}$ calculated from self-consistent-field atomic wave functions derived by Mayers and by Roothaan and Clementi (see ref. 3). (We have omitted any correction for the δ+ charge on nitrogen and the δ− charge on carbon: this would increase the spin density on carbon at the expense of the nitrogen.)

The calculated spin populations on nitrogen-14 and one of its nearest neighbour carbon-13 atoms are 0·29 and 0·79 respectively, so the electron is almost entirely localized on these atoms, and, contrary to common supposition, predominantly on the carbon. (The total calculated spin density of 1·08 is sufficiently close to unity to give some confidence that the calculations are reasonable.)

Prior to distortion, the bonding between nitrogen and any one carbon atom can be represented by the energy-levels of a pseudo diatomic molecule (Fig. 1), involving overlap of sp^3 hybrid orbitals. The unpaired electron is then accommodated in the σ*-antibonding orbital with a consequent increase in the bond length. As a result of this relaxation, there will be an increase in the *p*-character of the orbitals involved in bonding between nitrogen and carbon, and because the unpaired electron is more closely associated with the carbon atom, a relatively greater increase of *p*-character in the carbon orbital is expected. Thus the energy separation between the nitrogen and carbon *s*–*p* hybrid orbitals will be increased, as depicted in Fig. 1, and this results in an even greater concentration of the antibonding electron on the carbon. In the limit of complete separation, the unpaired electron would be in a pure *p* orbital of the carbon, and the bonding electrons would become a lone-pair on the nitrogen, but the constraints of the lattice prevent such a limit being reached. This accounts for the calculated values of the p/s ratio (λ^2), which are 10·9 for carbon-13 and 3·6 for nitrogen-14.

Loubser and du Preez[2] found three additional groups of lines (centres II, III and IV in Table 1), ascribed to

Table 1

interaction of the unpaired electron with carbon-13 nuclei other than C_a (centre I). They assigned the centre with the largest hyperfine coupling (centre II) to carbon-13 in one of the three positions basal to the nitrogen (C_b in Fig. 2), on the assumption that the unpaired electron spends more of its time close to the nitrogen. However, even if this assignment is altered to carbon-13 in positions basal to the carbon in the N–C_a bond (C_c in Fig. 2), since our calculations have shown that the greatest spin density is on the C_a carbon, there would seem to be no explanation for the fact that the hyperfine interaction is axially symmetric about the N–C_a bond axis. Therefore, we suggest that the lines of centre II arise from unpaired electron density on the carbon atoms C_d, that

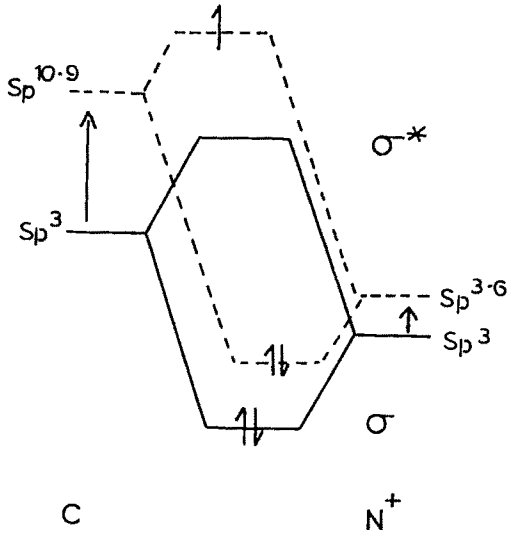

Fig. 1. Energy-level diagrams for the pseudo-molecule CN^+. The full lines represent the undistorted centre, and the dashed lines show the effect of distortion on the energy-levels

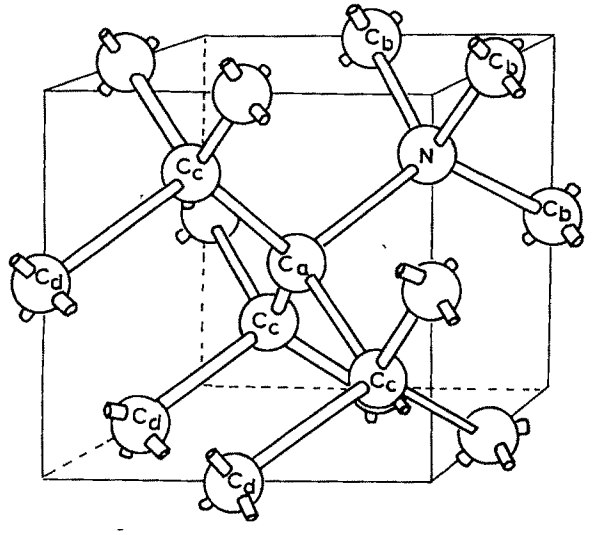

Fig. 2. Part of the diamond lattice showing the nitrogen impurity and the carbon atoms C_a, C_b, C_c and C_d referred to in the text

is, carbon atoms in the β-position with respect to C_a. Hyperfine interaction with the C_d carbons would be expected to have axial symmetry about the C_c–C_d bond, which is parallel to the C_a–N bond direction. Thus the observed dependence of the hyperfine splitting on the direction of the external magnetic field would be explained. It is envisaged that transfer of spin density into the C_c–C_d bond might occur by a mechanism similar to hyperconjugation, the effect being enhanced by the relatively large C_a carbon p-character in the antibonding orbital. Since this effect depends on the fact that the C_c–C_d and C_a–N directions are parallel it is possible to see why interactions with only three of the nine β-carbon atoms are detected. The minor deviations from axial symmetry that were observed can be explained qualitatively in terms of a direct dipolar interaction with spin on C_a. Centres III and IV may be reasonably assigned to carbon atoms C_c and C_b, respectively.

It is interesting to compare the manner in which an extra electron is accommodated in other nominally tetrahedral structures. In phosphorus-doped silicon, electron spin resonance investigations have shown that the phosphorus hyperfine coupling is purely isotropic[4]. The extra electron is no longer mainly localized in any one bond, but is dispersed widely throughout the silicon lattice, with only a very small spin density (0·01) at the phosphorus atom. Thus the electron has avoided the energetically unfavourable antibonding site occupied in diamond by becoming delocalized on to many silicon atoms. This contrast is most readily understood in terms of the presence of relatively low energy 3d levels on the silicon atoms.

In PF_4, however, the unpaired electron causes considerable distortion from the tetrahedral symmetry of the PF_4^+ cation[5], thereby reducing its antibonding character. In this case, the molecule is free to distort in a manner which is virtually impossible for carbon in the diamond lattice. For nitrogen in diamond, the electron in an undistorted frame would be accommodated in an antibonding molecular orbital probably having a_1 symmetry, as in the case of undistorted PF_4 molecule[5]. It becomes localized in a single C–N bond only as a result of the distortion already discussed. It is interesting to note that this distortion does not have the dynamic character often associated with Jahn–Teller distortions, in that the extra electron remains in any one C_a–N σ*-orbital for a time that is long compared with the hyperfine frequencies for carbon-13 and nitrogen-14.

We thank the Science Research Council for a maintenance grant.

Note added in proof. Our attention has been directed to a recent communication[6] in which a molecular orbital treatment is given for this centre and conclusions are drawn which are very similar to our own.

2537 Å Mercury Photosensitization of Liquid Water

THE solubility of mercury in water is 0·32 μM at 25° C and 1·7 μM at 90° C (ref. 1). The dissolved mercury absorbs the 2537 Å resonance line although not to the same extent as in the vapour phase due to the solvation broadening of its absorption band[2]. It has been shown that mercury-saturated liquid hydrocarbons will undergo photosensitization[3–6] and the results of these investigations have been compared with those from high-energy radiolysis indicating that the process can be of value in the study of the behaviour of molecular fragments and excited states in the liquid. This communication reports some preliminary results in the photosensitization of liquid water and its application to the characterization of the intermediates involved in the radiolysis.

A Hanovia *SC*-2537 low-pressure mercury resonance lamp was used which surrounded the cylindrical cell fabricated from type 7910 'Vycor' (transparent to $\lambda > 2100$ Å). Triply-distilled conductivity water from a tin-lined Barnstead still was shaken with liquid mercury at 80° C for 30 min. Nitrogen or other gases were bubbled through the solution for 20 min before irradiation and, unless otherwise noted, the solution was constantly swept during photolysis. Liquid mercury was always present in order to ensure saturation and the cell and lamp were air thermostated at 80° ± 3° C. The gas phase zone was masked. Only in runs longer than 4 h was evaporation appreciable (> 10 per cent).

Hydrogen peroxide was determined spectrophotometrically[7]. Fig. 1 shows the yield of hydrogen peroxide as a function of exposure time with nitrogen or argon as the bubbling gas. The fall-off of the initial linear rate after 3 h is attributed to photolysis and secondary reactions of the peroxide. The initial quantum yield of hydrogen peroxide formation is about 0·005—based on uranyl oxalate actinometry[8]. No hydrogen peroxide was produced in the absence of mercury.

The formation of hydrogen peroxide can be explained by the combination of OH radicals formed in some primary energy transfer step such as:

$$Hg^* + H_2O \rightarrow H + OH + Hg \quad (1)$$

or:

$$\rightarrow HgH + OH \quad (2)$$

$$\rightarrow Hg + H \quad (2a)$$

where $Hg^* = Hg(6^3P_1)$ and $Hg = Hg(6^1S_0)$. Step 1 is endothermic and can be eliminated. From either step H atoms would be expected to be present; their combination would produce hydrogen. Hydrogen gas is a good scavenger for OH radicals[9], and if not swept from the system would be expected to cause a reduction in the yield of hydrogen peroxide. When no gas was swept through the deaerated solution during exposure, the yield of hydrogen peroxide built up to a steady but low concentration as shown in Fig. 1. Furthermore, when hydrogen was used as the sweeping gas, no hydrogen peroxide was observed for exposures as long as 4 h. In addition, the use of OH scavengers[9,10] such as carbon monoxide, methane, ethane and butane as the sweeping gas caused the complete quenching of the yield of hydrogen peroxide.

This behaviour of the system toward the nature of the sweeping gas strongly suggests that H and OH radicals are present. However, the molecular generation of hydrogen and hydrogen peroxide from an excited state of water according to steps similar to those proposed by Anbar, Guttmann and Stein[11] cannot be immediately discounted:

$$Hg^* + H_2O \rightarrow H_2O^* + Hg \quad (3)$$

$$H_2O^* + H_2O \text{ (or } H_2O^*) \rightarrow H_2O_2 + H + H \text{ (or } H_2) \quad (4)$$

Such an excited state, which could be the precursor of H and OH radicals as well, may be a metastable long-lived

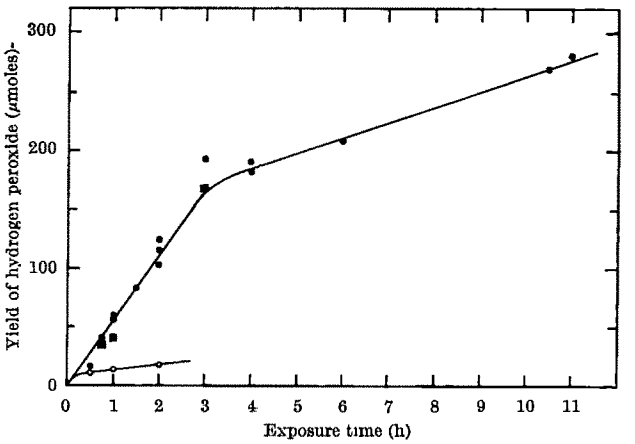

Fig. 1 Production of hydrogen peroxide in the 2537 Å mercury photosensitization of liquid water, ●, nitrogen bubbling; ■, argon bubbling; ○, presaturation with nitrogen but no bubbling during photolysis

triplet state and may be the excited water molecule proposed by several workers[11–13] to explain isotope scrambling and 'residual hydrogen' yields. If H_2O^* is indeed present in irradiated water, its yield, as shown recently[14], is very low.

It is possible to use the technique of liquid phase mercury photosensitization to generate radicals or excited states in liquid water conveniently without the use of ionizing radiation or vacuum ultra-violet techniques.

We thank Prof. G. Stein for his advice in this work, which was partially supported by a grant from the National Institutes of Health.

Note added in proof. M. Chevion, U. Sokolov and G. Stein (unpublished results) have measured the quantum yield of H_2 evolution in the 2537 Å mercury photosensitized decomposition of liquid water and find $\varphi_{H_2} \simeq 0{\cdot}003$, in fair agreement with our value for $\varphi_{H_2O_2}$.

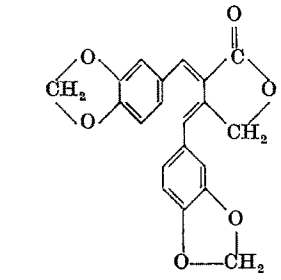
Polyamide Layer Chromatography of Lactones

POLYAMIDE is a specific chromatographic adsorbent for several kinds of organic compounds, as has been shown by Carelli *et al.*[1] (phenols and fatty acids by powder column), Davidek[2] (antioxidants by powder thin layer), Endres[3] (aromatic nitro compounds and sulphonic acids by powder column) and Wang[4] (indoles by polyamide layer). In the extension of the uses of polyamide layer as a chromatographic media, we found it suitable for the separation of lactones.



We selected seven lactonic compounds as examples for testing the separation of lactones on polyamide layer.

Table 1 gives the R_F values of lactones in three solvent systems.

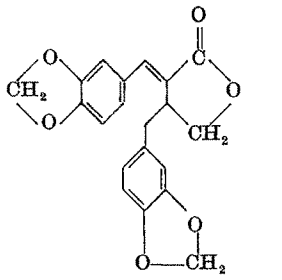


Table 1. R_F VALUES OF LACTONES ON POLYAMIDE* LAYER ACCORDING TO WANG (REF. 7)

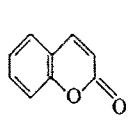
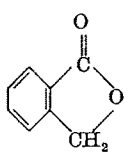
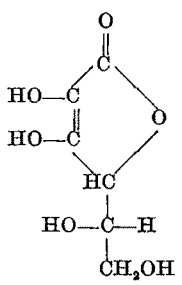
Taiwanin *A*



Savinin



Santonin



Toddalolactone

Coumarin

Phthalide

Ascorbic acid

Taiwanin *A*[5] and savinin were isolated in our laboratory from *Taiwania cryptomerioides* Hayata. They are typical lignin-type lactones and differ only in the degree of unsaturation. Santonin is a sesquiterpenoid lactone. Its ketonic group probably has some affinity to polyamide. Toddalolactone is a coumarin derivative. The low R_F value of toddalolactone in carbon tetrachloride/glacial acetic acid (9/1) system as compared with coumarin itself reflects on the fact that the two alcoholic hydroxyl groups in the molecule seem to form rather strong hydrogen bonds with polyamide. This is consistent with the behaviour of oestrone, oestradiol and oestriol which, it has been found[6], show a large difference in their R_F values on polyamide layer chromatogram. In the solvent system formic acid/water (1/2), the order is reversed and the hydrophilic hydroxyl groups make toddalolactone move faster with the aqueous mobile phase. The large number of polar groups in ascorbic acid are responsible for it remaining at the origin in the carbon tetrachloride/glacial acetic acid (9/1) system but moving to the solvent front in the formic acid/water (1/2) system. *n*-Butanol/formic acid (9/1) has been found to be the most satisfactory solvent system.

Lactones occur widely as natural products, for example, sesquiterpenoid lactones. It is preferable to separate them on polyamide due to the fact that they are less likely to be decomposed by the adsorbent.

METALLURGY

Formation of New Intermetallic Phases in Binary Eutectic Systems by Drastic Undercooling of the Melt

IT has earlier been reported[1–3] from our Laboratory that some eutectic binary alloys solidify in an amorphous condition on rapid cooling from the liquid state. The present communication deals with new crystalline phases obtained by subjecting liquid alloys of eutectic systems to severe undercooling during solidification.

A large number of alloys, covering the full composition ranges of four simple eutectic systems[4], namely silver–silicon, silver–germanium, gold–silicon and gold–germanium, were examined in the course of the present work. Small quantities of the homogenized alloys were quenched from the melt on to a copper substrate by the 'gun' technique[5], which has recently been shown[6] to produce cooling rates ranging from 10^6 to 10^8 °C/sec. The quenched thin layers of alloy were subjected to Debye–Scherrer examination at room temperature immediately after quenching as well as after annealing at higher temperatures. Details of alloy preparation, quenching procedure and X-ray examination have been described earlier[7].

Full and partial amorphous solidification was observed in gold–silicon and gold–germanium alloys respectively around the eutectic composition. Slight extension of solid solubility was noted for germanium in both silver and gold. Alloys of the silver–silicon and silver–germanium systems having somewhat higher eutectic temperatures[4] gave no evidence for amorphous solidification. There was no evidence from lattice parameters for any solid solubility of silicon in either silver or gold.

Details of crystal structures and composition of the six new intermetallic phases obtained in the present work are given in Table 1. All these phases, except γ gold–silicon, could be reproduced very well at the indicated composition ranges and proved quite stable at room temperature. Only γ gold–germanium could be obtained strictly homogeneous over an appreciable range of composition. There was strong evidence for X-ray line-broadening characteristic of stacking faults[8] in β silver–silicon, β silver–germanium, γ gold–silicon and β gold–germanium. In case of the three hexagonal close-packed structures, which could be visualized as resulting from face-centred cubic lattices by a change in stacking sequence of the close-packed layers, the stacking faults could be identified as predominantly of the growth type with a random fault for every 5 to 10 layers in the extreme cases. The β gold–silicon, γ gold–silicon and γ gold–germanium structures seem to be complex superlattices, in the light of the relations between their lattice parameters and the unit cell dimension for the adjoining face-centred cubic phase. Among these six phases, β silver–germanium and γ gold–germanium have been shown to be superconducting at 0·85° and 1·63° K respectively[9].

Table 1. Composition Range, Crystal Structure and Relation to Adjoining Face-centred Cubic Phase of the New Intermetallic Phases in Silver–Silicon, Silver–Germanium, Gold–Silicon and Gold–Germanium Systems

There seems to be a close parallel between these new crystalline phases in eutectic systems and the martensitic phases formed in some eutectoid systems (such as iron–carbon and copper–aluminium). In both instances, a new non-equilibrium single phase is produced irreversibly by a non-nucleation-and-growth mechanism from a parent phase in place of a two-phase equilibrium mixture. One may well speculate whether such so-called non-equilibrium phases in eutectic and eutectoid systems are actually the stable phases at room and lower temperatures, but are prevented from formation on slow cooling only by the extremely sluggish nature of the diffusion-controlled peritectoid reactions necessary to produce them. It is significant to note in this connexion that the equilibrium close-packed phases of comparable composition in the copper–silicon and copper–antimony systems[9] are both formed by peritectoid reactions on cooling.

The authors are grateful to Prof. Pol Duwez for suggesting this problem and for valuable comments.

BIOCHEMISTRY

Collagen-plasticizing Function of Carbohydrate Polymers

The amino-sugar-containing polysaccharides (glycosaminoglycans) of native connective tissues have engaged the attention of a large and diverse group of investigators. However, only a few[1–4] have seriously considered the possible mechanical functions which these macromolecules, either alone or in association with non-collagen proteins, might subserve *in vivo*.

Recent investigations in this laboratory indicate that 'ground-substance' carbohydrates undergo very characteristic alterations (decreased content and, possibly, depolymerization) during natural ageing processes and that these may very largely be responsible for the topological properties of native connective tissue networks[5]. Conversely, it also appears that certain carbohydrate polymers can act *in vitro* much like polymer-siluents, or plasticizers for native and 'purified' collagen matrices[6].

The present investigation was prompted by these observations. It was undertaken specifically to determine whether or not prototype carbohydrate polymers could act as 'good' solvents (and, hence, concurrently, impart both an increase in equilibrium swelling volumes and a decrease in elastic moduli[7]) for specific fibrous protein networks. The matrices selected were goatskin collagens, prepared as outlined previously[8], which were substantially free of all components except collagen. 5 per cent aqueous solutions of 'Dextran-500' and 'Dextran-500 sulphate' (purchased from Pharmacia Fine Chemicals, Inc., New Market, New Jersey) and of dialdehyde starch (100 per cent carbonyl form, kindly donated by Dr. C. L. Mehltretter, U.S. Department of Agriculture, Peoria, Illinois) were used as the 'solvent' phases.

One-inch square segments of the skins were used for the swelling investigations, and dumbbell-shaped specimens (necked-down portion = 1·58 cm) were used with a *TM* model 'Instron' tensile testing apparatus for determination of apparent elastic moduli. (The latter were determined on skin samples cut with their longitudinal axes parallel to that of the animal's vertebral column and were assumed, for purposes of the present comparative investigation only, to behave as if homogeneous and isotropic which they obviously are not. The rate of cross-head travel was 0·5 cm/min in all experiments. The 'modulus' was determined from values of nominal tensile stress-at-break using micrometer measurements of the sample thickness to determine the cross-sectional area of the necked-down portion of the test sample.) The difference in the weight of samples before and after 48 h immersion in each of the solvent phases was corrected for the observed densities of each medium to yield values for the change in sample volume. These were arbitrarily taken as the 'equilibrium' swelling volumes.

Mean values for 10–20 determinations of both equilibrium swelling volume (V_e) and apparent elastic modulus (A.E.M.) in each of the four 'solvent' media (for example, water, dextran sulphate, dextran and dialdehyde starch) are summarized in Table 1, together with data on the observed nominal tensile stress-at-break (σ_u) and change in elongation (ΔL).

Table 1. Physical Properties of Hydrated Goatskin Collagen Matrices in Various 'Solvent' Media

Compound	σ_u	ΔL	A.E.M.	ΔV_e	pH$_i$
Dextran-sulphate	32 9	2·7	1·9	+0·13	7·2
Dextran	91·4	2·4	5 9	+0·08	6·6
Water	99·2	2·3	6·7	—	6·5
Dialdehyde starch	100 9	2·2	7·0	−0·06	7·4

σ_u is the nominal tensile stress-at-break, in kg/cm^2; ΔL is the measured changed in length (cross-head displacement), in cm; A.E.M. is apparent elastic modulus, in dynes/cm^2 × 10^7 after 18 h immersion. ΔV_e is change in volume per g of initial hydrated weight, in ml./g, after 48 h immersion. pH$_i$ is the initial pH of the solvent phase.

The data obviously suggest that unoxidized carbohydrate polymers act, within physiological pH limits and directly on collagen polypeptide chains, as effective plasticizers to 'soften' collagen matrices, more or less permanently. The nominal tensile strengths and apparent elastic moduli of the skin samples were significantly decreased and both the equilibrium swelling volumes and mechanical extensibilities were increased, relative to data obtained for samples in water, in exact accord with the behaviour expected of a 'good' solvent. On the other hand, analogues which have been oxidized to the corresponding dialdehyde form[9] no longer possess this property, and in fact behave, like other aldehydes[8], as potent cross-linking agents for collagen structures.

The possibility thus exists that changes demonstrated at least in the content of the polysaccharide phases of native connective tissues may have very important secondary consequences so far as the mechanical properties of these tissues are concerned. It is also conceivable in the light both of the present data and of an expanding literature on the function of lysosomal enzymes that disruption of the sulphate moiety alone, or more general depolymerization of ground-substance carbohydrates, may, perhaps *per se*, account for the pathogenesis of a number of clinical and experimental abnormalities of the connective tissue system.

This investigation was aided, in part, by grants from the National Institute of Arthritis and Metabolic Diseases and the American Cancer Society. The invaluable technical assistance of Richard A. Murray is gratefully acknowledged.

Binding of Aliphatic Aldehydes to Collagen and Elastin Matrices

PREVIOUS publications from this laboratory have demonstrated that specific hydrated aliphatic aldehydes[1,2] react both *in vitro* and *in vivo*[3–5] with the freely rotatable nitrogen atoms[6] of native and 'purified' collagen and elastin chains. The resulting products are highly cross-linked network structures[7] which are characterized by 'locking-in' of dipoles[8] normally present along the respective polypeptide chains. Unfortunately, little is known about the quantitative aspects of the involved reactions. The presently reported investigation was accordingly prompted, in which the binding of two specific C_3 aldehydes to hide powder collagen, extracted aortic elastin, intact (control) bovine thoracic aortae and sonicated bovine thoracic aorta preparations were investigated.

The prototype aldehydes selected were propionaldehyde, a highly charged (specific conductivity, 345 μmho/cm) non-cross-linking agent which exists in solution in the unhydrated or free carbonyl form, and acrolein, a weakly charged (specific conductivity, 9·3 μmho/cm) but potent cross-linking agent which exists in solution in the hydrated aldol (β-hydroxy-carbonyl) form[1].

The hide powder (American Standard) collagen sample, which had been previously limed and neutralized, was purchased from F. R. Marshall, Ridgeway, Pennsylvania, and had a known shelf life of about 3 years. Bovine thoracic aortae, freshly obtained from a local abattoir, were used for the remaining preparations. Elastin was isolated at 45° C for 45 h from defatted aortae according to the formic acid procedure described by Hass[9]. Sonicated aorta preparations were made by sonicating control specimens in 2 per cent sodium hydroxide in sealed 'Pyrex' tubes within the water-filled well of a commercial apparatus ('DiSONtegrator', system 40, Ultrasonic Industries Inc., Engineers Hill, New York) for 24 h. The final temperature was 45° C. All matrices were thoroughly washed in cold, running tap water for 24 h, ground twice in an ordinary household meat grinder and finally dehydrated *in vacuo* over calcium chloride and silica gel at room temperature before use. No attempt was made to achieve uniformity in the particle size of the respective tissue samples.

Microscopic sections, stained by the van Gieson–Verhoeff, periodic acid–Schiff and hematoxylin-and-eosin techniques, revealed the presence of only collagen and elastin fibres, respectively, in the hide powder and aortic elastin samples. The control aorta preparation possessed normal compact architecture with intact cells and fibres. The sonicated preparations were composed of a loosely arranged, entirely acellular matrix with variably disrupted fibres; these stained positively with elastin histochemical stains, and were apparently devoid of any associated ground-substance materials. Electrophoretic patterns of each matrix, obtained after dichloracetic acid solubilization by the method of Milch, Gey and Naughton[10], revealed distinctly different patterns for each of the respective matrices (Fig. 1).

200-mg aliquots of each dried matrix were overlaid with 10 ml. of 0·15-M aqueous aldehyde solutions in stoppered tubes. Three control tubes (aldehyde solution alone) and five experimental tubes (aldehyde + matrix) were used in every run. Between five and seven runs were made with each aldehyde and each matrix. In each, approximately 2 μl. of the supernatant liquid phase were removed from all tubes after 1, 2, 3, 4, 5 and 24 h of interaction and analysed by a gas chromatographic procedure recently described by Clifford and Karmen[11]. (A 'Packard' coiled glass column (10′ × 2 mm internal diameter, catalogue No. 5392910), packed with 14 per cent ethylene glycol adipate, was used with an '*IDS*' model 20 Barber Coleman gas chromatograph. The latter was equipped with a hydrogen flame detector. The inlet temperature was 140° C and the column temperature was 80° C.) The extent of binding was calculated from mean values of the measured differences in supernate aldehyde concentration between the control and experimental tubes at each stipulated time. No corrections were made for volume losses due either to sampling or to evaporation, since both were well within the limits of error of the analytical procedure.

Representative data are summarized in Table 1.

These indicate that essentially identical amounts of both acrolein or propionaldehyde were bound by each matrix over the first 3 h of interaction, in the order: sonicated aorta > hide powder collagen > control aorta > aortic elastin.

Little or no additional binding occurred with propionaldehyde over the ensuing 21 h. With acrolein, however, continued binding over the remaining 21 h of the experimental period was observed with all of the matrices except elastin. Binding capacity was again greatest with the sonicated aorta preparation; lesser amounts were

Table 1. BINDING OF ALDEHYDES TO CONNECTIVE TISSUE MATRICES

Matrix	Propionaldehyde						Acrolein					
	1	2	3	4	5	24	1	2	3	4	5	24
Hide collagen	67 5	64 4	64·0	66 6	70 1	64·4	49·6	63 9	61 0	85·3	95·0	100 9
Elastin	17 0	27·4	25 2	30 5	39·2	41 8	13·1	16 4	25 6	30 7	39 1	40 8
Aorta	19 6	36·2	40 1	36 2	38 8	34·9	16·4	39 5	48 8	49·4	63·9	108·9
Sonicated aorta	56 2	54 9	78 9	80 6	68 8	77 1	51 7	60·9	72 8	102 6	103 0	247 7

Binding is expressed in terms of mg bound/g initial dry weight after stipulated number of hours of interaction.

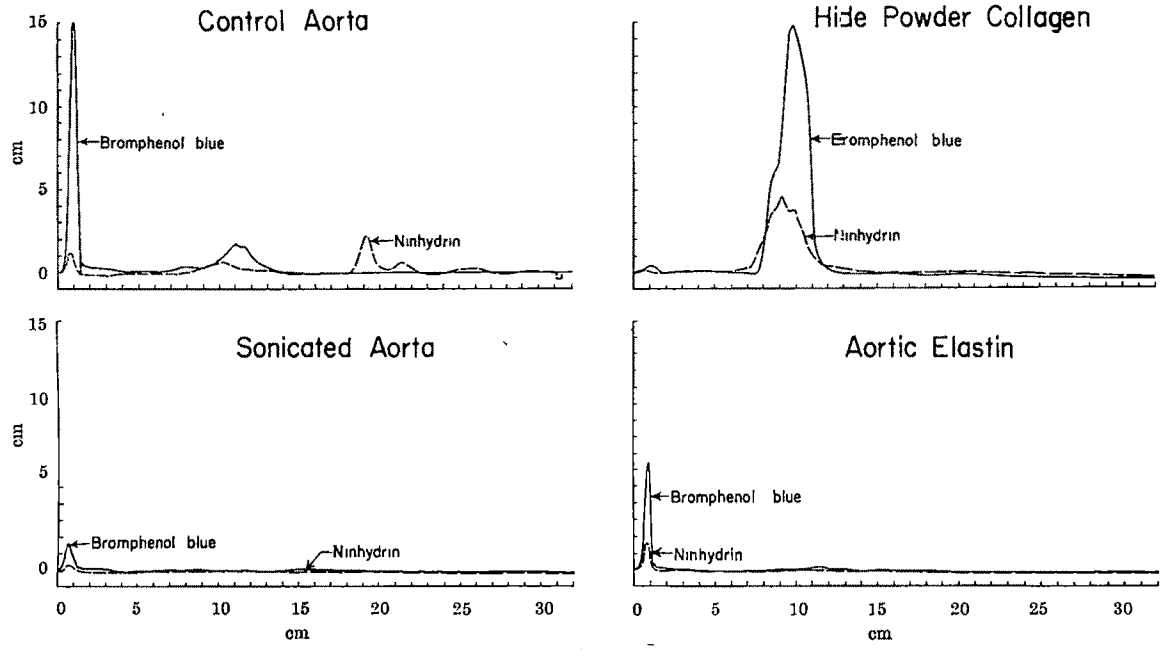

Fig. 1

bound by hide powder collagen and the untreated aorta preparations. Elastin showed the least amount of binding.

Elastin chains prepared as outlined here thus presumably possess but a limited number of sites to which aldehydes can bind, irrespective of their conformation, the time of interaction or the ion-dipole or dipole-dipole nature of the involved reactions. The same appears to be true for all other matrices over the first three hours of interaction. Thereafter, however, additional sites evidently become available for acrolein but not for propionaldehyde molecules. These possibly arise in consequence of chain scission phenomena, which appear to accompany interchain cross-linking reactions at high aldehyde concentrations[8,12], such as used here.

These differences in the binding capacity of each matrix for either of the two aldehydes may be explained, in part, by differences in the gross or 'fabric' structure of the respective matrices. In larger part, however, the differences are probably best accounted for in terms of the network structure of the respective fibres and fibre bundles. Hide collagen fibres with low internal cross-link densities and substantively free of associated carbohydrate components would be expected, in agreement with the experimental observations, to possess relatively more apparent binding sites for aldehydes than do the more highly cross-linked polypeptide chain networks, such as represented by the elastin and the control aorta preparations. Similarly, it might also be predicted that more or less selective extraction of the alkali-labile protein-polysaccharide complexes of native ground-substance materials[13,14] would liberate chemically or sterically hindered protein N—H groups and thus increase relative aldehyde-binding capacities. This also accords with the experimental observations. Finally, 'purified' matrix fibres which possess relatively few reactive amino and/or amide groups per unit length of polypeptide chain, such as elastin[15], would also be expected to possess relatively low aldehyde binding capacities. This, too, is in agreement with what was found.

The data thus support the conclusion that, in fibrous protein networks, the availability of freely rotatable amino nitrogen atoms[6] to reactive aldehydes is governed not only by the number of such groups but also by both the internal (intra- and inter-chain) cross-link density of the respective chains and the presence (and probably aggregation state) of the associated ground-substance protein-polysaccharide copolymers[14]. Furthermore, the quantitative extent of binding appears to be critically dependent on the nature of the binding reactions, becoming generally asymptotic with non-cross-linking aldehydes and increasing progressively (concomitant with and probably due to backbone chain scission) with cross-linking aldehydes.

This work was supported, in part, by a gift from the Alan Wurtzburger Memorial Fund of the Johns Hopkins Hospital and by a grant from the National Institute of Arthritis and Metabolic Diseases.

Ribonucleic Acid Polymerase Activity in Extended and Contracted Chromosomes

VARIOUS reports have appeared in the literature concerning the absence of RNA synthesis in metaphase cells. An explanation commonly given is that the condensed or compacted state of chromosomes prohibits DNA trans-

scription[1]. This explanation is supported by evidence that regions of condensed chromatin in an interphase nucleus are sites of minimal RNA synthesis[2]. We wish to report some results of recent studies on RNA metabolism during the meiotic cycle which provide additional evidence on the relationship between the physical state of the chromosomes and RNA synthesis. Two features of meiosis are relevant to this report: (1) Cells in early prophase of meiosis (leptotene) synthesize RNA at a much higher rate than those at metaphase[3]. Indeed, it is probable that no RNA is synthesized during metaphase. (2) At leptotene, chromosomes are in their most extended form; at metaphase, they are in their most contracted form. The biochemical and cytological data are thus consistent with the view that the capacities of chromosomes to transcribe DNA into RNA are inversely related to their degree of condensation. We addressed ourselves to the question of whether *in vitro* studies of isolated nuclei and chromosomes could yield information on the respective roles of RNA polymerase and template availability in accounting for established observations. Meiotic cells obtained from anthers of *Tulipa gesneriana* were used in these experiments.

Leptotene nuclei or metaphase chromosomes were isolated from tulip microsporocytes in a 1 : 1 (v/v) glycerol: water mixture containing the following molarities of solutes: sucrose, 0·5; potassium chloride, 0·01; ethylenediamine tetraacetic acid (EDTA), 0·002; sodium–potassium phosphate buffer (*p*H 6·95), 0·01. The cells were disrupted by means of a 'French' pressure cell and the suspension then fractionated by differential centrifugation. Details of the procedure are described elsewhere[3]. The isolated fractions were incubated in 0·2 ml. of medium containing the following components (in μmoles): *tris* buffer (*p*H 7·9), 8·0; manganese chloride, 0·2; magnesium chloride, 0·8 ; 2-mercaptoethanol, 2·5; each of the four nucleotide triphosphates (ATP, GTP, UTP, CTP), 0·08. Assays were carried out at 37° C for 10 min according to the procedure of Chamberlin and Berg[4]. This time interval was chosen because rates were found to be linear for the first 15 min. Assays of RNase and nucleotidases indicated no significant differences in activities between the stages studied. Moreover, the magnitudes of the activities were low enough to be overlooked in determining the comparative rates of RNA synthesis in the different preparations.

Evidence that the RNA synthesized *in vitro* is a product of DNA-dependent RNA polymerase is summarized in Table 1. Omission of any one of the four triphosphates resulted in activities which were below the limits of detection. Treatment with DNase or actinomycin *D* abolished 80–90 per cent of the activity. Higher percentages of inhibition could not be obtained by increasing the concentrations of either DNase or actinomycin *D* (up to 5 μg/ml.). This minor component of RNA synthesis was not further investigated. The efficiency of the isolated fractions in synthesizing RNA may be judged by comparing the results with those of Huang and Bonner[5]. The endogenous activity of their crude chromatin preparations was of the order of 200 μmoles nucleotide incorporated per mg DNA in 10 min at 37° C. The activities of the isolated nuclei or chromosomes are of the order of 2–3 mμmoles. The reason for this ten-fold difference in rate is not apparent since meiotic cells are probably less active in RNA synthesis than embryonic cells.

Table 1. EFFECTS OF VARIOUS FACTORS ON RNA SYNTHESIS BY ISOLATED NUCLEI AND CHROMOSOMES FROM MEIOTIC CELLS OF TULIPS

Preparation	Control	+4 μg DNase	+8 μg DNase	+Actinomycin *D* (0·5 μg/ml)	−GTP	−CTP	−ATP
Nuclei	99	7	7	12	<5	<5	<5
Contracted chromosomes	107	11	11	28	<5	<5	<5

Nuclei were obtained from cells in early prophase. Contracted chromosomes were obtained from cells of which about 70 per cent were in metaphase and the remainder in diakinesis or anaphase. Numbers represent μμmoles of $UT^{32}P$ incorporated per 100 mμmoles of DNA-nucleotide in 10 min at 37° C.

Table 2. RNA POLYMERASE ACTIVITIES IN EXTENDED AND CONTRACTED CHROMOSOMES

Chromosome type	Series 1 ($UT^{32}P$) Intact	Series 1 ($UT^{32}P$) Broken	Series 2 ($GT^{32}P$) Intact	Series 2 ($GT^{32}P$) Broken	Series 3 ($GT^{32}P$) Intact	Series 3 ($GT^{32}P$) Broken +DNA
Extended	68	92	65	150	102	160
Contracted	47	92	48	129	105	175

Conditions of assay and expression of activities are the same as those described for Table 1. Nuclei and chromosomes were broken by rapid dilution of the suspension medium (1·5 M to 0·15 M sucrose). All suspensions were assayed in the presence of 0·5 M sucrose. Each series represents the average of 2–3 sets of measurements made at the same time. Within a series variations were of the order of ±15 per cent. Differences between series are discussed in the text. The labelled substrate used in each series is indicated. 50 mμmoles (nucleotide equivalents) of purified tulip DNA were added in Series 3.

Although considerable variability (one- to two-fold) was found in RNA polymerase activities between different batches of tulips, relative activities with respect to meiotic stage were similar within each set of preparations. One comparison between leptotene nuclei and metaphase chromosomes is shown in Table 1 and three others are shown in Table 2. In general, but not always, polymerase activity of nuclei prepared from leptotene cells is slightly higher than that of metaphase chromosomes. The activity increases if the preparations are partially fragmented but the relative activities of the extended and contracted chromosomes remain the same. Addition of purified DNA also has a stimulating effect, but again, the degree of stimulation is similar for both groups. We infer from these observations that the polymerase enzyme remains associated with the chromosomal complex through the meiotic cycle, and that the absence of RNA synthesis in living cells at metaphase is not due to a loss of enzyme from the chromosomes. The possibility that the enzyme might somehow be inactivated within the living cell during this stage cannot be excluded, but if so, *in vitro* measurements of RNA polymerase activity cannot have much significance in the interpretation of *in vivo* behaviour.

Our failure to observe a differential effect of added DNA on the respective polymerase activities of leptotene and metaphase chromosomes raised the possibility that the enzyme itself might be the limiting factor in the *in vitro* system. In order to test whether extended chromosomes provided better templates for RNA synthesis than contracted ones, purified RNA polymerase prepared from *E. coli* was added to the different fractions. In the case of intact nuclei and chromosomes a two- to three-fold increase in RNA synthesis was observed among the different stages (Table 3). Small differences in activity between different types of chromosomes may be seen in the table, but at best, these would be feeble evidence for a correlation between the microscopic morphology of the chromosomes and the regulation of RNA synthesis in their host cells. Bigger differences were observed when the polymerase was added to fragmented nuclei or chromosomes, an effect which is most easily explained by a more extensive diffusion of the enzyme into the chromosomal network. Even these differences, however, are of insufficient magnitude to account for the observed differences in rates of RNA synthesis within the intact cells. Our data on *in vivo* incorporation of uridine into RNA,

Table 3. EFFECT OF ADDED RNA POLYMERASE ON RNA SYNTHESIS IN EXTENDED AND CONTRACTED CHROMOSOMES

Chromosome stage	Series 1 (intact) Control	Series 1 (intact) +Polymerase	Series 2 (broken) Control	Series 2 (broken) +Polymerase
Leptotene	95	175	65	230
Metaphase	65	135	45	170
Post-meiotic	85	275	45	350

In these tests nuclei from cells which had just completed meiosis are included for comparison. RNA polymerase was prepared from *Escherichia coli* according to the method of Chamberlin and Berg (ref 4). The amount of enzyme used in the tests catalysed the incorporation of 6·4 mμmoles $GT^{32}P$ in 10 min at 37° C in the presence of 100 mμmoles purified tulip DNA. Activities are expressed as in Table 1. Conditions of assay were the same as those described under Table 1 except for a 30-min 'preincubation treatment' which is outlined in the text and under Table 4. The treatment was introduced in order to make these tests comparable with those concerned with the effects of mercaptoethanol

Table 4 EFFECT OF 2-MERCAPTOETHANOL ON RNA SYNTHESIS IN ISOLATED NUCLEI AND CHROMOSOMES SUPPLEMENTED WITH BACTERIAL RNA POLYMERASE

Chromosome stage	Series 1 (intact, 30′)				Series 2 (broken, 30′)			Series 3 (broken, 60′)		
	Control		Polymerase		Control	Polymerase		Control	Polymerase	
	−	+	−	+	+	−	+	+	−	+
Leptotene	100	110	175	1,120	75	230	1,180	95	485	1,600
Metaphase	70	90	140	210	40	160	190	70	165	190
Post-meiotic	85	110	300	435	45	350	550	85	350	625

Conditions of assay were the same as those under Table 3 Nuclei and chromosomes were preincubated for 30 or 60 min at 0° C in the presence of standard medium containing 0 05 M 2-mercaptoethanol. At the termination of the preincubation period, the suspensions were centrifuged and the nuclei or chromosomes resuspended in the standard assay medium. Activities are expressed as in Table 1. The time interval of preincubation and the physical state of the chromosomes or nuclei are shown in parentheses following the series number '+' and '−' indicate the presence or absence of mercaptoethanol during pretreatment.

based on analyses of cell populations similar to the ones used in these studies, indicated a five-fold difference in rate between leptotene and metaphase cells[3].

Striking differences in response were observed when nuclei or chromosomes were pretreated with 2-mercaptoethanol, an agent which causes nuclear swelling[6]. The effect was readily observed under the microscope when leptotene nuclei or metaphase chromosomes were exposed to 0·05 M mercaptoethanol at 0° C for 30–60 min. When various preparations were thus treated and then assayed in a standard incubation medium, two sets of results were obtained. In the absence of added polymerase, no appreciable increases in RNA synthesis were observed (Table 4, Series 1). In the presence of added polymerase leptotene chromosomes showed a fifteen- to seventeen-fold increase in activity; post-meiotic chromosomes showed a seven- to twelve-fold increase; metaphase chromosomes showed a three- to five-fold increase (Table 4, Series 2 and 3). The differences are even more striking if a comparison is made between preparations which were pretreated with mercaptoethanol followed by polymerase addition, and those which were preincubated without mercaptoethanol followed by polymerase addition. Under this regime, the condensed chromosomes showed very little response to the thiol reagent.

We have drawn two conclusions from the results: (1) Mercaptoethanol may have a profound effect on the capacity of chromosomes to act as templates for RNA synthesis *in vitro*. (2) The effect is observed in chromosomes which are already in the extended form as defined by cytological technique, but not in contracted chromosomes. The significance of this observation to the behaviour of chromosomes *in situ* is difficult to assess. The absolute activities of leptotene chromosomes pretreated for 60 min are in themselves impressive. Deproteinized DNA is only four times more active as template material than are these chromosomes (Table 4). Although we have not measured the amount of histone retained by the chromosomes after mercaptoethanol treatment, an appreciable loss of this chromosomal component was not observed when mercaptoethanol was used in the course of DNA preparation[7]. The suggestion has been made, however, that some proteins may be bound to DNA by disulphide bridges[6]. Whatever the effect of this reagent, we doubt whether its effect *in vitro* has any direct bearing on the intracellular regulation of RNA synthesis. More likely, it reflects certain structural changes which occur in the chromosomes during the cycle of contraction and extension.

That a change may be occurring during isolation of chromosomes and nuclei which affects the observed rates of RNA synthesis is evident on comparing the last two series in Table 4. Broken leptotene nuclei are significantly affected by the length of the preincubation period, whether or not mercaptoethanol is added. Metaphase chromosomes, on the other hand, are not affected at all whereas post-meiotic nuclei are slightly affected. The probability therefore exists that, from the very beginning of the isolation procedure, the efficiency of chromosomes to act as templates for RNA polymerase is progressively altered, the degree of alteration depending on the structure of the native chromosome. The use of cell populations which differ with respect to chromosome morphology makes this probability apparent. Differential alterations within a nucleus containing partly extended and partly contracted chromosomes would be much more difficult to detect.

On the whole, these experiments indicate that relatively little information may be gained from the techniques here used for postulating a mechanism to explain the marked changes in RNA synthesis which cells undergo during the cycle of chromosome contraction and elongation. The evidence does invite the conclusion that the enzyme itself is not a determining factor. However, on the much-debated issue of the factors which control template availability in chromosomes, the evidence obtained mainly invites scepticism.

This work was supported by a grant from the U.S. National Science Foundation. We are indebted to the Laboratorium voor Eloembollenonderzoek (Lisse, The Netherlands) for its help in providing tulip bulbs for these studies.

Hexose Content of Bovine Fibrinogen and Fibrin, and Evidence against its Release by Fibrin Stabilizing Factor

FIBRINOGEN from several species contains a small amount of hexoses as well as some glucosamine and sialic acid[1]. It has been shown that a slight decrease in its hexose content occurs when fibrinogen is clotted with thrombin[2–6], though the fibrinopeptides released by thrombin contain no carbohydrate[5,7]. Recently, evidence has been put forward that this loss of hexose, and of sialic acid, is related to the action of fibrin stabilizing factor (FSF)[1,8–11]. Such evidence is, however, difficult to reconcile with the earlier findings of a loss of hexose in experimental conditions which, because of the absence of Ca^{++} ions, would not have allowed fibrin stabilization to occur[3–6]. Indeed, the fibrin clots described in one report were clearly not stabilized as 1 per cent monochloroacetic acid was used to dissolve them[5]. Furthermore, the failure to demonstrate hexose in clot liquors after clotting fibrin monomer in the presence of FSF and Ca^{++} ions[12] makes it difficult to ascribe the release of hexose, if any, to the action of FSF. The following experiments were made in an attempt to resolve these different findings.

Crude bovine fibrinogen (Armour Pharmaceutical Co., Ltd.) was purified by the method of Laki[13]; the final product contained 94–95 per cent clottable protein and was still contaminated with potentially active FSF. Bovine thrombin (Parke, Davis and Co., Ltd.) was made

up in 0·9 per cent sodium chloride. It was exhaustively dialysed against 0·9 per cent sodium chloride to remove a contaminant found to interfere in the hexose assay. Clotting of fibrinogen was carried out in *tris*-hydrochloric acid buffer (0·05 M, *p*H 7·4) in the presence of cysteine (final concentration 0·01 M) and with or without the addition of calcium chloride (final concentration 0·01 M). In the presence of both of these latter reagents and thrombin, the fibrin formed was proved by the insolubility of control clots in 2 per cent (v/v) acetic acid to be of the fibrin$_I$ type. Conversely, fibrin$_S$ (soluble in 2 per cent acetic acid) was formed when sodium chloride was substituted for calcium chloride. The clotting mixture contained approximately 75 mg of fibrinogen and 20 N.I.H. units of thrombin, in a final volume of 6 ml. Clots were allowed to form at 37° C for 1 h and were then collected on to glass rods, so making it possible to press them out thoroughly and force out the liquors. The clots were washed with distilled water followed by 95 per cent ethanol; they were then air-dried and taken up in 3 ml. of 0·5 N sodium hydroxide for protein and hexose assays. 1 ml. of 20 per cent (w/v) trichloroacetic acid (TCA) was added to the clot liquors, whereon a slight precipitate formed which was centrifuged down and discarded. The supernatants were decanted, made up to 7·5 ml. with water and assayed for hexose. A control consisted of the entire clotting mixture except for thrombin. No clotting occurred and after 1 h at 37° C protein was precipitated by the addition of 1 ml. of 20 per cent TCA; thrombin (20 U.) was then added and the mixture centrifuged. The precipitate was washed with 95 per cent ethanol and then treated as described for the fibrin clots. The TCA supernatant was made up to 7·5 ml. with water and assayed for hexose.

Protein was determined by the method of Lowry *et al.*[14], using bovine serum albumin of known protein content as standard. Hexose was determined by the orcinol–sulphuric acid method[15], using an equimolar galactose and mannose solution as standard. A preliminary hexose assay showed that absorbance at 540 mμ was proportional to the amount of fibrinogen or fibrin used. All assays were done at least in duplicate, with appropriate reagent blanks. The entire experiment was repeated a further three times and the figures obtained were remarkably constant. The average of the results from the four experiments is shown in Table 1.

In no experiment was there found any difference, outside experimental error, in the hexose : protein ratio between fibrinogen and fibrin$_S$ or fibrin$_I$. Neither was there detected any hexose in the liquors derived from either fibrin$_S$ or fibrin$_I$ clots. If the action of FSF is to liberate 16–20 per cent of the total hexose as suggested[1,10,11], then the liquors from the fibrin$_I$ clots in the experiments reported here would be expected to contain 17–20 μg of hexose per 1 ml. Also, a significant drop in the hexose : protein ratio of fibrin$_I$ would be expected, as thrombin liberates only 3 per cent of the total protein from fibrinogen[1]. Fibrin$_S$ and fibrin$_I$ had the same hexose : protein ratio, however, and this together with the fact that no hexose was detected in the fibrin$_I$ clot liquors support the negative findings of Rosenberg and Carman[12] as to the supposed action of FSF. Moreover, these results do not agree with the earlier findings that fibrin (that is, fibrin$_S$) contains up to 20 per cent less hexose than fibrinogen. This is probably because these early hexose determinations were expressed as a percentage of dry weight[3–6], or merely in terms of absorbance at 540 mμ[8], rather than related to protein content. The work of Hormann and Gollwitzer[16,17] has shown that the anthrone and orcinol assays for hexose are subject to interference by tryptophan and that the degree of interference differs in fibrinogen and fibrin. These authors suggest that the reported difference in the percentage of hexose in fibrinogen and fibrin is due to artefacts inherent in the assay, and they found that the absolute amounts of hexose in bovine fibrinogen and fibrin are the same[17]. It should be noted that, in the experiments reported here, it is only when the hexose and protein figures are related that parity between fibrinogen, fibrin$_S$ and fibrin$_I$ is observed.

Table 1. RESULTS OF FOUR EXPERIMENTS TO DETERMINE THE HEXOSE : PROTEIN RATIO OF BOVINE FIBRINOGEN, FIBRIN$_S$ AND FIBRIN$_I$ CLOTS, AND THE HEXOSE CONTENT OF THE CLOT LIQUORS

Material tested	Mg protein per ml. Mean	(Range)	μg Hexose per ml. Mean	(Range)	μg Hexose per mg protein Mean	(Range)
Fibrinogen control	25·6	(24·3–26·0)	269	(261–285)	10·5	(10·1–10·8)
Fibrin$_S$ clot	23·1	(22·0–24·4)	245	(229–273)	10·6	(10·1–11·2)
Fibrin$_I$ clot	21·6	(21·2–21·8)	229	(205–253)	10·6	(9·7–11·6)
Fibrinogen control liquors	—		5·4	(0–8)*	—	
Fibrin$_S$ liquors	—		5·8	(0–11)*	—	
Fibrin$_I$ liquors	—		5·9	(2–11)*	—	

* These figures are below the limits of accuracy for the orcinol method, but they clearly indicate that there is no release of hexose into the fibrin$_S$ or fibrin$_I$ clot liquors.

From these experiments, it is concluded, therefore, that fibrin stabilization by FSF does not cause the release of hexose and that, irrespective of whether or not fibrin is stabilized, its hexose content remains the same as that of fibrinogen.

This work was supported by a grant from the Nuffield Foundation.

Note added in proof. Since this manuscript was prepared, the elegant investigation of Mester *et al.*[18] has come to my notice. These workers were also unable to demonstrate any release of carbohydrate material after clotting fibrinogen.

Dihydrodiol Formation from Indanones in Rats and Rabbits

DIHYDRODIOLS have been reported as metabolites of cyclic hydrocarbons after the administration of these compounds to animals. *trans*-Dihydrodiols have been isolated from the urine of animals after the separate administration of *cyclo*hexane[1], naphthalene[2], anthracene[3] and phenanthrene[4,5]. Both *cis*- and *trans*-dihydrodiols have been isolated from the urine of animals to which indene[6] and acenaphthylene[7] had been separately administered. Dihydrodiols do not appear to have been previously reported as metabolites of cyclic ketones.

In the present investigation indan-2-one was prepared by the distillation of *o*-phenylene-diacetic acid. The product was purified by steam distillation. Indan-1-one was obtained from Kodak, Ltd., London. (±)*cis*-Indane-1,2-diol (m.p. 98–99° C) and (±)*trans*-indane-1,2-diol (m.p. 158°–159° C) were prepared by the methods described by Brookes and Young[6].

Table 1. DIHYDRODIOLS DETECTED BY PAPER CHROMATOGRAPHY IN THE URINES OF ANIMALS DOSED WITH INDANONES

Substance dosed	Animals	Dihydrodiol detected	R_F values Solvent 1 Biosynthetic	Solvent 1 Synthetic	Solvent 2 Biosynthetic	Solvent 2 Synthetic	Solvent 3 Biosynthetic	Solvent 3 Synthetic
Indan-1-one	Rabbits	*cis*-	0·30	0·30	0·36	0·36	0·60	0·60
		trans-	0·08	0·07	0·08	0·08	0·36	0·36
Indan-1-one	Rats	*cis*-	0·30	0·30	0·35	0·35	0·62	0·61
		trans-	0·07	0·08	0·08	0·08	0·40	0·38
Indan-2-one	Rabbits	*cis*-	0·29	0·31	0·36	0·35	0·60	0·60
		trans-	0·07	0·08	0·10	0·10	0·36	0·36
Indan-2-one	Rats	*cis*-	0·31	0·29	0·35	0·35	0·61	0·60
		trans-	0·10	0·08	0·10	0·09	0·38	0·38

The solvents and detecting reagents have been described by Brookes and Young (ref. 6). Solvent 1, benzene–water–ammonia (sp. gr. 0·88) (5 : 4 : 1 v/v); solvent 2, benzene–water–acetic acid (5 : 4 : 1 v/v); solvent 3, benzene–water–ethyl acetate–acetic acid (4 : 4 : 1 : 1 v/v). The dried chromatograms were sprayed with 2 per cent (w/v) aqueous sodium periodate followed 15 min later by Schiff's reagent. The dihydrodiols were located as yellow spots on a magenta background.

Seven rabbits were each given 0·5 g indan-2-one by stomach tube. In a separate experiment seven rabbits were each given 0·5 g indan-1-one by the same route. The urines were collected daily for 2 days after dosing and stored in a refrigerator.

In experiments with rats, twenty-four rats (body-weight 200–250 g) were each given 100 mg indan-2-one dissolved in 1 ml. of sunflower oil, by subcutaneous injection. The rats were given a second equal dose 24 h later. A similar experiment was also carried out with twenty-four rats. Here, indan-1-one was substituted for indan-2-one as the compound under investigation. The urines were collected daily for 4 days after the initial dosing and stored in a refrigerator. The four urines were examined for dihydrodiols in an identical manner.

The urines were adjusted to *p*H 7 and continuously extracted with ether for 48 h. The ether extracts were reduced to about 20 ml. by evaporation and were then washed with dilute sodium hydroxide solution. Portions of the extracts were then examined by paper chromatography for dihydrodiols. When the presence of dihydrodiols in the urines was detected, attempts were made to isolate the compounds. The ether extracts were dried by the addition of anhydrous calcium sulphate and the filtrate was evaporated to dryness under reduced pressure. *cis*-Indane-1,2-diol was extracted from the residues using boiling *cyclo*hexane[5] and *trans*-indane-1,2-diol with boiling chloroform[5].

As shown in Table 1, both *cis*- and *trans*-indane-1,2-diols were detected in the urines of rats and rabbits dosed separately with indan-1-one and indan-2-one. In isolation experiments, 24 mg of *cis*-indane-1,2-diol, m.p. 98°–99° C (found: carbon, 72·3; hydrogen, 6·7 per cent. Calculated for $C_9H_{10}O_2$: carbon, 72·0; hydrogen, 6·7 per cent), $[\alpha]_D$ + 41° in chloroform, was isolated from the urine of rabbits dosed with indan-2-one. The melting point was not depressed by admixture with synthetic (±)*cis*-indane-1,2-diol. The compound was examined by ultra-violet spectroscopy and paper chromatography and was found to be identical with its synthetic analogue. A small amount (1 mg) of *trans*-indane-1,2-diol was also isolated from the rabbit urine. The amount isolated was insufficient to permit purification by recrystallization. The compound was dissolved in ethanol and identified by paper chromatography. *cis*-Indane-1,2-diol (44 mg), m.p. 96°–98° C, $[\alpha]_D$ + 40° in chloroform, was also isolated from the urine of rats dosed with indan-2-one. The melting point was not depressed by admixture with its synthetic analogue. The ultra-violet light-absorption and the paper chromatographic behaviour of the biosynthetic dihydrodiol was identical with that of the synthetic *cis*-dihydrodiol. In addition, *trans*-indane-1,2-diol (5 mg) was also isolated from the urine. The compound had a melting point at 183°–185° C, $[\alpha]_D$ + 30° in ethanol. The substance was examined by ultra-violet and infra-red spectroscopy and paper chromatography and found to be identical to synthetic *trans*-indane-1,2-diol. Brookes and Young[6] isolated *trans*-indane-1,2-diol, m.p. 184°–186° C, $[\alpha]_D$ + 31° in chloroform, from the urine of rats dosed with indene. They suggested that the compound was probably (+) *trans*-indane-1,2-diol.

Attempts to isolate *cis*- and *trans*-indane-1,2-diols from the urines of animals dosed with indan-1-one were unsuccessful.

In addition to the dihydrodiols, the presence of ketones, other than the compounds dosed, has been detected in the experimental urines by paper chromatography. The possibility that a ketol may act as an intermediate in the formation of the dihydrodiols from the indanones is being investigated.

The infra-red spectroscopy was carried out on the Unicam *SP*.200 spectrometer and the ultra-violet spectroscopy on the Unicam *SP*.700 spectrometer. Elementary analyses were carried out by Drs. Franz and Ellen Pascher, Bonn, Germany.

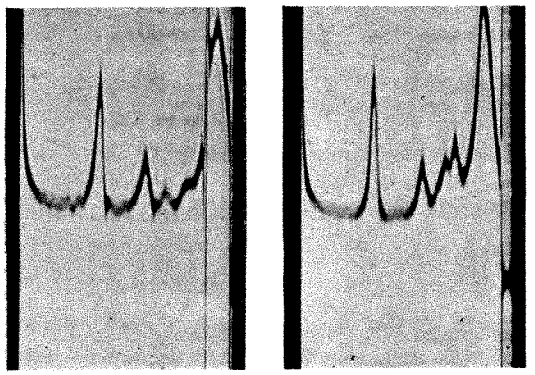
Consequences of Inhibition of *Escherichia coli* by Tetracycline Antibiotics



DURING incubation of *Staphylococcus aureus* with tetracycline, chlortetracycline or oxytetracycline, protein synthesis is inhibited to a much greater extent than the synthesis of ribonucleic acid (RNA)[1]. We have found these observations to apply also to inhibition of *Escherichia coli* and have extended them to include two other antibiotics of the tetracycline group. Table 1 shows that during incubation for 2 h with each of five tetracyclines, protein synthesis was almost completely inhibited, whereas increases in cellular RNA of from 56 per cent to 76 per cent were observed.

The RNA made by *E. coli* in the presence of chlortetracycline has been studied in some detail[2]; about 70 per cent is contained in particles that sediment more slowly than ribosomes and that give rise to two boundaries in schlieren diagrams during analytical ultracentrifuging of crude cell-free extracts. Incubation of *E. coli* with either oxytetracycline, tetracycline, demethylchlortetracycline or 6-methylene-5-hydroxytetracycline also led to the accumulation of similar particles which, like those produced by chlortetracycline action, were found to be

Table 1. SYNTHESIS OF RNA AND PROTEIN DURING INHIBITION BY TETRACYCLINE ANTIBIOTICS

Antibiotic	Percentage increase in RNA	Protein
Chlortetracycline	60	4
Oxytetracycline	64	7
Tetracycline	75	3
6-Methylene-5-hydroxytetracycline	76	4
Demethylchlortetracycline	56	2

Cells of *E. coli K*12 were incubated for 2 h at 30° C without aeration in a peptone medium (ref. 2) containing 15 μg of the appropriate antibiotic/ml. Estimations of RNA and protein were made on portions (5 ml.) of the suspension, using orcinol and Folin methods, respectively, and essentially as described by Fraenkel and Neidhardt (ref. 3).

a *b*

Fig. 1. Schlieren diagrams, after centrifuging for 20 min at 187,000*g* and room temperature, for cell-free extracts prepared from *E. coli* K12 in 15 mM potassium dihydrogen phosphate, *p*H 7·0, containing 0·1 mM magnesium acetate. Sedimentation is to the left. The bar angle was 40°. (*a*) Control; cells collected before addition of antibiotic. The extract shows major boundaries caused by 50 *S* and 30 *S* ribosomes, DNA and 'soluble' cell constituents. (*b*) Cells collected after inhibition for 2 h by 15 μg of demethylchlortetracycline/ml. One μg of deoxyribonuclease/ml. was added to the extract to eliminate convection caused by DNA synthesized during inhibition (ref. 2)

readily degraded by ribonuclease and ultrasonic vibrations under conditions which left ribosomes unaffected. Fig. 1 shows typical schlieren diagrams illustrating changes occurring during inhibition by demethylchlortetracycline.

These results suggest that the accumulation of RNA, largely contained in particulate material that sediments more slowly than ribosomes, may be a general consequence of inhibition by antibiotics of the tetracycline group. Particles resembling those accumulated during the action of the tetracyclines are also present after inhibition of *E. coli* by chloramphenicol or puromycin, two other antibiotics that inhibit protein synthesis but permit continued synthesis of RNA; these particles are thought to be precursors of the ribosomes[4,5]. The results of inhibition by these different antibiotics may be similar because chloramphenicol, puromycin and the tetracyclines inhibit protein synthesis at stages after the formation of aminoacyl-transfer RNA complexes[6–8]. According to the hypothesis proposed by Kurland and Maaløe[9], in which synthesis of RNA is suggested as being repressed by species of transfer RNA uncombined with amino-acids, the inhibition of protein synthesis effected by these antibiotics would not then cause an immediate reduction in the rate of synthesis of RNA.

We thank Pfizer, Ltd., for a grant towards the cost of this work.

In vitro Metabolism of *p,p'*DDT in Pigeon Liver

DESPITE the widespread use of DDT*, knowledge of its metabolism in vertebrates is incomplete, and is based almost entirely on experiments carried out on mammals *in vivo*. There have been no unequivocal reports of *in vitro* conversions to support these findings. Woodward, Davidow and Lehman[1] have reported the disappearance of DDT from homogenized liver of rabbits injected intravenously with emulsions of DDT prior to death, but no metabolites were isolated. Judah[2] incubated rat liver, kidney and diaphragm with DDT, but found no DDD or DDE and obtained only a very small conversion to DDA. Peterson and Robison[3] have recently put forward a metabolic pathway for DDT in rats which was based on feeding the pesticide and its postulated metabolites, and analysing residues in the liver and kidney. In the course of these experiments, liver homogenate was incubated for 6 days with DDT, and DDD was isolated with a final ratio of DDT : DDD of 1 : 3, although, as the authors point out, this may have been due to bacterial action. No *in vitro* work has been reported with birds, which are probably the vertebrates most at risk from the agricultural use of DDT. We now wish to report the *in vitro* conversion of DDT to DDD and DDE by incubation of both homogenate and slices of pigeon liver.

All solutions referred to were made up in 0·1 per cent 'Triton *X*-100' (Lennig Chemicals, Ltd.) to facilitate the solution of DDT, which could otherwise be precipitated by centrifugation at 25,000*g*. Pigeons were killed by cervical dislocation and the livers excised and placed on ice as rapidly as possible. Slices were obtained with a Stadie–Riggs microtome[4], and 0·5 g batches were incubated with DDT under gentle agitation for 4 h at 41·5° C in 5 ml. of Krebs–Ringer bicarbonate. The incubation medium was pre-gassed either with oxygen–carbon dioxide (95 : 5) or with nitrogen and carbon dioxide separately. Incubations in the former medium were carried out under oxygen–carbon dioxide, and in the latter under nitrogen. Redistilled propylene glycol, 0·1 ml., containing 20 μg of DDT was added to each flask after the addition of the slices. Reduced glutathione (7·5 mg/flask) was also incorporated into certain flasks. Liver homogenates were obtained with a Potter–Elvehjem[5] apparatus in two volumes of 0·25 M sucrose. Equal portions of homogenate equivalent to 0·5 g of liver were incubated with DDT and 4 ml. of Krebs–Ringer bicarbonate for 4 h or 24 h under exactly the same conditions as already described for slices. Some homogenates used for 24 h incubations were made in sucrose containing 25,000 U./ml. of penicillin *G* to prevent bacterial action, but this addition was shown to have no effect on the results obtained. All incubations were terminated by the addition of 1 ml. of 10 per cent trichloroacetic acid, followed by maceration and extraction by a modification of the method of Taylor, Rea and Kirby[6]. The final hexane extract was subjected to a further clean-up step with concentrated sulphuric acid before examination by gas–liquid chromatography[7,8]. The identity of the metabolites has been confirmed in a number of instances by the use of an additional column packing (*QF*-1) with gas–liquid chromatography or, where sufficient material was available, by the use of thin-layer chromatography. Appropriate blank incubations were run in all cases, and the recovery of DDT, DDD and DDE in the absence of liver was shown to be about 80 per cent.

The preliminary results which are summarized in Table 1 clearly demonstrate that two distinct reactions

Table 1. INCUBATION OF PIGEON LIVER WITH DDT

Tissue preparation	Incubation time (h)	Atmosphere	Special conditions	Molecular recovery (per cent) DDT	DDD	DDE

Slices	4	N_2	None	15·5	47·6	0·4
Slices	4	O_2/CO_2	Reduced glutathione	63·7	0	1·5

* Abbreviations: DDT, 1,1-di(*p*-chlorophenyl)-2,2,2-trichloroethane; DDE, 1,1-di-(*p*-chlorophenyl)-2,2-dichloroethylene; DDD, 1,1-di(*p*-chlorophenyl)-2,2-dichloroethane; DDA, di(*p*-chlorophenyl)acetic acid.

occur with both slices and homogenates. Under anaerobic conditions there is considerable conversion of DDT to DDD. A very small amount of DDE similar in magnitude to that found under aerobic conditions is also produced. The fact that the conversion to DDD still occurs after a homogenate has been maintained under nitrogen at 75° C for 10 min suggests that this may be a non-enzymatic reaction similar to that of DDT with reduced porphyrins recently described by Miskus, Blair and Casida[9]. Under aerobic conditions the overall reaction of DDT is much slower. A very small amount of DDE is produced unless reduced glutathione is included in the incubation medium, when a four- to six-fold increase in this conversion occurs. This reaction appears to proceed marginally better with homogenates than with slices. No other non-polar metabolite was found in any incubation and, despite a careful search in a separate experiment, neither was DDA. Some incubations using rat liver homogenate under the same conditions suggest that the same two pathways also operate, but that the formation of DDD is even more favoured under anaerobic conditions than in the pigeon, while the amount of DDE formed is slightly less.

Further work on the *in vitro* metabolism of DDT and its metabolites is in progress.

BIOLOGY

Scanning Electron Microscopy of Biological Material

The scanning electron microscope has been used for biological work[1,2] but in general the results were disappointing because of the poor contrast obtained with secondary or back-scattered electron read-out.

This communication reports some preliminary results obtained with a different contrast mechanism. In these experiments, the fine electron beam is scanned across the specimen and the light, excited by the beam at different points on the specimen, is detected on a photomultiplier and the signal obtained is used to build up the microscope image on the face of a cathode ray tube. This contrast mechanism has been used by other workers[3-4] for studying cathodo-luminescence but, as far as we are aware, it has not been used for biological applications.

Some biological material (such as cotton fibre) is cathodo-luminescent without any treatment; other material can be selectively stained with a cathodo-luminescent dye, such as thioflavin *T*, to render the material visible. Micrographs have been obtained under both conditions; Fig. 1 shows a micrograph of spinach leaf in which the dye, thioflavin *T*, is apparently selectively taken up on the cell walls and gives rise to the high signal from these regions. This conclusion was supported by a similar image obtained by visible light fluorescence microscopy. However, the advantage of the scanning electron microscope is that the ultimate resolution obtainable (about 100 Å)[5] is much higher than is possible with fluorescent light microscopy. At the present time,

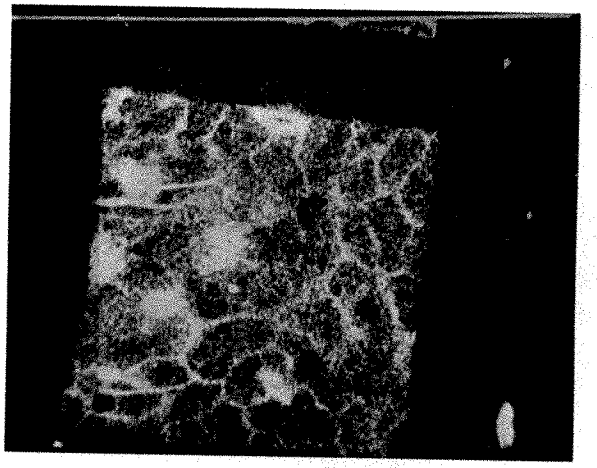

Fig. 1. Scanning electron micrograph of spinach leaf stained with thioflavin *T* using light collection only to build up the image. Beam current, $i = 10^{-8}$ amp; beam voltage, $V = 27$ kV; exposure time, 30 sec. (×240)

the highest useful magnification of scanning micrographs with this contrast mechanism is about 5,000 ×.

A number of problems are associated with this technique. The first is to ensure that the signal is due to light and not to scattered electrons. This has now been solved with a system of light collection that uses metallized mirrors. The second problem is to obtain sufficient signal to build up a useful image (see Fig. 1). This is not simply a question of focusing more electrons into the fine beam since 'poisoning' of the cathodo-luminescent material can occur and has been observed on a number of occasions with beam currents of the order of 10^{-9} amps. Hence, it may be necessary to use longer exposures (up to 30 min) and very stable power supplies for the electron optical column. As an alternative, stains may be found which are more resistant to electron bombardment.

If both these problems can be overcome, it should be possible to realize the potential of this method and to obtain micrographs showing resolution of a few hundred Ångstroms. An obvious extension of this technique is to identify different cathodo-luminescent materials by spectral analysis of the emitted light.

Lift produced by the Heterocercal Tail of *Acipenser*

The upward forces produced by the heterocercal tails of two species of Selachii, moving transversely through water at various speeds, have recently been measured[1]. It was found that the lift was approximately proportional to the 1·4th power of the transverse speed. The equilibrium of the fish, swimming horizontally, was discussed, and it was estimated that in each case the lift

required for equilibrium would be obtained at swimming speeds around 0·5 body lengths/sec. At higher speeds, more lift would be obtained if the hypocaudal lobe acted passively, but it was thought probable that the lift could be adjusted to the required value by means of the radial muscles of the hypocaudal lobe.

Heterocercal tails were almost universal in the early Osteichthyes, which presumably had negative buoyancy. Among modern Osteichthyes, however, only the Acipenseriformes have a markedly heterocercal tail.

Experiments have now been carried out on the tail of a sturgeon, *Acipenser sturio* L. The fish weighed 9 kg and was about 120 cm long. It was caught on March 15, and the tail arrived at this laboratory, apparently in fresh condition, on March 19. It had been packed in ice for most of the intervening period but had not at any time been frozen. The experiments were performed on March 19 and 20.

The method was that used for Selachii[1]. In some of the experiments the prongs of the apparatus extended 3 cm beyond the leading edge of the hypocaudal lobe, as in the majority of experiments with the rather smaller selachian tails, and in some they extended 5 cm beyond it. There was no appreciable difference between the two sets of results (Fig. 1).

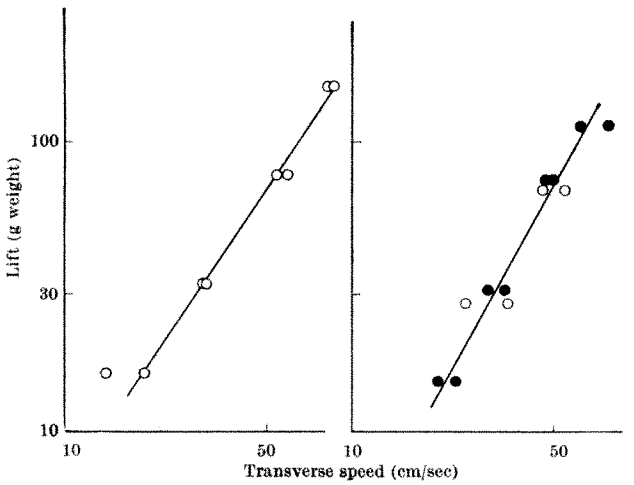

Fig. 1. Graphs of lift against transverse speed for the tails of *Galeichthys* (left, after ref. 1) and *Acipenser*. Measurements made with the prongs extending 3 cm (○) and 5 cm (●) beyond the leading edge of the hypocaudal lobe

The lift was found to be proportional to the 1·7th power of the speed, whereas in the experiments with selachians it was found to be proportional to the 1·4th power.

At any given speed, the lift was close to the lift given at the same speed by the tail of a specimen of the selachian *Galeichthys* (Fig. 1). The specimen of *Acipenser* was, however, much larger than the specimen of *Galeichthys*, which was about 95 cm long and probably weighed about 3·5 kg. If lift is expressed as a percentage of body weight, and speed in body lengths/sec, the lift produced by the *Acipenser* tail at a given speed is only about 50 per cent of that produced by the *Galeichthys* tail.

This difference seems appropriate in view of the difference in specific gravity between the fish. The specific gravity of *Acipenser*, which has a small swimbladder, is 1·05, whereas that of *Galeichthys* is 1·07 (ref. 2). If these values are reliable (they were obtained by the very inaccurate method of direct measurement of weight and volume) *Acipenser* will only require a little more than half as much lift as *Galeichthys* of similar weight when swimming in sea water of specific gravity 1·026. The swimming speeds at which the hypocaudal lobe, acting passively, would give the required lift may therefore be similar. It is not, however, clear whether the proportion of the total lift which must be provided by the tail is the same in both cases. In selachians, the pectoral fins seem to be the main source of lift anterior to the centre of gravity[3], but it seems possible that in *Acipenser* the ventral surface of the snout may be more important. If so, a greater proportion of the lift would have to be provided by the tail to balance the moments.

The hypocaudal lobe of the tail of *Acipenser* has radial muscles which can presumably be used to adjust the lift to the required value.

Response to Cercal Stimulation recorded in the Cricket Brain

THE responses of the cercal receptors of orthopterous insects have been known for a long time. In cockroaches and crickets nerve fibres from the sense organs synapse in the last abdominal ganglion with giant fibres; in the former insect at least the system is a simple relay initiating escape responses[1,2]. In crickets the cerci possess a variety of mechanoreceptors and have, among others, a tactile function in song and courtship[3,4]. Although the brain is primarily responsible for controlling speed and duration of movement of the animal following cercal stimulation[4,5], neural activity in response to such stimulation has been recorded only as far forward as the suboesophageal ganglion[4].

During a micro-electrode study of responses to visual stimuli in the brain of the house cricket, *Gryllus domesticus*, the results of which will be published elsewhere, we attempted in six preparations to record also units in the brain responding to cercal stimulation. In one of these we were successful, and the data are shown plotted in Fig. 1. A spontaneously firing unit was found which increased its impulse frequency in response to a puff of air directed through a pipette at the ipsilateral cercus. After the initial increase in rate, there was a gradual decline until cessation of the stimulus whereupon there was an inhibitory 'off-effect' followed by a return to base level. The brief decline in frequency immediately following onset of stimulus seems to be real and not artefact; although small, the effect was seen in all eight trials of the unit. The unit did not respond to puffs of air directed at the contralateral cercus or elsewhere on the body, nor did it respond to tactile stimulation of the ipsilateral cercus or of any other area.

Although we attempted to record cercal responses in only six animals, we did survey rather extensive areas of the brain. The fact that we found only one unit which

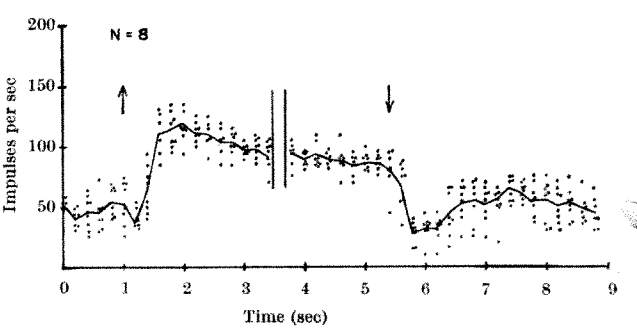

Fig. 1. Response of unit in cricket brain to a puff of air on the ipsilateral cercus. Duration of puff varies from 5–7 sec; all eight responses plotted with respect to beginning and end of stimulus indicated by arrows

exhibited such responses implies that these units are confined to a fairly limited area. No attempt was made to locate the above unit precisely, but its position could be roughly determined from surface contours and measurement of electrode penetration. It was located somewhat lateral and considerably ventral to the mushroom body; the electrode was deep enough to be quite possibly recording from the vicinity of fibres entering the brain from the circumoesophageal connectives. The occurrence of the unit here reported seems to be the first direct evidence of electrical activity within the insect brain as a result of cercal stimulation.

An *in vivo* Method for studying the Hair Cycle

STUDIES of the hair cycle have been carried out for many years on fixed material[1,2] and, more recently, in tissue culture[3]. In neither case can environmental influences on the initiation of the hair cycle, such as microcirculatory changes and presence or absence of oedema, be determined satisfactorily. In the following *in vivo* method, single follicles may be mapped and observed repeatedly at any time-intervals thereafter.

Young mice, 3–4 weeks old, of *BUB* (albino) strain, or C_3Hp (lightly pigmented) strain, are anaesthetized intraperitoneally with 'Nembutal', 75 mg/kg. The mouse rests horizontally on a holder with a long coverslip covering the dorsal surface of the pinna and adhering to it by means of glycerine. The holder fits on to the stage of a light microscope, the ear being transilluminated from below.

Blood vessels are mapped using sequential magnifications of 10–600 times, and the hair follicles, marked by the prominent sebaceous glands, are mapped in relation to the smaller blood vessels. The diameter of mapped blood vessels can be measured with a calibrated ocular micrometer, and comparative measurements made at different times and under different conditions.

The hair follicles in the apex of the mouse pinna are in the resting stage (telogen) until the animal reaches an age of about 6 months. They can be experimentally activated by various means, including applications of a dekeratinizing agent (commercial hair remover such as 'Neet'), or by plucking the hair. 'Neet' applied for 5 min will remove the external hair, and exert a minimal effect on regrowth. If applied for a longer time, it often causes vasodilatation and oedema, which can be observed under the microscope, and it hastens regrowth. Once the follicles are activated, all stages of the hair cycle except early anagen can be observed and studied.

The activity of the apical follicles of the pinna is much slower than the follicles of body skin, both with regard to spontaneous and induced cycles, thus facilitating time analyses. Figs. 1–3 show the same area of pinna on day 10 after plucking the hair (follicle inactive), on day 24 (follicle in anagen), and on day 32 (follicle in catagen).

The method has been used to study vasodilatation and oedema in relation to the hair cycle. It is at present being used to explore endogenous factors which are involved in the initiation of anagen.

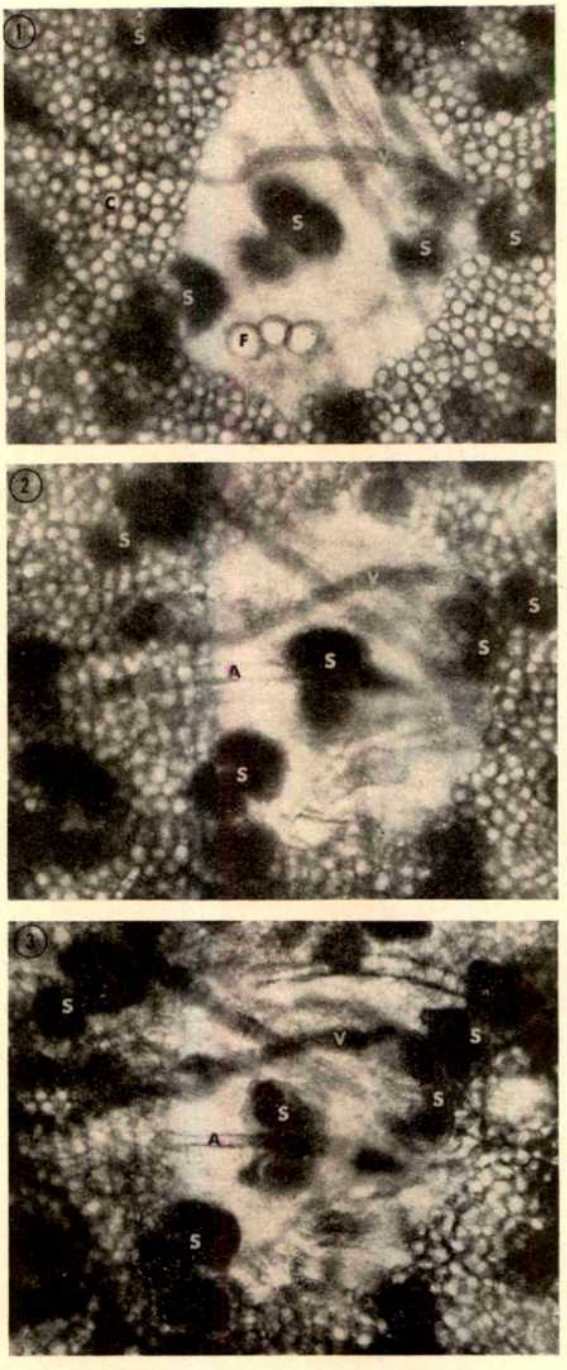

Fig. 1. Area of living mouse pinna, transilluminated, on day 10 after plucking the hairs. Sebaceous glands (*S*) are all that can be seen of the pilosebaceous units. The follicles are inactive. *C*, Cartilage; *F*, fat cell. (×150)

ENTOMOLOGY

Reversion of the Toxicity of Tricalcium Phosphate to Insects by Trehalose

EARLIER we reported[1] data on the exceptional toxicity of tricalcium phosphate to insects. The symptoms of toxicity on larvae were supernumerary moulting, mottling of cuticle, reduction in growth, malformation and death. Further experiments were carried out to investigate the action of sugars on the toxicity of tricalcium phosphate. The sugars (A.R.) were incorporated into tricalcium phosphate at the 5 per cent level. These premixes were mixed with broken rice at the 0, 0·05, 0·1, 0·5, 1·0 and 2·0 per cent levels. The test insects, second instar larvae of *Corcyra cephalonica* drawn from laboratory cultures, were released on 10 g of the medium. There were ten replicates for each treatment. Observations were made on the growth, mortality and histological changes in the larvae during 15 days' incubation at 25° C and 65 per cent relative humidity. Staining for fat and tissues was carried out by the procedures described by Conn and Darrow[2]. The results are given in Table 1.

The results of the experiments reveal that most of the sugars significantly enhanced the toxicity of tricalcium phosphate to insects. Only trehalose, a disaccharide, exerted any marked effect on the toxicity of tricalcium phosphate—it reversed its action. Even with the highest concentration of tricalcium phosphate (2 per cent and above) in the medium, trehalose produced almost total detoxification and no deaths were recorded among the test insects. This detoxification mechanism required further investigation. Whereas with the incorporation of glucose, sucrose, fructose, lactose, xylose, mannose and rhamnose, the toxicity of tricalcium phosphate was markedly increased, raffinose and galactose reduced it to some extent.

Histopathological investigations of *C. cephalonica* larvae showed that tricalcium phosphate reduced the fat deposition in the larvae, disintegrated the striated border and the midgut epithelium and induced great degenerative changes in the alimentary canal and other surrounding tissues (Fig. 1). In the absence of trehalose, these pathological symptoms could be observed at concentrations of 0·5 per cent and greater of tricalcium phosphate after a period of 6 days. These histopathological symptoms were absent in larvae fed on tricalcium phosphate containing trehalose. It was of interest to note that when the quantity of trehalose in tricalcium phosphate was small, and when the mixture was incorporated into the growth medium at the 2 per cent level (tricalcium phosphate 20 mg/g + trehalose 1 mg/g), the larvae grew

as well as with the control medium in which tricalcium phosphate was absent. The reversion of the toxicity of tricalcium phosphate to insects by trehalose, as indicated by the histological and growth investigations, is of considerable interest. On the other hand, glucose, sucrose and inulin exerted a considerable potentiating effect on the toxicity of tricalcium phosphate to larvae of *C. cephalonica*, and induced rapid pathological changes in tissues. Similar interactions of sugars on the toxic effects of tricalcium phosphate were also observed with larval stages of *Tribolium castaneum* and *Ephestia cautella*. These results on the pathological effects of the tricalcium phosphate potentiating effect of some of the sugars and the detoxifying action of trehalose should have far-reaching effects in any future search for a specific insecticidal substance.

Wyatt and Kalf[3] reported that the non-reducing disaccharide α-α-trehalose was the major sugar in insect plasma (compared with mammals). It is believed that it plays a significant part in carbohydrate transport in insects, perhaps conveying glucose units from fat body glycogen to the site of the metabolism in other tissues. Since glucose, fructose and sucrose occur in small amounts or in traces in the larval blood, and trehalose is present to the extent of 90 per cent of the blood sugar level[3], the role of tricalcium phosphate seems to be related to the imbalance created in the energy metabolism of larva. This imbalance is accelerated by sugars such as glucose, sucrose, mannose, fructose, rhamnose and xylose, and corrected by trehalose.

The results obtained on the outstanding toxicity of tricalcium phosphate and the reversion of its toxicity by trehalose and enhancement of toxicity by glucose and other sugars on insects indicate that the comparative biochemistry of insects and mammals is involved in this specific toxicity. Vertebrates are characterized by an endo-skeleton with 99 per cent of the body calcium bound in the hydroxyapatite crystallites of bone and teeth. Their requirement of calcium salts contrasts strongly with that of invertebrates. Other physiological and biochemical differences between the mammals and arthropods[4] also seem to be implicated in the action of tricalcium phosphate on insect as a metabolic poison even at low concentration. These aspects are being investigated.

Generation-to-generation Passage of the Nuclear Polyhedral Virus of *Spodoptera exempta* (Wlk.)

GENERATION-TO-GENERATION passage of polyhedral viruses has been reported for a number of insects[1–5]. Previous work with the nuclear polyhedral virus of *Spodoptera exempta* (Wlk.) indicated that generation-to-generation passage of the virus occurred in this insect, but the evidence was inadequate to decide whether the virus passed within the egg or by contamination of the egg shell[6]. This communication presents the results of experiments on this question.

A virus-free culture of *S. exempta* was maintained in the insectary from the middle of 1964 and throughout the period of the experiments until the end of March 1965. No deaths due to polyhedrosis occurred in these 9 months and no signs of the disease were observed. The two experiments next described were done simultaneously in the same room as that in which the virus-free stock was maintained. Identical methods were used, and larval food, which alone could not be sterilized, was distributed at random between the virus-free and experimental larvae. In the first experiment, carried out during February 1965, egg batches from three parent moths of the virus-free stock were each divided into three and the following treatments carried out: (*a*) control, untreated; (*b*) eggs dipped 15 min in a virus suspension of known concentration; (*c*) eggs dipped as in (*b*), air-dried and then dipped 90 min in 10 per cent formalin and 0·1 per cent 'Teepol' and finally rinsed in distilled water. The results presented in Table 1 show that dipping in virus suspension led to 100 per cent mortality due to polyhedrosis; additional treatment with 10 per cent formalin and 0·1 per cent 'Teepol' completely prevented death due to polyhedrosis, presumably by destroying the virus contaminating the egg shell.

Table 1. DIPPING EXPERIMENTS WITH EGGS OF VIRUS-FREE STOCK OF *Spodoptera exempta*

Batch No.	Treatment	Total larvae	Percentage dead due to polyhedrosis	Percentage pupated
1	(*a*) Control, untreated	33	0	78·8
	(*b*) Dipped 15 min. in suspension of 5,000 polyhedra/mm³ + 0·1 per cent teepol	44	100	—
	(*c*) As (*b*), followed by dipping 90 min. in 10 per cent formalin + 0·1 per cent teepol	46	0	91·3

Treatments: *A*, control, untreated; *B*, eggs dipped 90 min in 10 per cent formalin + 0·1 per cent 'Teepol'.

In the second experiment, wild female moths, which could be expected to carry polyhedrosis virus, were caught alive in a Robinson-type mercury-vapour light trap, and the eggs from each were divided into two. One moiety was left untreated; the eggs in the other were dipped 90 min in 10 per cent formalin and 0·1 per cent 'Teepol' and then rinsed in distilled water. The eggs were allowed to hatch and the resulting larvae from each batch were reared as an aggregate. All larvae that died were examined for polyhedra, as Giemsa-stained smears, using an oil-immersion objective. The results of this experiment are presented in Table 2, and show that larvae from eggs laid by all seven moths became infected with polyhedrosis. It is known from individual rearing that only a proportion of larvae from a particular egg batch will show infection[6]. This probably accounts for the absence of polyhedrosis in the untreated moieties from moths 1 and 3. Since polyhedrosis appeared in larvae from five of the seven batches of eggs that were surface-sterilized, passage of the virus in the interior of the egg would appear to have occurred.

It is unlikely, though not impossible, that the last-mentioned infections resulted from contamination of larval food. The larvae in the experiments and the virus-free culture were fed from a common food source throughout. Under these circumstances the chances of giving

contaminated food only to larvae in the second experiment were very small ($P = 0.006$).

PHYSIOLOGY

Tonic Activity of Lung Receptors in Normal and Pathological States

ADRIAN[1] was the first to investigate the activity of single afferent vagal fibres. He showed that, in normal breathing, the vagal effect on respiration was due mainly to the impulses from the stretch endings in the lungs. These impulses have an inhibitory effect on the respiratory centre and thus contribute to the self-regulation of breathing.

Respiratory acceleration is one of the most significant symptoms of lung diseases. On the basis of Adrian's investigation it was supposed that dyspnoea depended on the increased sensitivity of stretch endings in the lungs[2]. Investigation of the activity in single afferent vagal fibres during experimental congestion[3–5], oedema[6,7], embolism[8] and pneumonia[9] did not, however, confirm this assumption.

The single-fibre technique allows easy detection of the activity of the group *A* vagal fibres, that is, the pulmonary stretch receptors. Using this method, it is, however, very difficult to detect the activity of the non-medullated *C* fibres. It has been shown histologically that most of the vagal fibres, including their bronchial branches, belong to the *C* group[10].

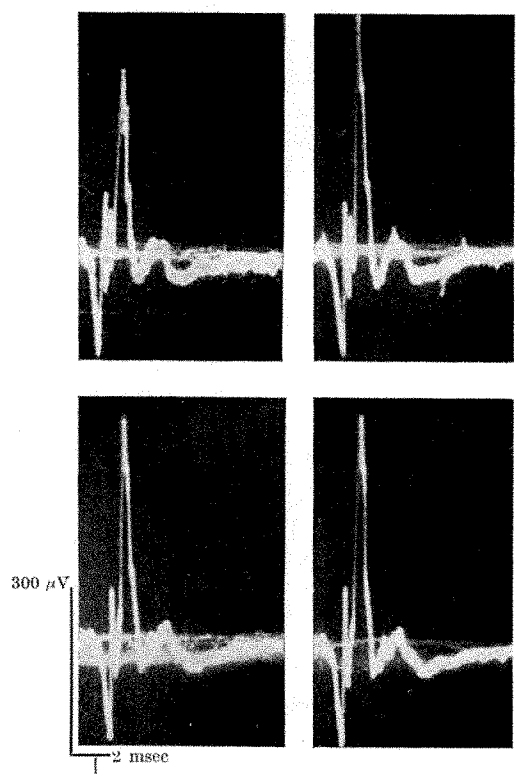

Fig. 1. Records of the rise of the action potential of the *A* fibres of cat's cervical vagus. Top, before oedema of the lungs. The amplitude of the *A* elevation during inflation (left) is smaller than that of the *A* elevation during deflation (right). Bottom, during oedema of the lungs. The amplitude of the *A* elevation during inflation (left) increases and becomes just equal to that of the *A* elevation during deflation (right). In this and subsequent records the distance between the stimulating and recording electrodes was 58 mm. The nerve was stimulated once per sec during inflation or deflation. Each record was made by superposing five sweeps

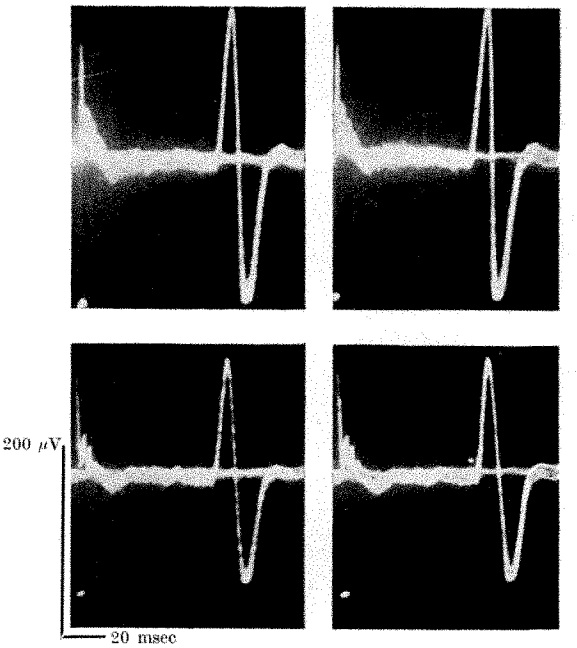

Fig. 2. Records of the rise of the action potential of *C* fibres of cat's cervical vagus. Top, before oedema of the lungs. The amplitude of the *C* elevation during inflation (left) is equal to that of *C* elevation during deflation (right). Bottom, during oedema of the lungs the amplitude of *C* elevation decreases equally during inflation (left) and deflation (right)

To investigate the whole activity of pulmonary receptors during oedema and pneumonia we used the method of Douglas and Ritchie[11], which allowed us to detect the activity of both the *A* and the *C* fibres.

The experiments were carried out on cats anaesthetized with urethane and chloralose. The chest was widely opened and artificial respiration was carried out. The right cervical vagus was cut just below the nodose ganglion. A pair of stimulating platinum electrodes was placed close to the peripheral cut end of the nerve, and another pair of recording electrodes was placed about 50–90 mm more distally. For stimulation of the nerve, rectangular pulses of 0·1–0·5 msec duration were used, the stimuli used being supramaximal for both *A* and *C* components. To exclude the impulses from other organs, the left and right vagi were cut over the diaphragm and the majority of cardiac branches of the right vagus were also cut. Oedema and pneumonia were evoked by the injection of 0·5 c.c. of 40 per cent glucose solution and 2·0 c.c. of hot water, respectively, in each lobe of the right lung.

Before the injection, there was a regular variation in the size of the *A* wave of the evoked antidromic vagal action: the potential was at a maximum during deflation, when the natural orthodromic activity was least, and at a minimum during inflation, when the natural orthodromic activity was at a maximum (top records of Fig. 1). The size of the evoked action potential varied with the amount of spontaneous activity in the vagus. The greater the degree of inflation, the smaller was the evoked action potential.

On the other hand, the size of the *C* wave of the evoked action potential did not change with changes in the respiratory volume (Fig. 2, top). This is in agreement with Adrian's observation that only the stretch receptors show periodic activity in normal breathing.

Both the oedema and the pneumonia caused characteristic changes in the size of the evoked action potential.

The size of the *A* wave increased during inflation and sometimes became equal to that of the *A* wave during deflation (Fig. 1, bottom). This means that there is no increase in sensitivity of the stretch endings following injury to the lung. On the contrary, there is some decrease in sensitivity of the stretch endings.

The *C* wave also underwent modification. During the oedema and pneumonia the size of the *C* wave of the antidromic action potential was decreased both during inflation and deflation (Fig. 2, bottom). This shows that pathological processes increase the sensitivity of the non-medullated *C* fibres.

It is known that oedema and pneumonia are accompanied by an increase in the concentration of potassium ions. In this connexion it seems to be interesting that the size of the *C* wave also increases after intravenous injection of potassium ions[12].

These experiments give a new explanation of the mechanism of the respiratory acceleration during pathological processes in the lungs. It has recently been shown that cathodic polarization evoked facilitation of respiratory neurones[13]. It is possible that the constant increase of impulses from *C* fibres also evokes facilitation and this could be the reason for the observed respiratory acceleration.

The tonic activity of the lung receptors can have great significance not only in the pathological breathing but also in the normal breathing. It has been shown that the lung receptors take part in the regulation of the activity of the gamma motoneurones of the respiratory muscles[14–20]. The activity of the gamma motoneurones is mainly tonic. It is therefore possible that it can be supported by the tonic activity of the aforementioned lung receptors.

Potentials evoked *in vitro* in Preparations from the Mammalian Brain

MANY parts of the mammalian brain, isolated and examined in simple media *in vitro*, afford metabolic responses to electrical stimulation. It has not hitherto been established whether this implies neuronal responses detectable electrically. Thus in spite of much effort, no responses were recorded from the surface of slices of mammalian cerebral cortex[1], though metabolic sequelae to stimulation were observed.

In the present experiments, slices 0·35 mm thick were prepared from the anterior portion of the piriform lobe

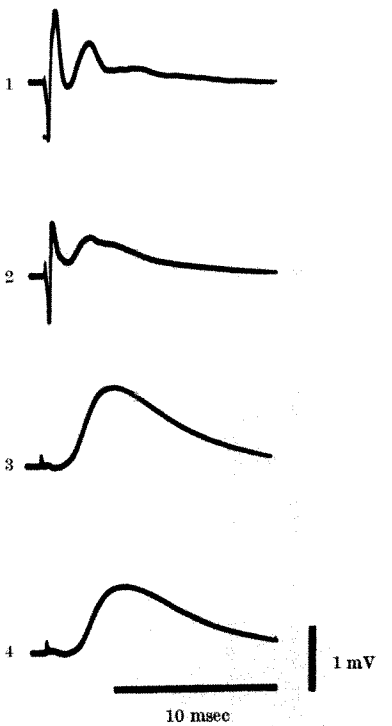

Fig. 1. Distribution of the evoked potential recorded from the surface of the slice in response to a single shock to the lateral olfactory tract. A recording electrode was put either on the tract (record 1) or at different distances along a line perpendicular to the tract and 5 mm from the stimulating electrodes. This gave records at distances of 0·5 mm (record 2), 1·5 mm (record 3) and 2·5 mm (record 4) from the tract. The action potential of the tract decreased in amplitude from record 1 to 4, while the *N*-wave attained its maximum height at a distance of 1·5 mm. Upward deflexions, negative. Calibration, 1 mV and 10 m.sec

(prepiriform area) of the guinea-pig cerebral cortex. The samples were incubated in a glucose-saline medium saturated by 95 per cent oxygen and 5 per cent carbon dioxide at 37° C in apparatus previously described[2]. The stimulating electrodes were a pair of ball-tipped silver wires connected to a Grass stimulus-isolation unit. The recording electrode was also a ball-tipped silver wire. The stimulus was applied to the frontal end of the lateral olfactory tract, which sends axon terminals extensively to the nerve cells in the prepiriform area[3,4].

Fig. 1 illustrates potentials generated on the surface of the slice in response to a single shock to the lateral olfactory tract. The potential recorded on the tract (record 1) was composed of an initial biphasic sharp deflexion, and a following slow negative wave—the latter being called the '*N*-wave' in this report. The initial deflexion was the action potential of the nerve fibres in the lateral olfactory tract. Thus, when the electrode was placed on the prepiriform area and the distance between the tract and the recording point was successively increased, the initial sharp deflexion decreased in amplitude in record 2 and disappeared in records 3 and 4. On the other hand, the *N*-wave increased in amplitude at these latter points. The irregular descending phase of the *N*-wave in record 1 became smoother in records 3 and 4.

By further investigating the properties of the *N*-wave, it was revealed that the *N*-wave was enhanced when it resulted from a stimulus which was preceded by a conditioning shock at short interval; it was obliterated by high-frequency stimulation (85 c/s) and was potentiated after tetanic stimulation (post-tetanic potentiation). The *N*-wave was sensitive to sodium phenobarbitone, to γ-aminobutyric acid and to chlorpromazine.

These findings exclude the possibility that the *N*-wave is the action potential of the slowly conducting nerve fibres in the lateral olfactory tract but indicate that it is a postsynaptic potential generated at cortical neurones.

It is therefore concluded that sections from the mammalian brain can maintain *in vitro* the synaptic organization which elicits the postsynaptic potential[5,6].

It is not quite clear whether or not these neurones retain the intact spike-generating mechanism. However, irregularities on the *N*-wave in records 1 and 2 might indicate that the neurones near the tract produce spike potentials. If so, the smaller amplitude of the *N*-wave in these records can be explained by thinking that the postsynaptic potential was abolished by a spike potential or that it was diminished by polysynaptic inhibitory mechanisms.

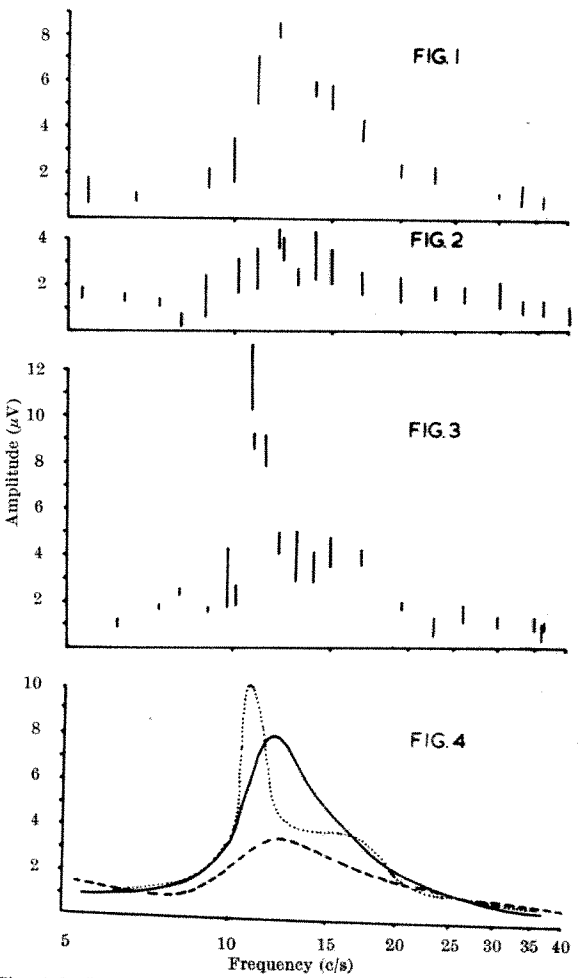
An Effect of Stimulus Colour on Average Steady-state Potentials evoked in Man



SCALP potentials evoked by sinusoidally modulated light have been measured for various monochromatic stimuli of equal retinal illuminations. The correlation apparatus made use of the orthogonality of sinusoids to extract from the electroencephalogram the sinusoidal evoked component at stimulus frequency (synchronous component), and to measure its amplitude and phase[1,2]. It was found that if the light stimulus were viewed with good voluntary fixation, and if its frequency and peak intensity were accurately maintained constant, an average steady-state régime occurred from about 12–20 sec after stimulus onset until at least 70 sec, during which the running average of the amplitude and phase of the synchronous component remained constant[1]. Data for one subject are described.

The stimuli were all of 9,000 trolands retinal illumination, of 14° subtense with a central fixation cross and with dark surround. An artificial pupil was used with Maxwellian view. The first electrode was placed 8 cm above the inion, the second 5 cm to the right of this and the earth placed 1 cm above the inion. Monochromation was by interference filters of about 10 nm half-width, and peak transmissions at 435, 589 and 634 nm. The colour vision of the subject was examined by the Ishihara test and found to be normal.

Figs. 1, 2 and 3 show the relationship between the peak-to-peak amplitude of the synchronous component of the evoked potential, and the modulation frequency for 100 per cent sinusoidal modulation. In Fig. 4, curves drawn through each of Figs. 1, 2 and 3 have been superposed to show the differences between the synchronous components of the potentials evoked by the red, yellow and blue stimuli. It can be seen that for both blue and red the low-frequency flank of the amplitude peak is very steep, but that the high-frequency flank is less steep for blue than for red. Red has the most selective amplitude peak, and yellow the least. It should be mentioned here that with the dark surround used, scattered light was found to make an important contribution to the evoked potential. Any dependence of this contribution on colour, however, might be expected to result in bodily shifts of the data of Figs. 1–3 along the ordinate, without affecting the shapes of the graphs.

The graphs of the phase of the synchronous component versus stimulus frequency all show a rapid phase shift near the amplitude peak followed at higher frequencies by a linear region of reduced slope. The similarity shown in Fig. 5 between the graphs of phase versus stimulus frequency in the vicinity of the amplitude peaks suggests that neither variations in the selectivity nor the contribution of a resonant-like filter is a major factor underlying the different amplitude-frequency characteristics of different colours shown in Figs. 1–4. Van der Tweel[3,4] has found that the amount of harmonic distortion may be very different at quite closely separated stimulus frequencies, and has suggested that this distortion may occur at an early stage in the visual pathways, while the more central region acts as a filter which responds selectively in the region of 10 c/s.

If the amount of harmonic distortion generated at a particular stimulus frequency depended on the colour of the stimulus, a peaking of the amplitude of the synchronous evoked component could be produced, which was additional to any effect of resonant-like filtering. Differently shaped peaks for different colours such as those presented in Figs. 1–4 could then result, while near the amplitude peaks, the phase versus frequency graphs remained unaffected by stimulus colour. This hypothesis is under investigation.

Figs. 1–3. Peak-to-peak amplitude of the synchronous component of the evoked response versus stimulus modulation frequency. Stimuli all of 9,000 trolands retinal illumination, 14° field with dark surround centrally viewed, and 100 per cent sinusoidally modulated in intensity. Fig. 1, blue 435 nm; Fig. 2, yellow 589 nm; Fig. 3, red 634 nm. Lines indicate range of each measurement

Fig. 4. Smooth curves drawn through Figs. 1–3 and superposed to demonstrate different amplitude-frequency characteristics for different colours

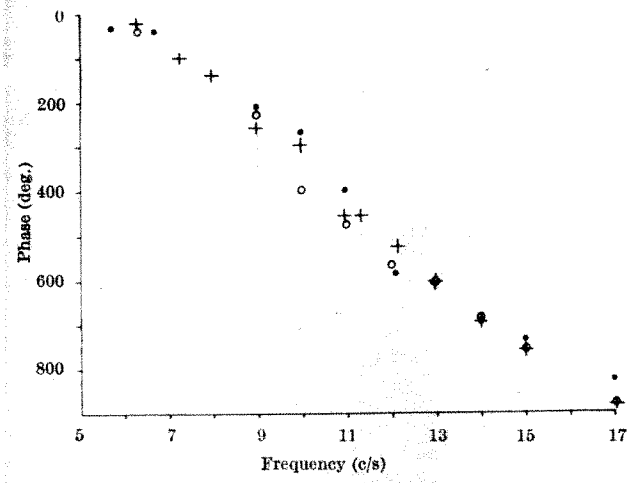


Fig. 5. Phase of the synchronous component of the evoked response versus stimulus modulation frequency for the same measurements as Figs. 1–3. Note the linear frequency scale. The zero of phase for each colour is arbitrary. ●, Blue; +, yellow; ○, red. Range of each measurement is typically ±10°

Evidence for Adrenergic Transmission of the Carotid Chemoreceptor Impulses in the Toad

RECENTLY when recording afferent impulse activity in the nerve supplying the carotid labyrinth in the toad, we have found chemoreceptor fibres which show increased discharge in response to hypoxia just as do those of the mammalian carotid body[1]. Although acetylcholine has been proposed as the normal chemical transmitter of the mammalian glomus nerve-endings[2–8] the evidence is not as yet wholly conclusive. Indeed, electron microscopy has revealed that the mammalian glomus epithelioid cells show numerous catecholamine-containing granules and the opinion has been advanced that the catecholamine may be the transmitter substance[3]. There is little physiological evidence for this, however, and even noradrenaline itself does not stimulate chemoreceptor discharge[6]. Based on the standpoint that the adrenaline-like substance produced in the body is not necessarily solely identifiable with noradrenaline, we have tried to stimulate carotid chemoreceptor discharge by electrical excitation of the cardiac sympathetic fibres. Our results indicate that an adrenergic mechanism is responsible for chemosensory transmission.

A pithed toad was laid on its back and the left carotid labyrinth was exposed. Afferent impulse activity was recorded from the cut 'carotid labyrinth nerve'. The left internal carotid artery was cannulated and all other branches of the left aortic trunk were tied, as was the external carotid artery. One of the large veins entering the sinus venosus was cannulated and all other cardiac veins were ligated. The right aortic trunk was cannulated and the cannula led to a reservoir *R* (Fig. 1) which in turn supplied the only patent cardiac vein. The heart, supplied with Ringer's solution from the reservoir, on contracting expelled the fluid into the carotid labyrinth and internal carotid artery, from which it escaped in drops, and simultaneously through the cannula in the right aortic trunk to return to the reservoir. The major part of the systolic volume was returned to the reservoir. Finally, the right vago-sympathetic nerve trunk and jugular ganglion were exposed and separated and the sympathetic nerve, cut at the second sympathetic ganglion, prepared for electrical stimulation.

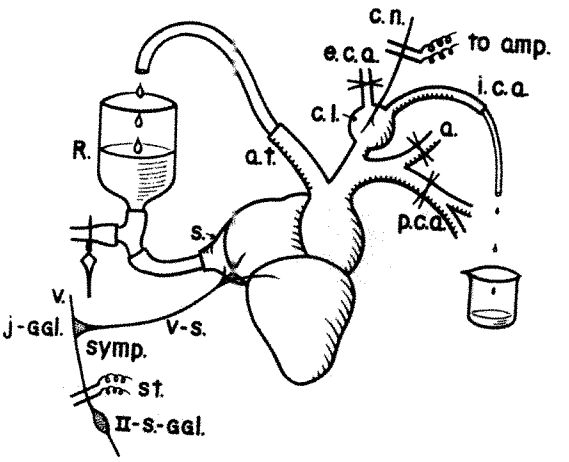

Fig. 1. Arrangement of the apparatus for stimulating the sympathetic nerve and also for recording the chemosensory impulses originating in the carotid labyrinth which was perfused with Ringer's solution through the heart. *c.l.*, Carotid labyrinth; *c.n.*, carotid nerve; *II-S-GGl.*, second sympathetic ganglion; *j-GGl.*, jugular ganglion; *symp.*, sympathetic nerve; *v.*, vagus nerve; *v-s.*, vago-sympathetic nerve trunk; *s.*, sinus of the heart; *a.*, aorta; *a.t.*, aortic trunk; *e.c.a.*, external carotid artery; *i.c.a.*, internal carotid artery; *p.c.a.*, pulmo-cutaneous artery; *R.*, reservoir of Ringer's solution (10 c.c.)

Faradic stimulation of the sympathetic fibres for 30 sec caused an increase in force and rate of the heart beat. There was an obvious increase in perfusate throughout the carotid labyrinth. On ceasing sympathetic stimulation, carotid chemoreceptor activity was reduced temporarily, whereas barosensory impulse discharge was transiently increased. After 1 min chemosensory discharge began to increase until it reached a maximum in about 3 min (Fig. 2)—this intensification of impulse discharge was sustained as long as there was evidence of increased cardiac rate. Afterwards, the impulse activity subsided to that of the control level. The return to the control level of impulse activity was hastened by replacement of the perfusate with fresh Ringer's solution.

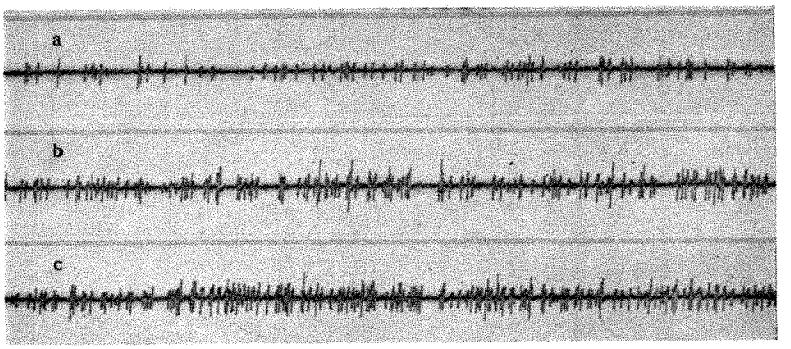

Fig. 2. Effect of adrenaline-like substance liberated from the sympathetic nerve endings on the chemosensory impulses. The impulses were recorded from the left carotid nerve. The repetitive electrical stimulation was applied for 30 sec to the right sympathetic nerve which innervates the heart. *a*, Before stimulation; *b*, about 90 sec after the cessation of stimulation; *c*, about 200 sec after. Time: 50 c/s

The initial decrease of chemosensory impulse activity is most probably due to both the increased flow of perfusion fluid through the labyrinth and the fact that the adrenaline-like substance liberated from the post-ganglionic sympathetic nerve endings has not yet had time to gain access to the fluid in the cardiac chambers. It seems probable that the subsequent intensification of chemoreceptor impulse traffic is due to the effect of this substance on the chemosensory nerve endings. The *p*H of the perfusion fluid remained at 7·40 before and after sympathetic stimulation.

These results support the possibility that the natural chemical transmitter of the chemosensory apparatus of the toad is of adrenergic nature.

We have recently found that the chemoreceptor cells in the carotid labyrinth possess many catecholamine-containing granules in their cytoplasm (unpublished). Thus, it can be concluded that this catecholamine is closely related to the mechanism of chemosensory transmission in the carotid labyrinth of the toad.

Reflex Vascular Function in Unanaesthetized Rabbits

CHANGES in the calibre of vessels in the rabbit ear can be measured by a variety of methods. Assessment of the effect of various procedures on reflex vasomotor control requires direct stimulation of sympathetic nerves or ganglia, however, and is therefore unsuitable for unanaesthetized animals. It would be advantageous to induce predictable reflex vasomotor changes in intact animals which could be detected by a simple method. In man, reflex vasodilatation in the hand can be produced by heating the skin elsewhere[1]. This test depends on neural afferents from the heated area and sympathetic efferents to hand blood vessels and it has been used to measure autonomic function in diseases of the nervous system[2]. This test was adapted to the rabbit ear in order to investigate the effect on autonomic function produced by immunization with a variety of nervous antigens[3]. A diagrammatic representation of the test conditions is shown in Fig. 1. The animals were tested at constant environmental temperatures and silence was maintained throughout the procedure. To ensure that the rabbits were capable of vasodilatation at the time of the tests, 2 c.c. of 2 per cent procaine solution was injected subcutaneously around the base of the right ear. This produced vasomotor paralysis accompanied by a marked rise in temperature of the right ear. Reflex vasomotor changes in the left ear in response to heating the back for 40 sec were then monitored by thermocouples. When no vasodilatation occurred after the injection of local anaesthetic, the animal was presumed fully vasodilated and not testable. A normal record is shown in Fig. 2. Heating the shaved back produces an initial vasoconstriction in the ear vessels, of varying magnitude, which lasts 2–10 sec. This gives way to a marked vasodilatation which outlasts the stimulus by 10–30 sec before returning to preheating levels. Irradiation of the back can be repeated at 1-min intervals. The vasodilatation is associated with ear temperature changes ranging from 0·4°–1° C. This vasodilatation is independent of the rate of heating and the threshold is at about 225 W. Pretreatment with atropine, 2 mg/kg, abolishes reflex vasodilatation and 0·8 mg/kg of eserine enhances it. The pathways involved in these vasomotor changes are not fully known. It has been shown by Holton and Rand[4] that direct electrical stimulation of the superior cervical ganglion causes in rabbit ear vessels an initial vasoconstriction followed by vasodilatation and that the latter was abolished by atropine and enhanced by eserine. This vasodilator phase is presumably, therefore, due to postganglionic sympathetic cholinergic fibres. By analogy, brief heating of the back and direct electrical stimulation of the superior cervical ganglion utilize in the rabbit identical efferent pathways to the ear vessels. On the afferent side, heating the back produces its effect on ear blood flow probably by stimulation of receptors in the exposed skin rather than by warm blood. The short latency, the prompt return to baseline after cessation of the stimulus and the independence of the response on the rate of heating are all in keeping with this interpretation. This new test of vasomotor function in unanaesthetized rabbits was used in a large number of ani-

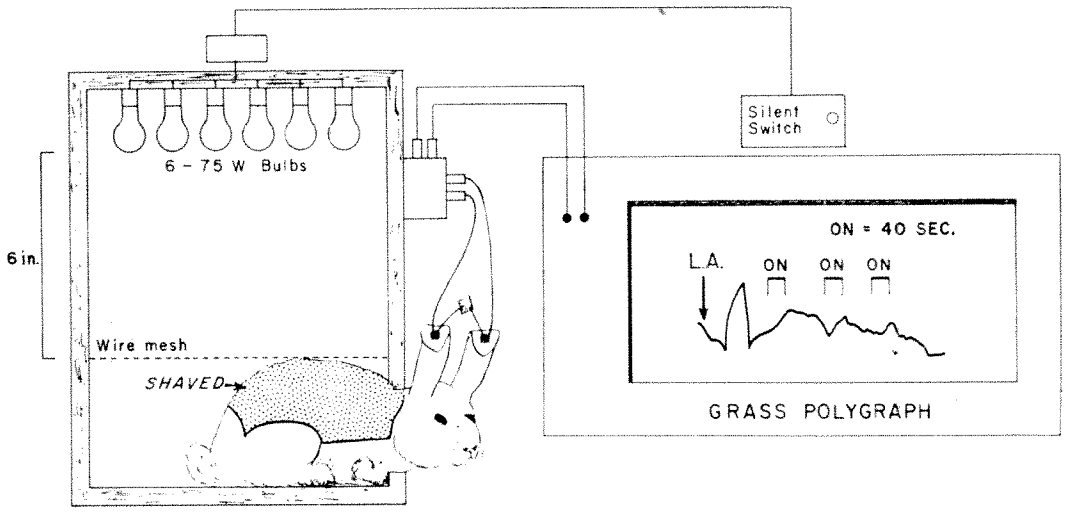

Fig. 1. Diagrammatic representation of the test conditions for reflex vasomotor function in the rabbit ear. Constantan-copper wire thermocouples were attached to each folded ear by loosely applied adhesive tape. They were so arranged that a change of 0·6° C in either ear produced a deflexion of 1·5 cm on the polygraph record. The wooden box fitted snugly around the animal's neck so that no light was visible when the bulbs were switched on by a noiseless switch

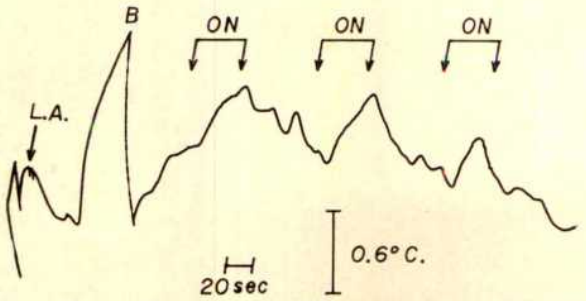

Fig. 2. Normal reflex vasomotor function in rabbit ears. After the subcutaneous injection of local anaesthetic (L.A.) around the base of the right ear, a marked rise in temperature occurred, necessitating the adjustment of the polygraph balance (B). When the lights were switched on for 40 sec (ON), an initial vasoconstriction followed by marked vasodilatation occurred as shown by the corresponding fall and rise in ear temperature

mals for a study of an experimental immunologically induced disorder of autonomic function.

Spinal Cord Hypothermia by Localized Perfusion Cooling

A NEW technique has been developed which will rapidly and selectively cool the mammalian spinal cord while the temperature of the body core remains near normothermic levels. This becomes specially relevant in the light of the utilization of profound hypothermic levels[1] and isolated cerebral perfusion techniques in neurovascular surgery[2,3]. With this method both acute and chronic preparations can be used to investigate the neurophysiological and cardiovascular events associated with spinal cord cooling as well as to evaluate the efficacy of hypothermia in clinical situations associated with spinal cord trauma and disease.

Young, healthy dogs were used, anaesthetized with 25 mg/kg sodium pentobarbital and a flexible wire spiral endotracheal tube inserted. A midline skin incision was made over the spinous processes from T_8 to L_1, the spinal muscles divided and the posterior elements of T_{10} removed. The perfusion area or 'cold sink' is represented by the surgically exposed wound in depth over the cord and this will hold a volume of 35·0 ± 10·0 ml. of perfusate.

A volume of cold isotonic saline entering at 4·0°–6·0° C is continuously re-circulated over the area of the exposed cord using a pump, heat exchanger and cooling reservoir. The circuit (Fig. 1) consists of: (1) A variable speed, variable occlusion DeBakey roller-type pump. Using 3/16-in. 'Tygon' tubing, flows of 50 and 100 ml./min have been used.

(2) A highly efficient stainless steel Mayo pediatric heat exchanger with a priming volume of 65·0 ml.

(3) A small submersible pump placed in a plastic basin filled with ice water is attached to tubing coming from the inlet and outlet junctions of the heat exchanger. In this manner, the degree of cooling of the perfusate can be regulated by the temperature of the fluid in the cooling reservoir as it circulates in the heat exchanger water jacket. Since the heat exchanger and tubing in the perfusion circuit can be autoclaved, a sterile system can be employed for chronic experiments.

Temperature data were obtained using a '*YSI*' telethermometer system. Spinal cord, brain and paravertebral muscle temperatures were taken with 24 gauge needle thermistors. Oesophageal, rectal inflow and outflow perfusate and cooling reservoir temperatures were taken with appropriate thermistor leads. Arterial blood pressure and pulse rates were obtained from a catheter in a femoral artery connected to a strain gauge transducer. Electrocortical brain activity was recorded from silver disk electrodes placed extradurally and connected to a 'Grass' electroencephalograph.

Table 1. MEAN TEMPERATURE RANGES IN TEN ANIMALS SUBJECTED TO LOCALIZED PERFUSION COOLING OF THE THORACIC SPINAL CORD; PERFUSATE FLOW 100 ML. PER MIN

Perfusion time	Temperature (° C) Spinal cord	Brain	Rectal	Oesophageal
Pre-perfusion	35·0 ± 2·5	34·5 ± 2·5	35·0 ± 2·5	35·0 ± 2·5
30 min	11·8 ± 2·3	34·5 ± 2·5	35·5 ± 2·5	35·0 ± 2·5
150 min	11·8 ± 2·3	34·0 ± 2·5	34·0 ± 2·5	34·0 ± 2·5

Using this technique with steady perfusion flows of 50 ml. per minute, fifteen adult dogs were investigated. Within 30 min after initiation of cooling, mean temperatures in the spinal cord fell from 35·5° ± 2·0° C to 20·0° ± 1·5° C and remained at this level during the remaining 2 h of perfusion (Fig. 2). In another group of ten adult dogs, spinal cord cooling with steady perfusion flows of 100 ml. min were used (Table 1). Within 30 min the mean temperature in the spinal cord fell from 35·0° ± 2·5° C to 11·8° ± 2·3° C and was easily maintained at these hypothermic levels for a subsequent period of 2 h. In both groups of animals, brain and oesophageal temperatures remained

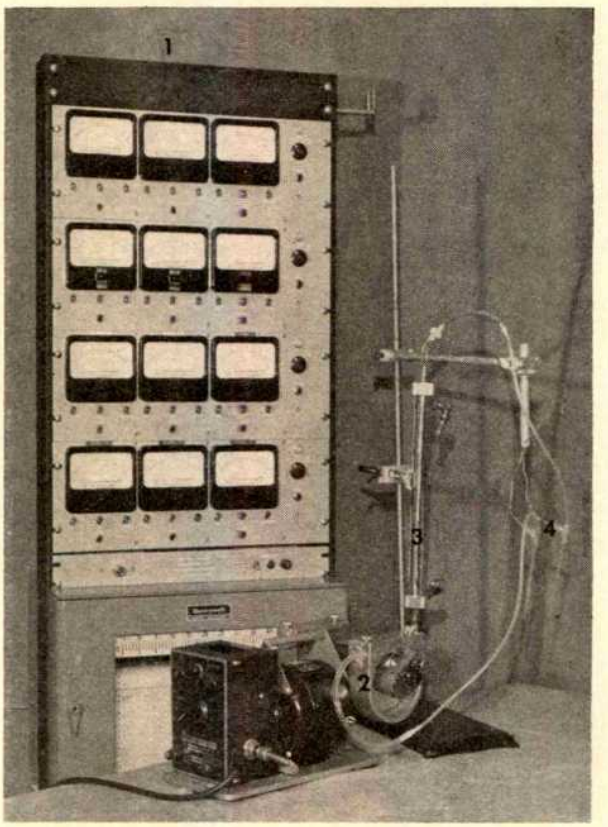

Fig. 1. Temperature recording and perfusion unit. Using the thermistors, temperatures are measured and recorded by the '*YSI*' module (1). Moved by an occlusive roller pump (2), the perfusate is cooled by the heat exchanger (3), pumped through tubing (4) into the area about the exposed spinal cord and then again returned to the heat exchanger by pump for recooling and recirculation

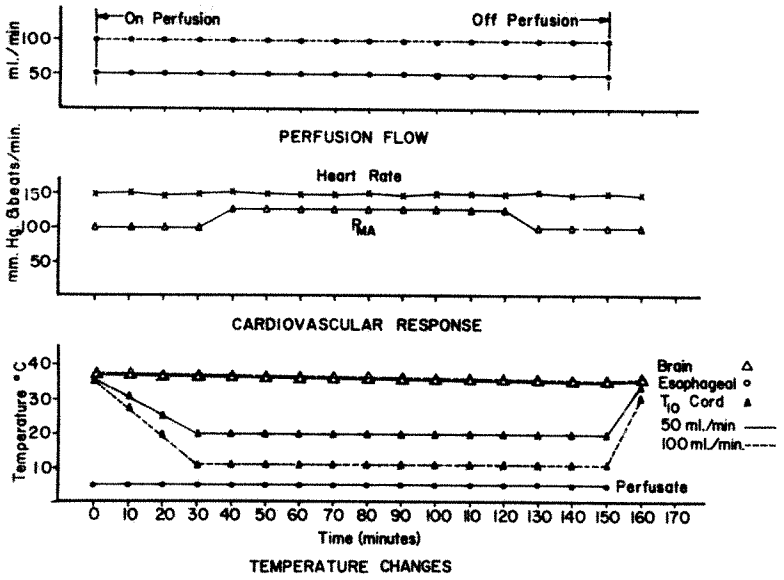

Fig. 2. Temperature changes, perfusion flows and cardiovascular responses during localized spinal cord hypothermia

near normothermic levels during perfusion. Within 10 min after termination of perfusion, spinal cord temperature in both groups returned to the pre-perfusion levels. In all animals, pulse rates remained stable during perfusion cooling and the electrocardiogram showed no abnormal changes. In both groups, the mean arterial blood pressure remained at the baseline level of 100 mm of mercury during the first 30 min of cooling, rose to and was sustained at 120 mm of mercury for 1·5 h and then returned to baseline. Electrocortical brain activity of the frontal, parietal and occipital areas monitored throughout the cooling period revealed no abnormal changes in wave forms in any of the animals during cooling.

In chronic experiments using a sterile technique, the spinal cord of five additional animals were perfusion cooled for 2·5 h at a flowrate of 100 ml./min, after which the surgical incision was closed and the animals were returned to their cages. No functional or neurological abnormality could be detected in any of the animals so cooled after repeated neurological examinations over a period of 2 weeks.

Cyclic Activity in the Male Hypothalamus

IT is well known that the administration of testosterone to female rats shortly after birth induces the differentiation of an acyclic male type of hypothalamus, resulting in permanent sterility and cystic ovaries lacking in corpora lutea[1]. The role of testosterone in the genetic male rat has been examined by the method of castration during infancy[2,3]. The findings have shown that deprivation of endogenous testosterone within 3 days of birth is followed by the differentiation of a cyclic female type of hypothalamus as seen by the presence of corpora lutea in ovarian transplants made during adult life. Castration more than 3 days after birth does not prevent the differentiation of the male type of hypothalamus, for ovaries grafted into animals so treated contained no corpora lutea in adulthood. These and other investigations[4] raised the possibility that the findings would be different if the transplantation and examination of the ovaries were carried out in the immature animal.

In the present experiments male rats were castrated either less than 20 h after birth or when 5–6 days old. All animals received at the time of castration an abdominal transplant of a whole ovary, containing no ripe follicles or corpora lutea, from a littermate. The animals were killed at times varying from 34 to 117 days after operation and the ovarian transplants serially sectioned and examined for corpora lutea. The latter were carefully searched for entrapped ova but none was found.

All three animals castrated at 5–6 days from birth and killed when 114–122 days old showed transplants containing only well-developed follicles and no corpora lutea, thus confirming previous findings[2,3]. The two animals that were castrated on the day of birth and killed at 72 days of age had transplants containing ripe follicles and fresh corpora lutea, again in agreement with the observations of previous workers[2,3]. A new finding was that in all seven male rats castrated 5–6 days after birth and killed at between 39 and 61 days of age the ovarian transplants contained several fresh corpora lutea as well as ripe follicles.

The presence of the testis (and physiological amounts of testosterone) during the critical 1–3 days after birth did not therefore prevent ovarian cycles during the first 8 weeks of life, but induced lack of ovulation in adulthood. Hence it may be inferred that the genetic, intact male hypothalamus behaves in a cyclic female manner for some weeks after birth and then loses its cyclicity and functions in the stable male manner. It has been reported[4] that female rats treated with testosterone shortly after birth exhibit ovarian cycles for a few weeks before developing the acyclic "early androgen syndrome". It would appear, then, that all hypothalami are of the female type during a significant part of the life-span and that the action of androgen, natural or pharmacological, in the neonatal period does not take effect until some time after puberty.

Changes in the Nervous System of Rabbits following the Administration of Sodium Diethyldithiocarbamate

IN 1956, Mûr, Zaruba and Charamza[1] reported myelin degeneration in twenty-one rabbits, of which sixteen had received repeated intravenous injections of α-benzoin oxime, and five had received repeated intravenous injections of diethyldithiocarbamate. The lesion, which was most marked in the spinal cord, was compared to that seen in swayback in lambs and disseminated sclerosis in man. They also reported a decrease in blood copper levels in nine out of twelve rabbits after intravenous admini-

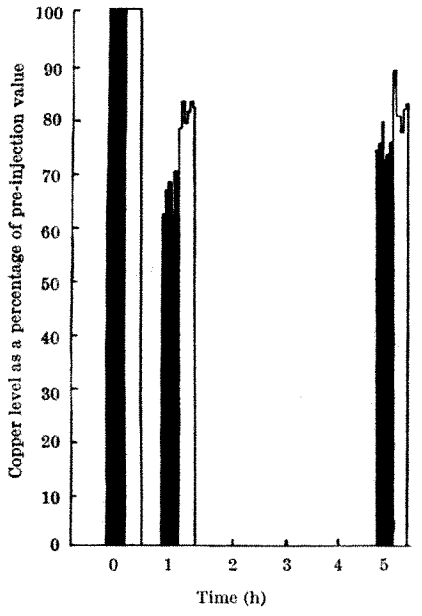

Fig. 1. Blood copper levels in six normal rabbits before, 1 h after, and 5 h after injection of NDDC. The effects of intravenous (■) and intraperitoneal (□) injections are compared

stration of α-benzoin oxime, and in two out of two rabbits following intravenous injection of diethyldithiocarbamate.

Howell[2] confirmed the depression of blood copper levels following the administration of sodium diethyldithiocarbamate (NDDC) and also reported that foetal resorption followed the administration of NDDC to pregnant rabbits. These were short-term experiments and the changes in myelin described by Mûr *et al.*[1] were not seen. Accordingly it was decided to give NDDC daily over a greater period of time in an attempt to produce a lesion in the myelin sheath. It is more convenient to give repeated injections intraperitoneally than intravenously. The effect of NDDC on blood copper levels when administered by the two routes was therefore compared in six rabbits. Methods of blood collection and analysis were as described previously[2]. The chelating agent was given as an isotonic solution, buffered after the method of Sunderman[3], and at a rate of 5 ml./kg body-weight. It can be seen (Fig. 1) that blood copper levels were depressed by either intraperitoneal or intravenous injection of NDDC.

One month before starting daily injections liver biopsies were taken from each of the eighteen Dutch and New Zealand rabbits and the copper content of the samples determined. Fifteen of the eighteen rabbits received daily injections of NDDC; three of these also received weekly subcutaneous injections of copper calcium EDTA; three also received, in addition to the weekly subcutaneous injection, a daily oral mineral supplement containing the elements iron, zinc, cobalt and manganese. The remaining three rabbits did not receive carbamate but were given a daily intraperitoneal injection of saline at a dosage of 5 ml./kg body-weight.

Daily injections for five months did not produce any significant change in pre-injection blood copper levels, nor could any sign of inco-ordination be detected. We therefore decided to kill six of the rabbits to determine the copper content of their tissues and to examine the peripheral and central nervous system histologically. The remaining twelve rabbits, two of which were receiving saline, were injected daily for a further two and a half months at a dosage of 10 ml./kg body-weight. Seven and a half months after the experiment began all the rabbits receiving NDDC showed varying degrees of inco-ordination. These rabbits were then killed and tissues again taken for histological examination and chemical analysis. The copper levels in the tissues of these twelve rabbits, together with the values of the initial liver biopsies, are recorded in Table 1. The copper levels of the liver and central nervous system of those rabbits which received carbamate were markedly increased whereas those of the rabbits receiving saline were not. This increase was in direct contrast to the postulation of Mûr and his colleagues[1]. The rabbits killed after five months' daily injections of NDDC showed a similar, though less marked, increase in copper levels.

Table 1

Treatment	No. of rabbits	Copper content in p.p.m. dry weight: Pre-injection Liver biopsy	Tissues taken at seven and a half months: Liver	Spinal cord	Kidney
Carbamate	7	11·6 (11·1–12·2)	235·4 (80·0–445·0)	28·2 (24·3–32·1)	15·5 (14·4–18·8)
Carbamate + copper EDTA	1	11·4	480·0	23·8	14·4
Carbamate + copper EDTA + minerals	2	10·8 (10·6–11·0)	857·0 (490·0–1,220)	45·9 (34·8–57·0)	17·1 (15·3–18·9)
Saline	2	11·3 (10·9–11·7)	16·4 (11·3–20·0)	3·1 (1·5–4·7)	11·5 (10·7–12·3)

The figures in parenthesis represent the range of values.

The spinal cord was fixed in Heidenhain's Susa while all other tissues were fixed in neutral formalin. Paraffin sections of peripheral and central nervous system were cut at 5μ or 15μ and stained by haematoxylin and eosin, luxol fast blue, the Nissl method, and Glees and Marsland's method for neuraxons. Histological examination of the white matter of the spinal cord of all rabbits that had received NDDC showed swollen axons and ballooned myelin sheaths (Fig. 2). In addition to these changes, which are characteristic of early Wallerian degeneration, several cords contained gitter cells. The lesion was found at all levels of the spinal cord and occurred predominantly in the periphery of the ventral and lateral columns. In six of the rabbits Wallerian degeneration was also seen in the dorsal columns. In the grey matter of the spinal cord some neurones had lost their structural detail and had a homogeneous eosinophilic appearance. This change was seen in ten of the fifteen rabbits receiving NDDC and occurred in Clarke's column and in ventral horn cells. Lesions typical of early Wallerian degeneration were also found in the sciatic nerves of eight of the rabbits receiving carbamate. None of these changes was seen in the tissues of the rabbits receiving injections of saline.

Although the lesion in the spinal cord was associated with a simultaneous accumulation of copper in the tissue, there was no evidence of pathological change in the corpus striatum of the brain, or of pigment deposits in Decemet's membrane, or of cirrhosis of the liver, or of permanently

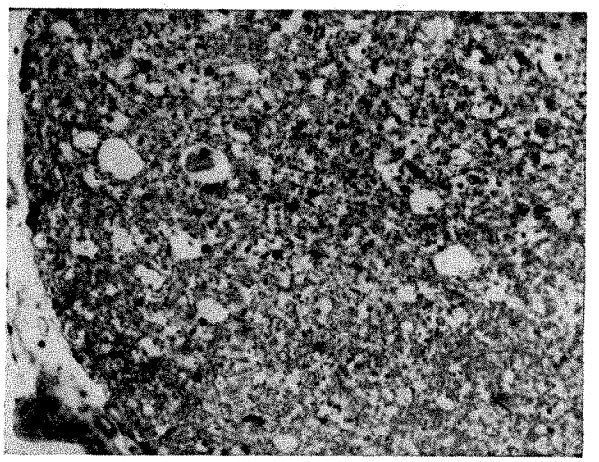

Fig. 2. Transverse section of lumbar spinal cord of a rabbit which had received daily intraperitoneal injections of NDDC for seven and a half months. The section shows axon swelling and ballooning of myelin sheaths. (Haematoxylin and eosin, ×150)

low caeruloplasmin levels. The condition cannot therefore be said to simulate Wilson's disease. The pathogenesis of the lesion produced in rabbits is not yet known. It may be associated with the ability of NDDC to inhibit enzymes[4].

PHARMACOLOGY

Muscle Contraction produced by Sulphydryl Inhibitors

IT was recently reported[1] that the sulphydryl (—SH) agent, parachloromercuribenzoate (PCMB), causes superprecipitation of actomyosin gel. Masking of an —SH group appears to prevent interaction between ATP and some inhibitory site on the protein, thus enabling ATP to induce superprecipitation through reaction with another site. If this phenomenon is related to changes occurring in the actomyosin system during muscle activity, then —SH agents should be expected to produce contraction. Accordingly, several such agents were tested on skeletal muscle, and they were found to cause various types of contractile phenomena.

All experiments were done on the sartorius muscle isolated from the frog *Rana pipiens* during winter and spring months. The muscle was placed in a chamber containing 10 ml. Ringer's solution (110·88 mM sodium chloride, 2·0 mM potassium chloride, 1·8 mM calcium chloride, 0·1 mM sodium phosphate, 2·02 mM sodium bicarbonate; *p*H 7·2; 22°–24° C). Contraction was recorded isometrically with a strain gauge and ink-writing oscillograph, background tension being initially adjusted to 0·5 g. After a control period in normal Ringer's, during which the muscle was stimulated directly once per min with supramaximal square wave pulses, the muscle bath was changed to a Ringer's containing *d*-tubocurarine chloride (5×10^{-5} g/ml.), and stimulation was continued for another 10 min. The bath was then changed to a tubocurarine–Ringer's which contained the test agent. The presence of a paralysing concentration of tubocurarine in these experiments is necessary because initial tests showed that some —SH inhibitors facilitate neuromuscular transmission.

After a latent period of about 1 min, PCMB causes repetitive low-amplitude contractions and a moderate increase in muscle tension (Fig. 1). After this effect, stimulus-evoked contractions begin to decline, and within another 15 min the muscle becomes completely unresponsive to direct stimulation. The poor aqueous solubility of PCMB limited its test concentration to 1 mM. The more soluble sulphonated analogue, parachloromercuribenzenesulphonate (PCMBS), was tested at a 3 mM concentration. After a latent period of 2–3 min, this agent causes repetitive low-amplitude contractions with no accompanying increase in tension (Fig. 1). About 20 min after termination of this effect, there begins a very slow-rising and irreversible increase in tension which reaches an amplitude of about half the maximum stimulus-evoked twitch.

The modest effects of the organomercurials and their poor aqueous solubilities discouraged further experiments with this type of —SH agent. Instead, attention was focused on *N*-ethylmaleimide (NEM). This agent contains an activated double bond which forms addition compounds with reactive —SH groups of protein, and at *p*H 7·2 the reaction is rapid and highly specific[2]. Fig. 2*A* shows that NEM has a striking biphasic action on skeletal muscle. The initial contractile effect is immediate in onset, reaches a peak within a few seconds, and is short-lived. This is followed by a slow-rising increase in tension which is incompletely reversed by repeated washings in normal Ringer's. The magnitude of the initial response to 5 mM NEM is 60–125 per cent of the maximum stimulus-evoked twitch. The secondary response to the same concentration of NEM is more constant and is always close to the maximum twitch amplitude. Repetitive low-amplitude contractions, similar to those produced by the organomercurials, always appear during and immediately after recovery from the initial NEM response. The response to direct electrical stimulation is severely attenuated during the peak of the secondary contractile effect; but for several minutes after NEM application and even at the time when the secondary response begins, there is marked twitch potentiation. Dose-response relationships were not thoroughly studied, but the available data indicate that threshold NEM concentration (for the initial response) is 0·5–1·0 mM, and the maximum effect is produced by 5–10 mM. Treatment of a muscle with equimolar concentrations of *l*-cysteine and NEM has no effect on muscle tension or on amplitude of stimulus-evoked contractions. This suggests that the —SH binding group of the NEM molecule is required for pharmacological activity.

Further investigation indicated that absence of external calcium or membrane depolarization blocks the initial response to NEM. The role of calcium is suggested by the type of experiment shown in Fig. 2*B*, in which the muscle is initially immersed for 30–50 min in calcium-free Ringer's containing ethylenediamine tetraacetic acid (EDTA; trisodium salt at *p*H 7·2); the initial contractile effect of NEM is completely blocked by such treatment,

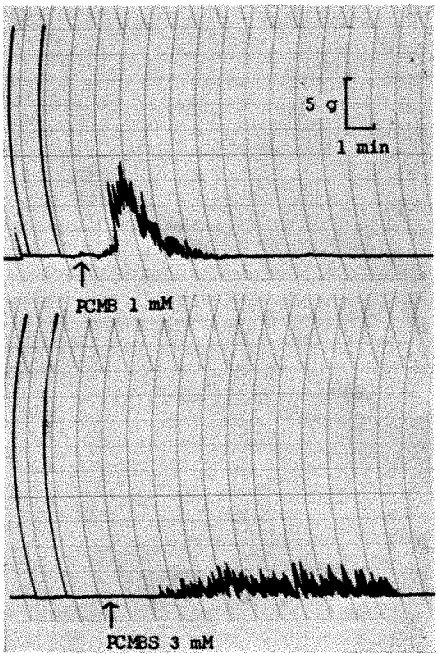

Fig. 1. Effects of PCMB and PCMBS on frog sartorius muscle. Arrows indicate time of application of test agent. Maximum stimulus-evoked twitches shown to left of arrows

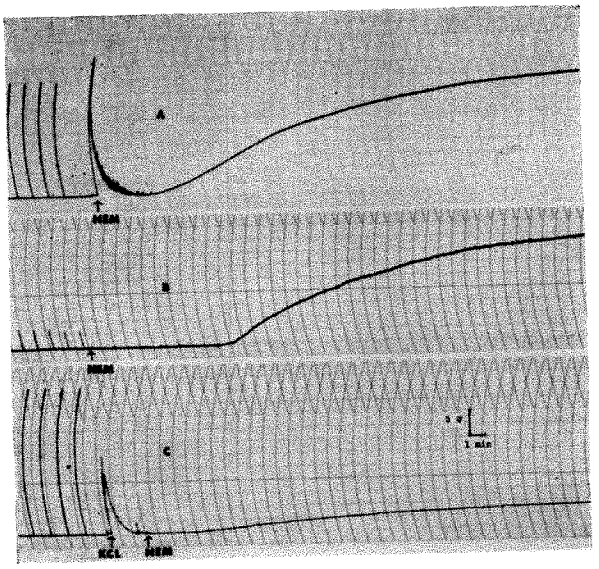

Fig. 2. Effects of NEM on frog sartorius muscle. *A*, Effect in normal Ringer's. *B*, Effect after 50 min of treatment in Ringer's containing 1 mM EDTA. *C*, Effect 3 min after application of 116 mM potassium chloride. Maximum stimulus-evoked twitches shown to left of arrows

but the secondary response is unaltered. Immersion of a muscle for the same amount of time in calcium-free Ringer's without EDTA has no effect on NEM action. Assuming that NEM produces its initial effect through binding of reactive —SH groups, it is interesting that low external calcium causes a pronounced decrease in the number of ionizable —SH groups in excitable tissue[3]. This suggests that protein configuration in EDTA–Ringer's is unfavourable for —SH group reactivity.

After pre-treating a muscle with isotonic potassium chloride, there is complete blockade of the initial NEM action, and this indicates a dependence of the NEM response on a normal resting membrane potential. Depolarization in isotonic potassium chloride may also be associated with changes in protein configuration which modify —SH group reactivity, for there is a marked loss of ATP and other organic phosphates from excitable cell membranes under these conditions[4]. In fact, this loss of organic phosphate also occurs in EDTA-treated tissues[4,5], so there may be a fundamental relationship between the two types of antagonism of NEM action, one by EDTA and the other by isotonic potassium chloride.

It seems unlikely that the exceedingly rapid and transient phase of NEM action is associated with a direct effect on contractile proteins. The secondary rise in tension may be related to such an effect and, if so, its resistance to EDTA is interesting. If the initial response involves a membrane action, NEM could serve as a useful tool in the study of molecular events underlying excitation and electromechanical coupling. Assuming that protein configuration changes are associated with these processes, the reactivity of cystein —SH groups could play a key part.

HAEMATOLOGY

Haemoglobin Variants in a Species of Wild Mice—*Peromyscus maniculatus*

HAEMOGLOBINS from various strains of mice have been referred to as single (Hb^s) or diffuse (Hb^d)[1–3], according to the appearance of the electrophoretic patterns of the haemoglobin haemolysates. Popp[1] has suggested that two allelic genes are responsible for the single or double (diffuse) bands. Recently, two investigators[4,5] have shown independently that the diffuse patterns are the result of polymerization of mouse haemoglobins to eight-chain double molecules, and hence from 4*S* to 7*S* tetramers. This transformation can be enhanced by reduced glutathione (GSH) or oxidized glutathione (GSSG) and inhibited by iodoacetamide (IOA). These polymerization products, frequently encountered with inbred strains and with domestic mice (*Mus musculus*), are not often found with wild species.

In a sub-species of the white-footed deer mouse, *Peromyscus maniculatus rufinus*, three highly significant morphological differences were found in haematological studies. These mice were trapped alive from two distinct ecological and geographical locations, one from an area at Gothic, Colorado, at an elevation of 10,450 ft. and another from an area on the north rim of Black Canyon of the Gunnison National Monument, Montrose, Colorado, at an elevation of 7,500 ft. The haematological data are shown in Table 1. The results are in complete agreement with Gough and Kilgore[6], but differ markedly from those previously reported[7–11].

Table 1. HAEMATOLOGICAL STUDIES ON *Peromyscus maniculatus rufinus* FROM 10,450 FT. AND 7,500 FT.

	No. of mice	Hb (g per cent)	Hct (per cent)	RBC 10^6/mm^3	MCV $c\mu$	MCH $\gamma\gamma$	MCHC (per cent)
P.m.r. (Gothic) 10,450 ft.	81	15·5 ± 1·2	46 ± 3	11·2 ± 1·3	41 ± 4	13·8 ± 1·4	33·5 ± 1·7
P.m.r. (Black Canyon) 7,500 ft.	41	14·9 ± 0·9	47 ± 2	12·9 ± 0·8	37 ± 2	11·7 ± 1·0	31·6 ± 1·2

From the data it is apparent that the mice at the higher altitude have larger erythrocytes, but a lower erythrocyte count and a greater mean corpuscular haemoglobin concentration. The relationship of cell size and altitude in these studies is exactly the converse of the expectation that, as altitude increases, the erythrocyte count should increase with an accompanying decrease in erythrocyte size. As Wintrobe[12] points out, the polycythaemia is absolute; erythrocyte counts are markedly elevated with an associated increase in haemoglobin and packed cell volume. A slight macrocytosis was observed by Wintrobe, attributable to an increased reticulocytosis; the mean corpuscular haemoglobin concentrations were not found to be altered from the normal.

Haemoglobin electrophoresis on each of these mice on starch gel at *p*H 8·1 revealed only single bands although, in other species and sub-species of *Peromyscus*, among some sixty mice both single and double but no diffuse bands were seen (Figs. 1 and 2). The single haemoglobin band from Black Canyon was faster than the haemoglobin from Gothic. When a mixture of these haemoglobins was chromatographed on DEAE cellulose 'Sephadex 40', two separate components were again identified.

To test the possibility that diffuse bands could be produced experimentally, samples were subjected to 37° C for several days or allowed to age at room temperature for up to 30 days. No diffuse bands were produced. However, incubation of samples with reduced and oxidized glutathione produced the characteristic diffuse bands (Fig. 2). Incubation by dialysis with 6·8 mg iodoacetamide/ml. of haemoglobin for 12–24 h prior to addition of GSH or GSSG did not prevent (Fig. 2) polymer formation but tended to decrease it.

The solubilities of both Gothic and Black Canyon haemoglobin types are identical, and molecular weights are identical with ultracentrifuge sedimentation values of $4{\cdot}2 \times 10^{-13}$.

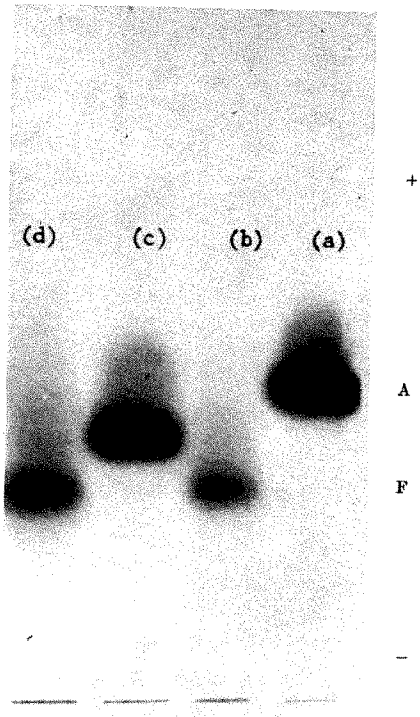

Fig. 1. Starch-gel electrophoresis at *p*H 8·1 of haemoglobin haemolysates from *Peromyscus maniculatus rufinus* at Gothic (10,450 ft.) and Black Canyon (7,500 ft.). Hb-A and F are used as markers. Hb-Gothic migrates slightly cathodal to Hb-Black Canyon. These samples were run before dialysis with iodoacetamide. (*a*) Hb-A; (*b*) Hb haemolysate-Black Canyon; (*c*) Hb-F; (*d*) haemolysate-Gothic

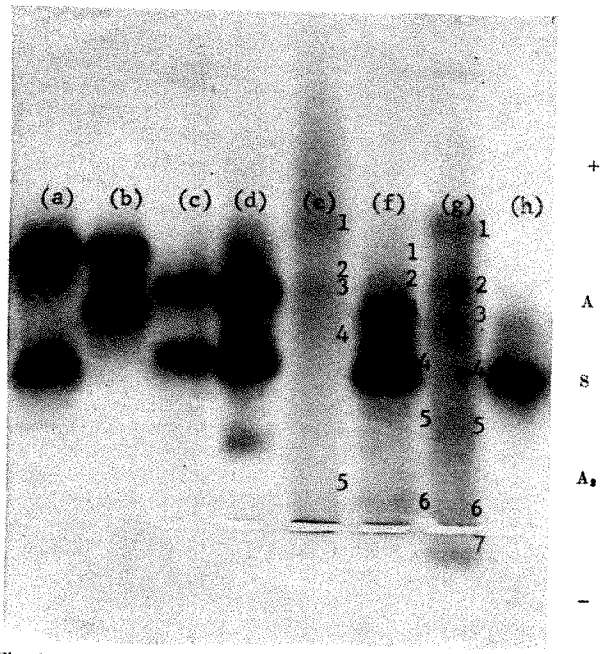

Fig. 2. Starch-gel electrophoresis (*p*H 8·1) of haemoglobin haemolysates from various sub-species of *Peromyscus maniculatus*. Hb-A and S are used as markers. The four samples on right of figure illustrate the diffuse six to seven banded components produced experimentally with GSSG and GSH mixtures from single banded *Peromyscus maniculatus rufinus* (Gothic) Hb haemolysate. (*a*) and (*b*) *Peromyscus maniculatus fulvus*; (*c*) *Peromyscus maniculatus blandus*; (*d*) Hb-A + S; (*e*) Hb haemolysate-(Gothic) + 10 mg GSSG and 20 mg GSH, after IOA dialysis; (*f*) Hb haemolysate-Gothic + 20 mg GSH after IOA dialysis; (*g*) Hb haemolysate Gothic + 20 mg GSSG—no IOA dialysis; (*h*) Hb-haemolysate-Gothic-untreated

Our findings, although still incomplete, suggest that natural selection has led to a more efficient type of haemoglobin, making possible the selection of the larger cell size. We thank Mrs. J. Odom for technical assistance and the Rocky Mountain Biological Laboratory at Gothic, Colorado, for the use of their facilities.

Radioactive (Chromium-51) Heinz Bodies

HEINZ bodies are refractile granules appearing within erythrocytes and stainable with certain dyes such as crystal violet[1–3]. In man, their appearance is often associated with anaemia due to drug administration (for example, phenylhydrazine, menadione) or contact with other agents (for example, aniline dyes), particularly in certain sensitive individuals. Although the granules can be readily prepared experimentally by treatment of animals or isolated erythrocytes with various drugs, their chemical composition is only partially resolved and their metabolic disposition is unknown.

A prime difficulty in investigating Heinz bodies has been the absence of methods for quantitative evaluation. Most research workers simply estimated the number and size of granules observed under the light microscope[4,5]. Beutler *et al.*[6], in their study of Heinz body formation during exposure of erythrocytes to acetylphenylhydrazine *in vitro*, distinguished sensitive glucose-6-phosphate dehydrogenase-deficient cells from insensitive normal cells by counting the percentage of cells with five or more inclusion bodies. Jandl *et al.*[7] obtained more quantitative estimates by weighing the precipitate obtained on lysis of cells.

During experiments dealing with erythrocyte survival in rabbits treated with phenylhydrazine, we noted that the precipitate isolated from chromium-51-labelled erythrocytes was radioactive. This observation provides a convenient and simple method for quantitative analyses. A few experiments illustrating applications of the method follow:

Erythrocytes were labelled with radiochromium by incubating 3 ml. of rabbit or human, heparinized, whole blood with 30 μc. of chromium-51-labelled sodium chromate (Squibb, 100 mc./mg) for 1 h at room temperature[8,9]. Samples were washed twice with ten volumes of isotonic saline for re-injection into rabbits, or washed three times, admixed with three volumes of unlabelled cells from the same donor, and then suspended in isotonic phosphate buffer, *p*H 7·4, for *in vitro* investigations; the washing procedure eliminated radio-labelled proteins in the plasma as well as any residual chromate. The *in vivo* investigations were performed by perfusion of the ear vein of rabbits at a constant speed of 0·5 ml./min (Harvard infusion pump) for 50 min. On the other hand, *in vitro*

investigations were performed on a Dubnoff metabolic incubator at 37° C. Phenylhydrazine-hydrochloride (Eastman Organic Chemicals), recrystallized from ethanol, was dissolved in isotonic buffer and neutralized by titration with sodium hydroxide.

Heinz bodies were isolated by lysis of cells in from ten to twenty volumes of distilled water followed by centrifugation at 5,000*g* for 20 min. The insoluble stroma (controls) or Heinz bodies with stroma (experimental samples) were washed twice with 10 ml. water, at which point the residual radioactivity of the supernatant wash fluid was negligible (0–60 c.p.m. for the wash fluid versus 2,000–100,000 c.p.m. for the Heinz body preparation). Generally, 0·5–1 ml. of whole blood (*in vivo* investigations) or of cell suspension (*in vitro* investigations) was sampled; later, 2 ml. from a total of 4 ml. suspension of washed precipitate in water was analysed in a well-type scintillation counter.

The data of Tables 1 and 2 illustrate the formation of increasing amounts of radioactive precipitate in erythrocytes exposed to increasing doses of phenylhydrazine. Table 1 is from an *in vitro* experiment with human cells; Table 2 is from an *in vivo* experiment with a group of rabbits. Increasing amounts of Heinz bodies with increasing dose of stressor agent were observed microscopically[6] in these experiments. Other investigators[5,7] have correlated the increased Heinz body formation with increasing amounts of insoluble material obtained after lysis. The insoluble radioactive precipitate was undoubtedly derived from haemoglobin which has been shown to account for a minimum of 78 per cent of the chromium label[8], although contributions from other, as yet unidentified, proteins cannot be rigorously excluded. The activity associated with stroma, 3·1 per cent and 3·8 per cent for two samples of human erythrocytes, and 2·9 per cent and 3·3 per cent for two rabbits, corresponds to the amount of haemoglobin associated with stroma in water-washed preparations[10,11].

Table 1. HEINZ BODY FORMATION AND LOSS OF 'INTACT HAEMOGLOBIN' IN HUMAN ERYTHROCYTES *in vitro*

Phenylhydrazine (μmoles/ml.)	Radioactivity in precipitate (as percentage of total radioactivity)	Loss of 'intact haemoglobin' (per cent)
0	3·1 (stroma)	—
2·5	10·7 (7·6 corr.)*	11
5·0	15·3 (12·2 corr.)	17
10·0	23·5 (20·4 corr.)	31
20·0	35·5 (32·4 corr.)	54

A 25 per cent cell suspension in isotonic buffer was used. The combined total of oxyhaemoglobin and methaemoglobin (intact haemoglobin) was measured with a cyanomethaemoglobin method. Measurements were made at 3 h.
* Figures in parentheses have been corrected for stromal radioactivity.

Table 2. HEINZ BODY FORMATION IN RABBITS

Phenylhydrazine administered (mg/kg body-weight)	Heinz body formation at 24 h (as percentage of total radioactivity)*
10	1·8, 3·4
20	4·5, 4·7
50	12·6, 10·2
100	21·3

* Values have been corrected for stromal radioactivity. A correction of 3·1 per cent was used; this was the average (2·9 per cent + 3·3 per cent) for two animals before infusion. Results listed are for individual animals.

The term 'intact haemoglobin' was originally used by Harley and Mauer[5] to designate the combined total of oxyhaemoglobin and methaemoglobin. In Table 1 the loss of 'intact haemoglobin' gives an estimate of the conversion of haemoglobin to various breakdown products including Heinz bodies. The radioactivity incorporated into the isolated precipitate (corrected for stromal radioactivity) accounted for 60–72 per cent of the loss in 'intact haemoglobin'. In a second experiment with blood from another human donor, similar results were obtained, except that there was greater haemoglobin loss and proportionately greater radioactivity in the precipitate due to a longer incubation time of 24 h (for example, with 20 μmoles phenylhydrazine per ml., there is 66 per cent loss in haemoglobin against 47 per cent radioactivity in the precipitate). The haemoglobin lost but not appearing in the radioactive precipitate may comprise very small granules, for example, those observed in the electron microscope[12] which may not sediment at 5,000*g*, or other intermediates between haemoglobin and the larger coalesced granules.

There has been some controversy concerning the question of a stromal or haemoglobin origin for Heinz bodies. The granules are observed most frequently at the periphery of cells, closely associated with the plasma membrane, but the available evidence favours the suggestion that they are derived from haemoglobin[7,12–14]. Further support for this point of view can be found in: (1) the incorporation of chromium-51-labelled haemoglobin into the granules in amounts very much in excess of that initially bound to stroma; (2) the proportionality (Table 1) between the extent of incorporation and the extent of haemoglobin destruction. However, the possibility of stromal participation in Heinz body formation has not as yet been tested. The data in Table 3 are from an experiment in which Heinz body formation in erythrocyte lysates (with and without stroma) was quantitatively evaluated. The amount of radioactive precipitate was the same in the presence or absence of stroma and thus the importance of stromal participation appeared negligibly small. The association of Heinz bodies with stroma in intact cells is probably due, as suggested by Rifkind and Danon[12], to migration of the Heinz bodies to the cell periphery during the coalescence stage.

Table 3. HEINZ BODY FORMATION IN THE PRESENCE AND ABSENCE OF STROMA

Phenylhydrazine (μmoles/ml.)	Radioactivity in precipitate (as percentage of total radioactivity) With stroma	Without stroma
0	3·8	0·1
8	19·6 (15·8 corr.)	16·3 (16·2 corr.)
16	32·4 (28·6 corr.)	26·7 (26.6 corr.)

A 10 per cent erythrocyte lysate in distilled water was used. Stroma were removed by centrifugation at 16,000*g*. Samples were analysed after 3 h.

Hydrogen peroxide is a toxic intermediate in the drug-induced anaemias associated with glucose-6-phosphate dehydrogenase deficiency[15,16]. Heinz bodies formed by the action of hydrogen peroxide have been observed in erythrocytes pretreated with the catalase inhibitor, cyanide[4], as well as in the absence of catalase inhibitors[17,18]. A quantitative evaluation of Heinz body formation in normal human erythrocytes exposed to hydrogen peroxide vapour is presented in Table 4. The increase in radioactivity associated with the stroma of the control after incubation for 24 h is in keeping with the known formation of Heinz bodies after prolonged incubation in the absence of stressor drugs[7]. After correction for the control, the conversion of haemoglobin to Heinz bodies by roughly 100 μmoles hydrogen peroxide acting on 0·4 ml. of erythrocytes was 8·0 per cent and 8·2 per cent, respectively.

Table 4. HEINZ BODY FORMATION AFTER EXPOSURE TO HYDROGEN PEROXIDE

Sample	Radioactivity in precipitate (as percentage of total radioactivity) Subject 1	Subject 2
Zero time	3·8	3·1
Control at 24 h	6·3	5·8
H_2O_2	14·3 (8·0 corr.)	14·0 (8·2 corr.)

4 ml. of a 10 per cent suspension of cells in isotonic buffer were exposed to 4·5 μmoles of hydrogen peroxide per hour with a diffusion method (ref. 16).

The foregoing experiments demonstrate the isolation of radioactive Heinz bodies from chromium-51-labelled erythrocytes, and the usefulness of radioactive measurements for obtaining quantitative estimates of Heinz body formation both *in vivo* and *in vitro*. The method should find ready application for such studies as: (1) comparing the relative efficacies of the various oxidant drugs; (2) comparing the degree of reaction in the various sensitive cell types[6,17–19]; (3) evaluating the kinetics of formation and elimination of Heinz bodies *in vivo*. In addition, the chromium-51 tracer provides a tool with

which to approach problems such as the structure, pathway of metabolism, relationship to other erythrocyte inclusion granules such as Schmauch bodies[20], and involvement of various haemoglobin forms. (In normal erythrocytes, the chromium-51 label is located almost exclusively on haemoglobin A_3; however, labelling of haemoglobins F, H and Bart's has been observed[21].)

I Antigen in Leukaemic Patients

FOLLOWING the report of McGinnis *et al.* that the red cells of fifteen out of forty patients with leukaemia tested by them had a diminution of I antigen[1], we tested red cells from fifteen patients with acute leukaemia using anti-I sera from the following three persons: (*a*) a group A patient with *M. pneumoniae* infection whose serum was obtained at the time of a transient rise of her cold agglutinin titre to 128 at 4° C; (*b*) a group A patient with the chronic cold agglutinin syndrome who had a cold agglutinin titre of 1,024 at 4° C; and (*c*) a healthy donor of group Ai who had a cold agglutinin titre of 8 at 4° C. These sera were used after neutralization of isoagglutinin anti-B with group B substance.

Fourteen of the patients investigated were children with acute leukaemia; five were investigated at the time of diagnosis or during subsequent relapse, five during partial remission and four during complete remission. Only three of the patients had been transfused during the 4 months before obtaining their red cells for testing. In addition, we were able to test red cells from an adult patient who initially came to us with a chronic myeloproliferative disorder and who 3 years later developed acute leukaemia.

The I status (agglutinability with anti-I) of red cells from the leukaemic patients was compared quantitatively with that of cells from normal subjects of I status, from a healthy donor of i status and from cord blood of $i_{(cord)}$ status. A 2 per cent saline suspension of washed red cells was prepared from each subject. Starting with a suitable initial dilution, serial two-fold dilutions of the anti-I sera were made. Then to one drop of each dilution of anti-I serum an equal volume of red cell suspension was added. Readings for the grading of agglutination were performed microscopically after 2 h incubation at 4° C.

When compared with normal I-positive red cells, none of the cells from the leukaemic patients showed reduction in agglutinability with any of the three anti-I sera. Initially the tests on the children were performed, a few at a time, using fresh red cells which had been taken into ACD. To achieve a more accurate comparison a sample of red cells from each donor and each leukaemic patient was stored in glycerol at −20° C (ref. 2) and the tests were repeated, all at one session, after storage times ranging between 3 and 10 months. Again no loss of I antigen was observed in the leukaemic patients. Some typical results are shown in Table 1. Red cells obtained from the adult patient during the myeloproliferative phase of his disease (stored at −20° C in glycerol for 7 months at the time of test) and those obtained when he entered the leukaemic phase (stored at −20° for 3 months) were tested at the same time using the same anti-I sera; both samples reacted strongly with all three anti-I sera, there being no diminution of agglutination in the second sample.

Our results are in agreement with those of Ducos *et al.* who, using a quantitative technique, also failed to detect loss of I antigen in leukaemic patients[3].

An observation worthy of note in Table 1 is that, under the conditions of these tests, the lack of I antigen in the cord blood cells was detected by the weak anti-I from the donor (*c*) but not by the stronger anti-I from donors (*a*) and (*b*), even though these latter two sera were suitably diluted for the test. It appears, therefore, that there may be differences in the ability of various anti-I sera to detect a partial lack of I antigen, as in $i_{(cord)}$ cells, whereas a severe lack of I antigen, as in adult i cells, is detected by all anti-I sera.

We thank Dr. W. J. Jenkins for the cells from the i donor, Dr. J. Wallace for the anti-I serum from donor (*c*), and Dr. W. Watkins for the group B substance.

Table 1. DEGREE OF AGGLUTINATION WITH ANTI-I OF RED CELLS FROM HEALTHY DONORS AND FROM PATIENTS WITH LEUKAEMIA
Tests performed at 4° C on cells stored in glycerol at −20° C

Source of red cells	Agglutination with anti-I* (reciprocal of serum dilution)								
	Anti-I serum (*a*)			Anti-I serum (*b*)			Anti-I serum (*c*)		
	32	64	128	512	1,024	2,048	3	8	16
Healthy controls									
I donor 1	+ + +	+ +	+	+ + +	+	−	+ +	−	−

Multiple Haemoglobins in Bats

MULTIPLE haemoglobins and variation in electrophoretic mobility have been reported for many animals. The physiological significance of these discoveries is not completely understood. Some investigators have compared haemoglobin electrophoretic properties and phylogeny. Dunlap, Johnson and Farner[1] analysed 21 species of birds and showed differences in haemoglobin apparently correlated with taxonomic kinship, and Marchlewska-Koj[2] noted that amphibian haemoglobin heterogeneity may serve as complementary data for taxonomy. Comparable investigations of fish haemoglobins have been conducted by Hashimoto and Matsuura[3,4], Smith[5], and others, and of mammalian haemoglobins by Blumberg, Allison and Garry[6], Foreman[7], Ewy and Wojcik[8], Buettner-Janusch[9], Buettner-Janusch and Buettner-Janusch[10] and others.

A search revealed no mention of electrophoretically distinct haemoglobin types in bats. Johnson and Wicks[11], using paper electrophoresis, found haemoglobin of the Mexican free-tailed bat (*Tadarida brasiliensis*) to be nearly isoelectric at *p*H 8·6. Foreman[12] published drawings of bat (identification uncertain) and human haemoglobin tryptic peptide chromatograms to show variations between distantly related taxa. It thus seemed of interest to investigate the existence of multiple haemoglobins in bats. Results showed that two of the five species investigated have electrophoretically heterogeneous haemoglobin.

Bat species and number used in this investigation were: big brown bat (*Eptesicus fuscus* (Beauvois)), 10; gray myotis (*Myotis grisescens* (Howell)), 9; big myotis (*Myotis lucifugus* (Le Conte)), 4; eastern pipistrelle (*Pipistrellus subflavus* (F. Cuvier)), 12; and big-eared bat (*Plecotus townsendii* Cooper), 4. Big-eared bats and big myotis were captured at Dillo cave, 2·1 miles north of Reed Springs, Stone Co., Missouri; some big brown bats were caught in a building in Kansas City, and all other animals were collected at Henson's cave, one-half mile west of Jane, McDonald Co., Missouri. Adult animals of both sexes were used.

Blood samples were drawn by heart puncture into a syringe wetted with cold 2 per cent sodium oxalate. From 0·1 to 0·5 c.c. of blood were received, added to equal volumes of cold isotonic saline (0·85 per cent sodium chloride) and centrifuged at low speed for 5 min. Washing with saline was repeated three times to remove all plasma constituents. Packed cells were lysed with 1·5 volumes of distilled water shaken for 5 min with 0·5 volumes of toluene, as recommended by Drabkin[13], and centrifuged at 3,000 r.p.m. for 15 min. The haemoglobin solution was removed from beneath the toluene layer with a fine capillary pipette. Some haemoglobin solutions were immediately analysed while others were frozen and stored at $-10°$ C until analysis. Freezing and thawing of samples up to three times resulted in no apparent difference in the ionograms.

Electrophoretic patterns were obtained with the Gelman electrophoresis apparatus (Gelman Instrument Co., Ann Arbor, Mich.) using Gelman 'Sepraphore III' cellulose polyacetate strips and barbitol buffer *p*H 8·6, ionic strength 0·05. Approximately 4 λ of haemoglobin solution was applied to the strip with the Gelman sample applicator. Separation was carried out using 300 V for 3 h. After separation strips were dried at room temperature, preparatory to staining, or placed immediately in Ponceau *S* stain (200 mg Ponceau in 100 ml. 5 per cent trichloroacetic acid) for 5 min, then in three consecutive rinses of 5 per cent acetic acid for 3 min each and then dried at room temperature. Immediate staining seemed to yield clearer ionograms.

Quantitation was accomplished by elution with 5·0 ml. of 0·1 N sodium hydroxide and measurement in a 'Spectronic 20' colorimeter (Bausch and Lomb Optical Co., Rochester, N.Y.) at 540 mμ. Hyland human haemoglobin electrophoresis controls AC (Hyland Laboratories, Los Angeles, Calif.) were subjected to electrophoresis simultaneously with bat specimens to serve as reference markers.

Alkali resistant haemoglobin was examined by the method of Singer, Chernoff and Singer[14], using the same colorimeter and wave-length. This portion of the investigation was severely limited by the small amount of material available.

Electrophoretic results showed that haemoglobin consists of two components in the eastern pipistrelle and big-eared bat, whereas haemoglobin of the big brown bat, gray myotis and big myotis are homogeneous. For sake of convenience the two haemoglobins of the eastern pipistrelle and big-eared bat have been designated, in the order of increasing electrophoretic mobility, Hb-PS_1, and Hb-PS_2, Hb-PT_1 and Hb-PT_2, respectively. Single haemoglobins from the big brown bat, gray myotis and big myotis have been designated Hb-EF, Hb-MG and Hb-ML, respectively.

Control human Hb-C migrated at a faster rate than human Hb-A. Hb-PS_1 and Hb-PT_1 were slightly slower than Hb-PS_2 and Hb-PT_2 (consistently 2 mm behind). Mobility of Hb-Ps_2, Hb-MG and Hb-ML was approximately equal to human Hb-A and Hb-PT_1 migrated at a rate equal to human Hb-C. Hb-EF was the fastest recorded, being appreciably in front of human Hb-C. All analyses were carried out at *p*H 8·6.

Quantitation of ionograms showed a relative distribution for the eastern pipistrelle of 34·5 per cent Hb-PS_2 (range 33·4 to 36·1) and 65·5 per cent Hb-PS_1 (range 63·9 to 66·6); for the big-eared bat 46·4 per cent Hb-PT_2 (range 46·3 to 46·5) and 53·6 per cent Hb-PT_1 (range 53·3 to 53·7). Pooled bloods gave comparable results to non-pooled samples. The minor component preceding the major has been shown by Matsuda *et al.*[15] for other mammals (monkey and human) using agar-gel electrophoresis, *p*H 8·6. Blood of every eastern pipistrelle and big-eared bat investigated contained haemoglobin of both varieties.

Alkali denaturation tests demonstrated small proportions of alkali-resistant pigments. These tests were difficult to conduct due to small samples of blood. The mean values for alkali-resistant pigment in the eastern pipistrelle, big-eared bat and gray myotis were 26 per cent, 12 per cent and 14 per cent, respectively. The amount of alkali-resistant pigment in the eastern pipistrelle and the presence of two electrophoretically separable haem components suggest that one of these bands may be the alkali-resistant pigment. All animals tested were adults and it was assumed that variation in resistance to denaturation and patterns after electrophoresis did not represent foetal haemoglobins. The difference in the proportions of alkali-resistant pigments between bats requires further study.

No sexual or age (as indicated by tooth wear) differences in haemoglobin distribution were observed. Blood from active big brown bats collected during July 1964 gave ionograms comparable with specimens in cold torpor collected during December 1964.

Conclusions with regard to specific problems in physiology and taxonomy are premature. A further detailed investigation will soon be conducted.

I thank the Kansas City Regional Council for Higher Education for supporting part of this investigation, Mr. William Roberts for assistance in the laboratory and Mr. Harold Strasser for aid in obtaining bats.

IMMUNOLOGY

Antigenicity of Conjugates of Arsanilic Acid in Inbred Guinea-pigs

RECENT investigations have shown that the genetic constitution of the host is of critical importance as regards the immune response to hapten poly-L-lysine conjugates[1,2], random linear copolymers[3] and reactivity in certain hypersensitivity phenomena such as experimental allergic encephalomyelitis[4] and thyroiditis[5]. This information was obtained with guinea-pigs of inbred strains 2 and 13 which had been demonstrated by Bauer in 1958 (ref. 6) to be histocompatible. Investigations on arsanilic acid conjugates of amino-acid polymers[7,8] have shown that these conjugates are antigenic in random-bred guinea-pigs. Accordingly, experiments were designed to assess the immune response of the inbred strains 2 and 13 to arsanilic acid conjugates of poly-L-lysine (ars-L) and poly-L-glutamic L-lysine L-tyrosine (ars-GLT).

Conjugates were prepared by adding the appropriate amounts of diazotized arsanilic acid to ice-cold solutions of carrier maintained at *p*H 8–9 (refs. 7 and 8). Synthetic polypeptides lysine and glutamic-lysine-tyrosine were conjugated with small amounts of hapten in order to provide one azophenyl arsonate group 1 ars per three lysine or tyrosine residues. Bovine serum albumin (BSA) and polytyrosine (T) were conjugated with excess arsanilic acid for use as test antigen. (Poly-L-tyrosine of mean molecular weight 10,000 was purchased from Yeda Research and Development Co., Rehovot, Israel.) A sample of random linear copolymer glutamic-lysine-tyrosine (GLT Lot No. *M*-12; molar ratio of amino-acids 58 : 38 : 4, kindly provided by Dr. Maurer) was also used as test antigen.

Guinea-pigs weighing 400 g were immunized by injection in the four foot-pads of 100 μg of conjugate in 0·4 ml. of Freund's adjuvant emulsion containing 0·2 ml. of oil phase so that each guinea-pig received 2 mg of killed *H37Rv* human mycobacterium. Two weeks later, skin tests were performed by intradermal injections of 0·1 ml. of various antigens. Reactions were considered to be 'immediate' if present at 3 or 6 h after injection, and 'delayed' if they appeared at 24 h and remained still strong at 48 h. Passive cutaneous anaphylaxis tests were performed in random-bred Hartley guinea-pigs, as described by Ovary[9]. Blood was drawn for passive cutaneous anaphylaxis tests 1 day before skin tests. Sera were used in 1 : 10 dilutions and the amount of antigen injected was 500 μg protein in the case of ars-BSA and 250 μg for the GLT copolymer.

Table 1. RESULTS OF IMMUNIZATION WITH CONJUGATES OF ARSANILIC ACID

* Size of reaction (mm) in positive guinea-pigs.
† PCA, passive cutaneous anaphylaxis.
N.d., not done.

The results of immunization with conjugates ars-L and ars-GLT are shown in Table 1. Positive responses were obtained in skin tests only in guinea-pigs of inbred strain 2 (delayed type) or random-bred Hartley (immediate and delayed types) and in none of guinea-pigs of strain 13. Delayed skin reactions in guinea-pigs of strain 2 were directed only against the homologous conjugate or homologous carrier (GLT). Some of the Hartley guinea-pigs reacted also with heterologous (ars-BSA, ars-EA, ars-PT in group ars-L; ars-BSA, ars-EA in group ars-GLT) conjugates in immediate skin reactions and in delayed skin reactions (ars-EA in group ars-L and ars-BSA, ars-EA in group ars-GLT). Sera of guinea-pigs of strains 2 and 13 immunized with ars-L conjugate were negative in passive cutaneous anaphylaxis reactions against ars-BSA conjugate. One out of four sera from group ars-L, Hartley guinea-pigs, was passive cutaneous anaphylaxis positive. Sera from guinea-pigs of all three strains immunized with ars-GLT were positive against ars-BSA conjugate. Passive cutaneous anaphylaxis tests gave positive results in this system with GLT copolymer in strain 2 (3/3), Hartley (2/4) and strain 13 (1/5).

The results of this investigation provide further evidence for the view that the ability to mount an immunological response is genetically controlled. In the present work, poly-L-lysine azobenzenearsonate was immunogenic for the random-bred Hartley guinea-pigs and for the strain 2 but not for the other inbred strain 13 guinea-pigs. These findings are consistent with the view expressed by Levine, Ojeda and Benacerraf[1,10] that the ability of guinea-pig strains to develop an immune response to hapten-poly-L-lysine conjugates is of an all-or-none character, that is to say, either a response is evolved by all the hapten-poly-L-lysine conjugates or by none of them.

A different pattern of response emerged from our investigations with ars-GLT conjugate, where all strains were found to respond immunologically, although in different ways. In the case of strain 2 guinea-pigs, the immune response could be detected by delayed skin reactions and was directed against the carrier copolymer as well as against the whole conjugate. Hapten-specific and carrier-specific antibodies were also produced. However, in the case of strain 13, no skin reactions were detected, but hapten-specific antibodies were revealed in all cases (5/5) in passive cutaneous anaphylaxis tests with ars-BSA conjugate. The positive passive cutaneous

anaphylaxis reaction observed with GLT copolymer and one anti-ars-GLT serum of strain 13 may indicate that either injection of an ars-GLT conjugate in guinea-pigs of strain 13 can induce formation of anti-GLT antibodies or that GLT copolymer can react with antibodies directed against the whole conjugate ars-GLT. It is of interest to mention that GLT copolymer itself proved to be immunogenic for strain 2 but not for strain 13 (ref. 3). It seems, therefore, that while GLT copolymer cannot induce an immune response in strain 13 guinea-pigs, it is still able to function as a carrier for arsanilic acid hapten. To the best of our knowledge, this is the first example of a completely synthetic, lysine containing antigen, acting in strain 13 as an effective carrier, despite the fact that it was not immunogenic for the same strain. This situation is in contrast to that reported by Benacerraf *et al.*[8], with arsanilic acid conjugates of non-immunogenic copolymers of D-amino-acid preparations, which were also unable to act as carriers. In strain 2 guinea-pigs, the specificity of delayed type skin reactions was strictly confined to the intact homologous conjugate (ars-PLL, ars-GLT, and to the carrier portion of the conjugate GLT). In Hartley guinea-pigs some dermal delayed type cross-reactions with other arsanilic acid conjugates were also observed (in addition to hapten-carrier and carrier delayed-type specificity). These findings may be indicative of the presence of hapten-specific delayed sensitivity as has been postulated previously by Leskowitz[7]. The results obtained with ars-GLT in the inbred strains 2 and 13 suggest that the genetic differences between the strains may be expressed not only on the level of the ability to respond immunologically, but also in the type of immune response elicited by the same antigen. This situation is similar to that reported by Arquilla and Finn[11], who showed that inbred strain 2 guinea-pigs produced antibodies to portions of beef insulin to which strain 13 guinea-pigs could not produce antibodies.

We thank Dr. M. Landy and Dr. H. Stone, from the National Institute of Allergy and Infectious Diseases, for their advice and criticism. We also thank Dr. Paul Maurer, of New Jersey College of Medicine, and Dr. Thomas Gill, of Harvard Medical School, for the provision of GLT copolymers, and Mr. J. Cunningham for his technical assistance.

Differentiation of Diffusing Proteins according to their Geometrical Patterns

THIS communication draws attention to a phenomenon which appears in the simultaneous diffusion of two different reactants from two sources, if the diffusing substance reacts with the medium to form a precipitate. We have previously shown[1,2] that when two diffusion processes of one reactant take place simultaneously they may interfere and produce crossing or coupling phenomena, which manifest themselves in an altered rate of diffusion. It was concluded that the mobility of each diffusing reactant depends on the other concentration gradient as well as on its own. These effects can be described mathematically by adding to Fick's Law a term proportional to the other concentration gradient. Where two non-identical reactants are involved it is possible that the rate of diffusion in the area between the diffusing sources will increase with one and decrease with the other diffusing reactant. These different rates of diffusion result in different geometry of the precipitation patterns, and from these geometrical patterns it is possible to conclude whether the diffusing reactants are identical or not.

De-ionized water saturated with air was used throughout. 0·3 per cent purified Difco agar containing 0·05 per cent metaphosphoric acid as an indicator was used. We used the metaphosphoric acid as an indicator because Liesegang[3] showed that it precipitates proteins. 10 ml. of melted agar with indicator were poured into a Petri dish (9·2 cm in diameter). After solidification two wells were punched with a tube of 0·6 cm outer diameter. The distance between the centres of the sources was 20 mm. The experiments were carried out in a humid chamber at about 25° C. Readings were made 7 days after setting up the dishes. The identical diffusing proteins used were normal human sera or crystalline human albumin (Pentex Inc., Illinois). The non-identical proteins were normal and abnormal human sera, or human gamma globulin, '*FR*. II' (Pentex Inc., Illinois), and crystalline human albumin (Pentex Inc., Illinois).

Fig. 1 shows a diffusion experiment involving two sources of identical reactants. The precipitation patterns

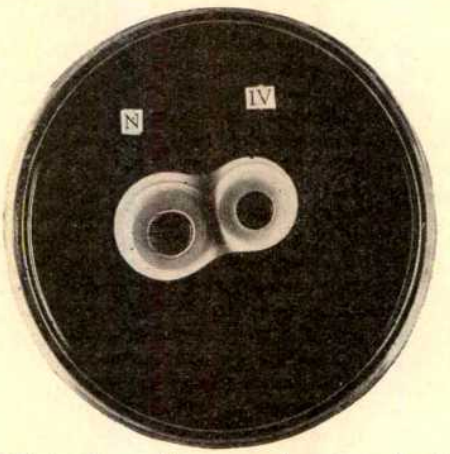

Fig. 1. Diffusion of normal human sera from two wells. Here the displacement of the precipitation patterns does not appear

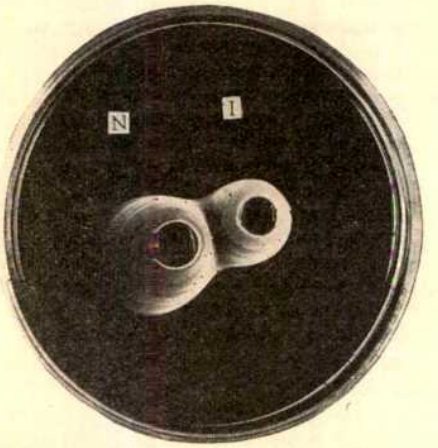

Fig. 2. The precipitation pattern of the normal human serum is displaced toward the opposite source, and the rate of diffusion of the pathological human serum is lowered toward the opposite source

are displaced toward the opposite source and between the two precipitation patterns a translucent zone without precipitate was produced. Fig. 2 shows that in the case of two non-identical diffusing reactants the precipitation pattern of one reactant is displaced toward the opposite source. This indicates that the rate of diffusion of this reactant is maximal along a line joining the centres of the wells and gradually decreases along other radii. The pattern of the reactant is not displaced, and the rate of diffusion of this reactant is minimal along a line joining the centres. From Fig. 2 it is evident that the boundary of the displaced pattern is concave toward the plane of separation. The boundary of the reactant which is not displaced is convex toward this plane.

Further research is in progress at the clinical department of this Institute on the differentiation of various pathological human sera by the method described here.

Elevation of Cord over Maternal IgG Immunoglobulin: Evidence for an Active Placental IgG Transport

EXISTING evidence suggests that the concentrations of IgG immunoglobulin* in maternal and cord sera are essentially the same. In 1963 von Muralt[1] concluded that no significant difference existed in the absolute concentration of gamma globulin in paired maternal-cord sera after reviewing forty-three published studies in which gamma globulin was quantitated in 1,542 maternal-cord pairs by a variety of methods. Recently, Gitlin *et al.*[2] reported cord IgG to be equal to or slightly lower than maternal. They did observe, however, that IgG labelled with iodine-131 was present in higher concentrations in cord than in maternal serum if the iodinated protein had been administered to the mother 25 or more days before parturition. The higher cord ^{131}I-IgG levels were felt to be a consequence of tracer kinetics and not an indication of higher cord endogenous IgG concentrations[2].

The present investigation was undertaken to re-evaluate the quantitative relationship of IgG in maternal and cord sera using antisera specific for IgG heavy chains with the antibody-agar plate technique ('Immunoplates', Hyland Laboratories)[3,4]. IgG levels were measured in forty-six pairs of normal maternal-cord sera. Paired sera were tested in the same plate and the diameter of the precipitin rings, formed by interaction of IgG and goat antiserum specific for IgG, measured after 24 h incubation at 4° C. Reference samples containing known amounts of human fraction II gamma globulin, further purified by DEAE chromatography, were run simultaneously. The coefficient of variation for IgG quantitation by this method is 8·1 per cent in our laboratory.

In Fig. 1, the concentrations of IgG present in cord sera are compared with maternal levels. The mean cord concentration of IgG was 1,512·5 mg per cent (*S.D.* 323, range 640–2250) and mean maternal 1,260·1 mg per cent (*S.D.* 286, range 600–1,875). This difference is highly significant with $P < 0{\cdot}01$ (Student's *t*-test). A considerable variation in the ratio of cord/maternal IgG was observed (Fig. 1) which ranged from 2·04 to 0·45; mean 1·2. Ratios of paired sera which varied significantly from the 1·2 mean were consistently reproducible and the significance of these variations is at present under study.

* Immunoglobin nomenclature as suggested in *Bull. World Health Org.*, **30**, 447 (1964).

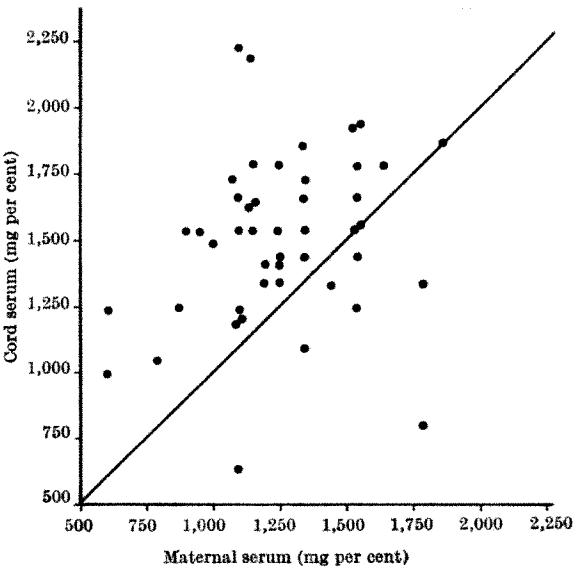

Fig. 1. Comparison of IgG concentrations in forty-six paired maternal-cord sera

Several experiments were carried out to verify the significant elevation of mean cord IgG as determined by the antibody-agar plate technique. First, agar plates were prepared which contained rabbit antiserum to purified (1) maternal IgG and (2) cord IgG from the same paired sera and to (3) heavy chains from pooled adult IgG. These preparations gave maternal-cord levels similar to those obtained with agar plates containing goat anti-IgG. Secondly, a spurious elevation of cord over maternal IgG might have occurred if cord IgG was a distinctly more antigenically homogeneous immunoglobulin than maternal IgG. For example, quantitation of isolated myeloma IgG by the antibody agar plate technique may give concentrations 60–90 per cent higher than by the Folin method[5]. This factitious elevation is the result of a lower agar concentration of antiserum capable of precipitating the monoclonal myeloma protein. IgG was therefore isolated from six maternal-cord pairs by DEAE chromatography and quantitated by the antibody-agar plate and Folin methods. The two methods were in close agreement and indicated that the foregoing consideration was not responsible for the observed elevation of cord IgG. Finally, absorption of rabbit antiserum to maternal IgG with cord IgG and vice versa completely removed the precipitating antibody.

The human placenta regulates the transfer of plasma proteins from mother to foetus in a highly selective manner and transfer of specific protein appears to be correlated with molecular configuration rather than molecular size[1,2]. The transplacental transfer of immunoglobulins is limited to IgG (7*S*) while the IgM (19*S*), IgA (7*S*–11*S*)[1] and IgD (7*S*)[6] immunoglobulins are essentially excluded from the foetal circulation. The present observations indicate that IgG is transferred from mother to foetus against a substantial concentration gradient: mean 252 mg per cent. It is highly unlikely that the mean difference can be attributed to foetal IgG synthesis. While IgG synthesis has been demonstrated in a 20-week-old foetus by sensitive *in vitro* techniques[6], it is not sufficient, even at term, to account for the differences observed in this investigation. Evidence for this is provided by the presence of extremely low IgG levels in two normal infants born to a mother with acquired agammaglobulinaemia[7]. The most reasonable explanation for the present observations is an active placental transport of IgG from mother to foetus.

The goat anti-IgG agar plates ('Immunoplates', Hyland) were kindly supplied by Mr. Charles Daniels. This work

was supported in part by a U.S. Public Health Service grant and a training grant.

Effect of Antigen on the Structural Configuration of Homologous Antibody following Antigen–Antibody Combination

THE exposure of new antigenic determinant groups in rabbit antibody following combination with homologous BSA antigen has been reported[1]. The structural alterations occurring in the rabbit antibody molecule as a result of such combination are similar to those which Ishizaka has shown to be responsible for irritative skin reactions of soluble antigen–antibody complexes in guinea-pigs[2]. Nevertheless, in the case of the low molecular weight antigens already investigated (for example, BSA and ovalbumin), only certain ratios of antigen to antibody —three molecules of antigen to two of antibody, for example—are effective in the induction of such alterations in the antibody molecule.

The present investigation was undertaken to establish whether the size of the antigen molecule influences the degree of structural alteration induced in the homologous antibody molecule. To this end, the previous investigations have been repeated and extended, using soluble complexes consisting of a considerably larger antigen molecule (ferritin) and its homologous rabbit antibody.

Sandy-lop rabbits of allotype *As* 1,4 were injected subcutaneously with a crystalline (×5) horse ferritin preparation (3 × 5 mg ferritin in Freund's complete adjuvant at weekly intervals). The γG globulin fraction from one of the immune sera was isolated by DEAE cellulose chromatography[3]. Soluble complexes were formed by addition of a predetermined amount of homologous antigen, equal to three times the equivalence ratio. After centrifugation, the resultant complexes were separated from uncombined ferritin by zone electrophoresis, on a 'Pevikon' block at *p*H 8·6. The soluble complexes (obtained by pooling appropriate fractions) were injected into rabbits of the same allotype as the antibody donor. The immunization course consisted primarily of six subcutaneous injections of 2 mg material on alternate days. Precipitating antibodies to ferritin were demonstrable in serum obtained after the fourth injection. After an interval of one week, six 1 mg aliquots were administered intravenously on alternate days.

Gel-diffusion precipitin analyses of the donor serum (1) and the anticomplex serum after the subcutaneous (2) and intravenous (3) courses are shown in Fig. 1. As will be seen, both ferritin–antiferritin complexes and ferritin alone gave identical precipitin lines on testing with the antiferritin serum (1). However, similar tests (2) and (3) with the anti-(ferritin–antiferritin) serum revealed an additional precipitin line. It is possible that these observations reflect the exposure of new immunogenic groups within the ferritin molecule, following combination with its specific antibody. The distribution of both precipitating antigens throughout the ferritin peak eluted from 'Sephadex *G*-200' provides evidence in support of this suggestion.

As was found in a previous investigation[1] with complexes of BSA and anti-BSA, it proved to be difficult to demonstrate a specific anti-antibody reaction. Nevertheless, the reaction of antiserum (3) with rabbit and human γG globulins provides indirect evidence of the exposure of new immunogenic determinants within the specific antibody molecule following combination with ferritin. The precipitin reaction between heterologous complexes and the rabbit anti-(ferritin–antiferritin) complex serum (as shown in Fig. 2) supports this contention.

Gel-diffusion precipitin analysis and haemagglutination procedures both revealed that the reaction against γG globulins occurred more readily with human γG globulin than with rabbit γG globulin. This behaviour was not observed in similar tests with the rabbit anti-(BSA–anti-BSA) complex serum described previously[1]. It appears to be analogous to the effect produced in rabbits by Milgrom and Witebsky[4], and in guinea-pigs by McCluskey *et al.*[5] following administration of denatured autologous γG globulin. There, too, the antibody obtained was directed primarily against heterologous γG globulin, and, although reacting with isolated rabbit γG globulin (5 g per cent), it failed to react with the rabbit γG globulin contained in the donor rabbit serum (Fig. 2).

It may be relevant that optical rotation measurements have shown that a combination of antigen and antibody involving the relatively large ferritin antigen leads to structural alteration of the antibody molecule of appreciably greater magnitude than that observed with BSA as antigen. Moreover, the structural changes evoked in homologous antibody by combination with ferritin are of a similar order of magnitude to those observed on heat denaturation of non-antibody γG globulin (Table 1).

The demonstration that soluble complexes comprising a number of heterologous antigens and rabbit antibody also gave a precipitin line with the antiserum raised against ferritin–antiferritin complexes (Fig. 2) confirms earlier findings that similar structural alterations are induced in the rabbit antibody molecule following antigen–antibody combination, whatever the antigen.

Gel-diffusion tests, employing sub-units of γG globulin as reference substances, indicate that the new antigenic

Other symbols as in Fig. 1

determinants revealed on the antibody molecule were situated along the whole of the heavy chain. Preparations of Fab and Fc papain digestion fragments both react with the antiferritin complex serum. On the other hand, homogeneous light chain preparations, prepared by the method of Fleischman *et al.*[6], invariably failed to give a precipitin line. In the previous investigation[1] with soluble complexes of BSA and its homologous antibody, new structural determinants were apparent over only a fairly limited range of ratios of antigen to antibody (between 2 and 5 to 1). By contrast, soluble ferritin complexes comprising a far wider range of antigen/antibody ratios (up to 20 : 1) all reacted with the antiserum raised against ferritin complexes formed at five times equivalence.

The present findings provide further evidence that combination of antigen and antibody (within certain ratios) is accompanied by the exposure of new structural determinants in the antibody molecule. Although these groupings are demonstrable in all soluble complexes formed with moderate excess of antigen, their character appears to depend on the nature of the antigen. The implication that larger antigens cause greater structural alterations of the antibody molecule is significant in attempts to explain the formation of anti-antibodies when large antigens such as viruses may be involved.

Table 1. SPECIFIC OPTICAL ROTATION CHANGES INDUCED IN RABBIT ANTIBODY γG GLOBULIN BY COMBINATION WITH SPECIFIC ANTIGEN

Antigen	Antigen/antibody weight ratio	Specific optical rotation at 589·5 mμ: Immune complexes	Antigen–non-antibody γG globulin mixture	Difference
BSA	1·9	−64·6	−58·8	+5·8
	2·4	−61·0	−59·3	+1·7
	3·2	−60·4	−59·8	+0·6
	4·5	−60·6	−60·3	+0·3
	9·1	−61·0	−61·1	−0·1
Ferritin	2·7	−40·2	−31·9	+8·3
	4·1	−35·2	−30·9	+4·3
	5·4	−33·8	−30·3	+3·5
	6·8	−30·2	−29·9	+0·3
	13·6	−28·3	−29·0	−0·7
	19·0	−28·6	−28·7	−0·1

Heat denaturation of human γG globulin (50° C for 10 min) produced a rise in specific optical rotation at 589·5 mμ of 9·8°.

These observations are part of a continuing investigation into the influence of antigenic size and shape on the tertiary structure of homologous antibody, following antigen–antibody combination.

We are grateful to Prof. P. G. H. Gell for advice and to Dr. E. A. Kabat for providing the anti-dextran serum. One of us (C. S. H.) held a Medical Research Council fellowship during this investigation.

PATHOLOGY

Normal Flora and Acute Inflammation

THE indigenous microbial flora has recently been recognized as being involved in the maintenance of the resistance of the host to infection. Oral administration of non-absorbable antibiotics produces a marked reduction in the enteric flora of the animal host, which is associated with an increased susceptibility of the host to parenteral infections[1]. Animals raised in the presence of a restricted gastrointestinal microflora likewise respond abnormally to experimental infections[2]. Animals reared in the germ-free state are also hypersusceptible to a variety of infectious agents administered by a number of different routes[3–6]. These findings leave no doubt that the normal flora somehow enhances the ability of the host to deal with infection, not only within the habitat of the flora, but systemically as well. The mechanism of this enhancement is obscure.

Because of the importance, in terms of host resistance, of events occurring during the early hours of acute inflammation, the effect of the normal flora on the mobilization of leucocytes and on the increase in vascular permeability to protein was assessed. This was accomplished by comparing the peritoneal inflammatory reaction elicited by a sterile starch tryptose irritant in mice harbouring a normal microbial flora with that elicited in mice having no demonstrable flora (germ-free mice). The number and types of leucocytes, and the total amount and electrophoretic pattern of protein appearing in the peritoneal exudates at various intervals after injection of the irritant, were determined. Parallel determinations were made on samples of peripheral blood from the same animals. The data relative to extravasation of protein are summarized in Fig. 1, and are compared with corresponding data concerning the emigration of leucocytes. Details of intravascular and extravascular mobilization of leucocytes have been presented elsewhere[7].

The average levels of total serum protein were virtually identical in germ-free and conventional mice, the values being 5·8 and 5·7 g per cent, respectively. As seen in Fig. 1, the mean amounts of protein extravasated into the peritoneal cavity in the two groups of animals were approximately the same at each of the intervals tested, none of the differences being statistically significant. In both groups, there was a marked outpouring of protein within the first hour of inflammation, with the level reached at 1 h being approximately maintained for the next few hours. Finally, in both germ-free and conventional mice, the values decreased sharply after 4 h, as vascular permeability began to return to normal. Thus, it was concluded that exudation of protein is not impaired in the absence of a normal microbial flora.

This, as shown in Fig. 1, stands in sharp contrast to the fact that exudation of leucocytes was found to be markedly deficient in germ-free animals. At the peak of the inflammatory process, almost twice as many leucocytes, on the average ($P < 0.01$), had been mobilized into the area of injury in conventional as compared to germ-free mice, this difference being independent of any difference in the availability of leucocytes from the circulating blood in the two groups of animals[7]. Another discrepancy between the outpouring of protein and that of leucocytes is that vascular permeability to protein began to wane after 4 h, at a time when emigration of leucocytes had yet to reach a peak. These findings are entirely consistent with other evidence indicating that the emigration of leucocytes and the increase in vascular permeability during acute inflammation are distinct phenomena, and are separately mediated[8]. It would appear that factors accounting for emigration of leucocytes are sharply influenced by the presence or absence of the flora, while the mediators of increase in vascular permeability to protein are not.

Cellulose acetate electrophoresis of the exudates revealed grossly similar patterns in germ-free and conventional mice. However, analysis by elution and spectrophotometry revealed the gamma globulin content of exudates to be significantly greater in conventional than in germ-free mice. In the former group, this fraction constituted 3·6 per cent of the total protein, as compared to 2·9 per cent in the latter group ($P < 0.05$). Not unexpectedly, this difference in the composition of the exudates was found to be the reflexion of an almost identical discrepancy in the level of serum gamma globulin in the two groups, the values being 3·4 per cent and 2·7 per cent, respectively.

At present, the biological significance of these results, in terms of reaction to living infectious organisms rather than to the sterile agents used in these experiments, is unknown. Unquestionably, however, cellular events and conditions prevailing in the immediate micro-environment of an invading organism, particularly in the first several hours of infection, are of vital importance in determining the ultimate course of the infection. It is reasonable, therefore, to predict that the enhancement of mobilization of leucocytes effected by the normal flora will prove to be a significant contribution to host resistance. Furthermore, although the total amount of protein exuded is unaffected by the flora, the amount of gamma globulin in the exudate is significantly influenced. Insofar as this larger fraction may contain a greater quantity of so-called natural antibody in conventional animals than in their germ-free counterparts (as it does in serum[9]) it may well act in synergy with the mobilized leucocytes, serving as yet another contribution of the normal flora to the defence of the host.

MICROBIOLOGY

New High-efficiency Light Source for Immunofluorescence Microscopy

THE light source usually employed in fluorescence microscopy is a high-pressure mercury vapour lamp; when Coon's antibody technique is used, this source has some disadvantages. The maximum absorption band of the fluorescein isothiocyanate which lies approximately between 440 and 510 nm (the continuous curve in Fig. 1) does not overlap with the mercury emission lines at 365, 405 and 435 nm used for exciting the fluorescence. Another inconvenience arises from the fact that there are two strong mercury lines (546 and 577 nm) in the fluorescence spectrum (the dotted curve in Fig. 1). This latter inconvenience is partially removed by the use of adecvated fluorescence and suppression filters.

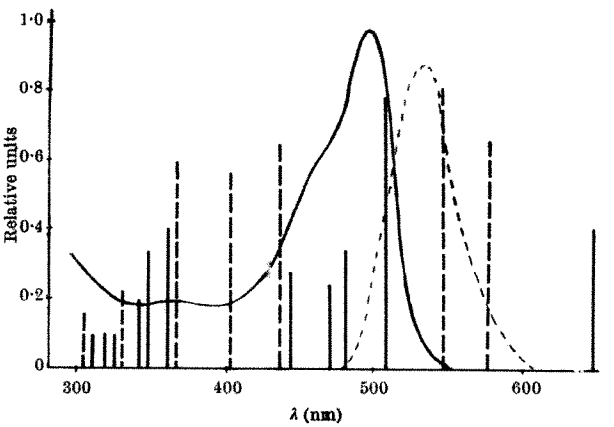

Fig. 1. The absorption curve of fluorescein isothiocyanate is continuous, the fluorescence curve is dotted; mercury and cadmium lines are dotted and full respectively

Among the elements, we have found that cadmium is the only element which has strong emission lines in the absorption band of the fluorescein isothiocyanate and, moreover, has no lines in the fluorescence band. The cadmium lamp can be used for transmitted and incident illumination. If a dark field condenser is used, only a suppression filter which would stop the waves under 510 nm is necessary. The red line of cadmium (644 nm) represents merely an advantage, because it ensures some illumination of the entire ground. This is useful for recognizing the sample. This red light contrasts strongly with the yellowish-green fluorescence, and if a bright field is used and the red line becomes annoying it can easily be suppressed using an adecvate filter.

The suppression of the ultra-violet radiations and the use of only the 468, 480 and 509 nm cadmium lines of maximum efficiency protect both the sample and the observer's eye. Hence it seems that the cadmium lamp is superior to the mercury lamp usually used.

We thank Prof. I. Agârbiceanu for his valuable suggestions in this work.

GENETICS

Deoxyribonucleic Acid Replication of Somatic Cells in the Chinese Hamster

OVER the past few years increasing attention has been focused on the relationship of gene inactivation to the phenomena of interphase DNA condensation and late DNA replication. It has been shown that the sex chromatin body of female mammalian cells appears during early embryogenesis[1] and is composed of one *X* chromosome[2]. In 1961 Lyon postulated that phenotypic variegation in heterozygotic female mice was a consequence of the inactivation of either the maternal or paternal *X* chromosome[3]. As well as being mostly metabolically inert, this *X* chromosome replicates late in the DNA synthetic period[4,5]. It has been assumed that the *Y* chromosome also becomes largely inactivated during early embryonic life, since it shows positive heteropyknosis in early prophase, is late replicating, and extra *Y* chromosomes produce no conspicuous phenotypic effects[6]. That late-replicating autosomal DNA may be related to gene inactivation is supported by the observation that the abnormal chromosome material found in most human autosomal chromosome abnormalities replicates toward the end of the DNA synthetic period. It was postulated that this late-replicating DNA is less deleterious than early replicating DNA when present in excess or deleted because it is relatively inert[6]. Furthermore, it has been shown that interphase heterochromatin is less active than euchromatin in that it produces less RNA[7,8], and that late-replicating chromosomes have less capacity for RNA synthesis[9].

Because of the obvious implications of DNA replication time as a monitor of cell differentiation, the investigation reported here attempted to compare the DNA replication patterns of somatic cells *in vivo* from the three germ layers of the adult Chinese hamster.

Chinese hamsters of both sexes were injected intraperitoneally with tritiated thymidine of specific activity 6·7 c./m mole (New England Nuclear Corporation) in a dosage of 10 μc./g weight. Two hours later 2 μg of 'Colcemid' (Ciba) were injected intraperitoneally, and after 4 h exposure to the tritiated thymidine the animals were killed and various tissues prepared. Bone marrow was prepared by a method similar to that described by Ford and Hamerton[10]. Corneal epithelial cells were prepared by the method of Fredga[11]. A cell suspension was prepared from a segment of jejunal mucosa by gentle trypsinization using 0·5 per cent trypsin at *p*H 8 for 30 min at 37° C. The cells were then washed and handled by a method similar to that used for bone marrow. Lymphoid cells from a hyperplastic popliteal node were prepared 48 h following the injection of about 0·1 c.c. complete Freund's adjuvant into the foot of the animal. The node was teased apart with dissecting needles in 1 per cent sodium citrate solution, and the cells were treated by the technique used for other tissues.

Orcein squash preparations were made and suitable mitoses selected and photographed. The coverslips were removed by the dry ice freezing technique and autoradiographs of the slides prepared[12]. Kodak '*NTB*$_2$' liquid emulsion diluted 1 : 1 with water was used to coat the slides. Slides were exposed for 30 days in the dark at 4° C, developed in Kodak '*D*19*b*' for 5 min at 4° C, and counterstained with Wright's stain. Previously photographed mitoses were relocated and post-autoradiography photomicrographs taken. Prints of mitoses before and after autoradiography were then made and analysis of radioactive label performed.

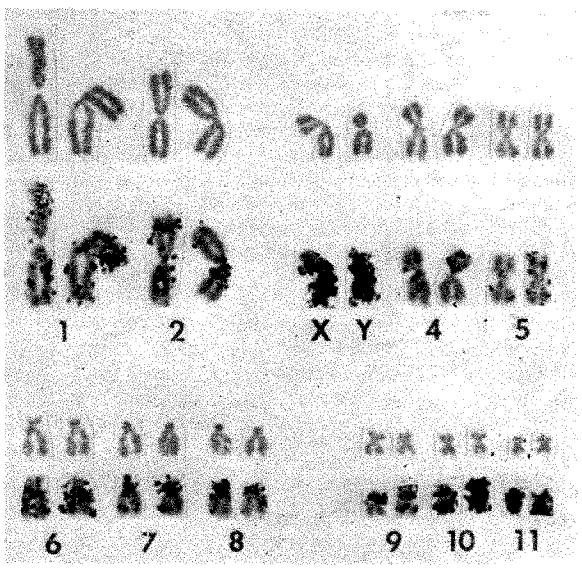

Fig. 1. Composite karyogram from a corneal epithelial cell of a male Chinese hamster exposed for 4 h to tritiated thymidine. In each chromosome group the upper and lower rows represent chromosomes before and after autoradiography. See text for description

Thirty-seven mitoses of corneal epithelium from two male animals, twenty-four mitoses of bone marrow from one female and two male animals, eighteen mitoses of lymphoid cells from one male animal, and five mitoses from jejunal crypt cells of one male animal were suitable for analysis. A characteristic, common labelling pattern was found for all tissues studied (Fig. 1). Late replicating chromosomes or chromosome segments were found to be the *Y* chromosome, the long arm of the *X* chromosome and chromosome pairs ten and eleven. In the female one entire *X* and the long arm of the other *X* replicated late. Relatively late replicating were the long arm of chromosome six, the short arm and centromeric region of chromosomes seven, eight, and nine, and the centromeric region of pairs four and five. In corneal cells, late replication was often observed in the distal portion of the short arm and near the distal end of the long arm of chromosome one, as well as the proximal and mid-portion of the long arm of

chromosome two. In other tissues, however, this pattern was less apparent.

Results from varying *in vivo* exposure times to tritiated thymidine indicate that the average G_2 period in corneal epithelium is about 3·25 h and that the average G_2 period of bone marrow and antigen-stimulated lymphoid cells is at least 1 h shorter. In this study the difficulty in analysing the labelling pattern of chromosomes one and two in cells other than corneal epithelium is probably a consequence of the difference in G_2 period observed.

The identification of Chinese hamster chromosomes has already been described[13]. This animal has twenty-two chromosomes of which all but pairs seven and eight and pairs ten and eleven can be easily distinguished by morphology. Since the late DNA replication pattern of these morphologically similar pairs is about the same, it is not essential to be able to distinguish them. In some mitoses, however, all pairs are morphologically identifiable. Frequently it is not possible to identify the arms of the nearly metacentric chromosome pair two. In Fig. 1 the arms of this pair were identified by autoradiography.

In this work no attempt was made to determine the bone marrow or lymph node cell type in mitosis. Because these tissues contain a heterogeneous cell population which is actively dividing, mitoses studied probably represent more than one cell type. However, the relative numbers of cell types and possible variations in the G_2 period might have favoured the selection of some of them.

The DNA replication pattern described here is similar to that described by Hsu in a strain of cultured fibroblasts of the Chinese hamster[14]. The results of this preliminary investigation suggest that this basic pattern of late DNA replication in the Chinese hamster is common to cells from the three germ layers *in vivo* as well. We are now trying to discern the subtleties of the DNA replication pattern of some somatic tissues in the hope that we can find some clues to the problem of cell differentiation.

CYTOLOGY

Aggregation of Dissociated Embryonic Chick Cells at 3° C

WHILE investigations of the effects of environmental factors on aggregation *in vitro* of dissociated embryonic cells were under way in this laboratory[1], Curtis reported[2] that "extensive visible coherent re-aggregation" occurred at 3° C in suspensions of embryonic chick limb bud cells in a medium without serum. He concluded that the cells were able to aggregate normally at low temperatures, and that horse serum inhibited cell aggregation at sub-optimal temperatures. These conclusions differed from the previously demonstrated[3,4] and corroborated[5] temperature-dependence of aggregation of trypsin-dissociated embryonic cells. Because versene (EDTA) was the dissociating agent used in Curtis's experiments, the possibility arose that, in contrast to trypsin-dissociated cells[3–5], cells dissociated with versene might be able to aggregate normally at low temperatures; since such differences in aggregation behaviour between differently dissociated cells would be of obvious interest and usefulness in studies on cell adhesiveness, attempts were made to repeat and extend Curtis's results, using his experimental procedures.

Cells from 7-day-old embryonic chick neural retinae and from 5-day-old embryonic chick limb buds were dissociated by the standard trypsin dissociation procedure of this laboratory[4] (using Worthington's crystalline-lyophilized-sterile trypsin), or by treatment for 10 min with 0·002 M ethylenediamine tetraacetic acid (EDTA) at *p*H 8·0 in calcium- and magnesium-free Hanks's solution[2]. The treated tissues were dispersed in calcium- and magnesium-free Hanks's solution by flushing with a pipette of 0·5 mm inside diameter. The culture media used were those of Curtis[2]: (1) equal parts of Hanks's saline and medium 199 (Microbiological Associates); (2) equal parts of Hanks's saline, medium 199 and horse serum (Colorado Serum Co.); the media were sterilized by passing them through 'Millipore' filters. The dissociated cell suspensions were diluted into these media with 15 per cent calcium- and magnesium-free Hanks's solution[2] at concentrations of about 0·5–1·0 × 10^6 cells per ml.; 3-ml. portions of the cell suspensions were dispensed into 25-ml. Erlenmeyer flasks and rotated at 38° C or at 3° C on a gyratory shaker according to the standardized procedure for testing cell aggregability[4]. Aggregation was measured: (1) by counting with a Coulter counter[6,7] the number of cells remaining free in suspension after 30–90 min, and again after 24 h; (2) by microscopic examination of the 24-h cultures. Unlike treatment with trypsin, versene treatment did not result in complete dissociation, and produced mixed suspensions of cells and tissue fragments.

A summary of the experimental conditions and cell-counting results for four experiments is given in Table 1.

¶ *NCTC*199 tissue culture medium, Microbiological Associates Inc., Bethesda, Maryland.

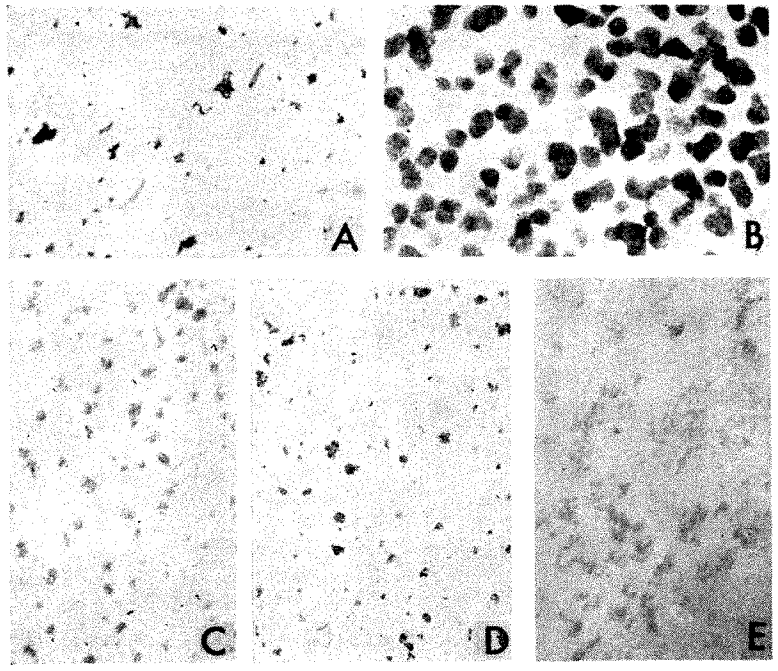

Fig. 1. Appearance of the aggregates after 24 h in rotation cultures (× *c.* 22): *A*, Retinal cells, trypsin-dissociated; medium with horse serum; 3° C. *B*, Retinal cells, trypsin-dissociated; medium with serum; 38° C. *C*, Retinal cells, trypsin-dissociated; medium without serum; 3° C. *D*, Retinal cells, versene-dissociated; medium without serum; 3° C. *E*, Limb bud cells, versene-dissociated; medium without serum; 3° C

The results clearly demonstrate that in both tissues, with both dissociation procedures and at either temperature, horse serum enhanced the formation of cell cluster as evidenced by the reduction in the number of free cells; in serum-free medium, the fraction of the initial cell number remaining at 30–90 min at 24 h was always larger than in cultures with serum. Therefore, the data do not support the statements[2] that cells aggregate normally at 3° C or that horse serum inhibits normal cell aggregation.

Turning now in more detail to the aggregation of retinal cells at 3° C (Table 1, experiments 1 and 2), it was found that at this temperature, both in the presence and absence of serum, trypsin-dissociated cells formed only small clusters of loosely adherent cells (Fig. 1*A*) and that their combination into normally sized, compact aggregates was prevented; this is consistent with the general results of previous investigations on cell aggregation at low temperatures[3–5]. In the presence of serum, the number of single cells remaining at 60–90 min was similar at 3° C and at 38° C (Table 1, experiment 2). The presence of the loosely adherent cell clusters at 3° C indicates that the re-adhesion of these dissociated embryonic cells may require both temperature-sensitive and temperature-insensitive processes; it further indicates that the suggested dependence of initial cell contacts on surface motility[6] is not the temperature-sensitive component of the aggregation process.

The results with versene-dissociated cells at 3° C were comparable with those already described, in that the formation of aggregates was inhibited by the low temperature both in the presence and absence of serum; only small, loosely packed clusters of cells were present at 24 h. In medium with serum, the number of free cells declined at a slower rate at 3° C than at 38° C, unlike following trypsin dissociation (Table 1, experiments 1 and 2). Since versene treatment did not produce a complete dispersal of the tissue into single cells, some of the clusters found at 24 h may have been residual tissue fragments (Fig. 1*C* and *D*); the increase in the number of free cells that occurred in serum-free medium between 90 min and 24 h at 38° C (Table 1, experiments 1 and 2) may have been due to disintegration of these fragments.

The results obtained with versene-dissociated 5-day-old chick limb bud cells were consistent with the data obtained for retinal cells and provided no evidence of the suggested[2] enhancement of normal cell aggregation at 3° C in serum-free medium (Table 1, experiments 3 and 4; Fig. 1*E*). Taken as a whole, the results show that under these experimental conditions both retina and limb bud cells, dissociated with trypsin or with versene, require temperature-dependent processes for the normal progression of aggregation. The difference in temperature-sensitivity between the initial and the subsequent stages of aggregation suggests the involvement of both temperature-independent and temperature-dependent processes in the aggregation of these cells[1].

The temperature- and serum-dependence of aggregation described in this report are not consistent with the findings[2] which prompted this series of tests. Recently, Dr. Curtis has informed me[8] that he has isolated a serum protein (mol. wt. 140,000) which inhibits aggregation and a second protein (mol. wt. 20,000) which promotes aggregation. The inhibitory protein is destroyed at incubation temperatures above 14° C (ref. 8). He reports that most sera tested have more inhibiting than promoting activity at 3° C, but that some have mostly promoting activity. Thus, the difference between the serum effect described by Curtis and that reported here may reflect the use of different sera. Our findings with respect to the temperature-dependence of aggregate formation are still not in agreement, and this disparity is at present unexplained.

This investigation was part of a programme supported by a grant to Dr. A. A. Moscona from the U.S. Public Health Service.

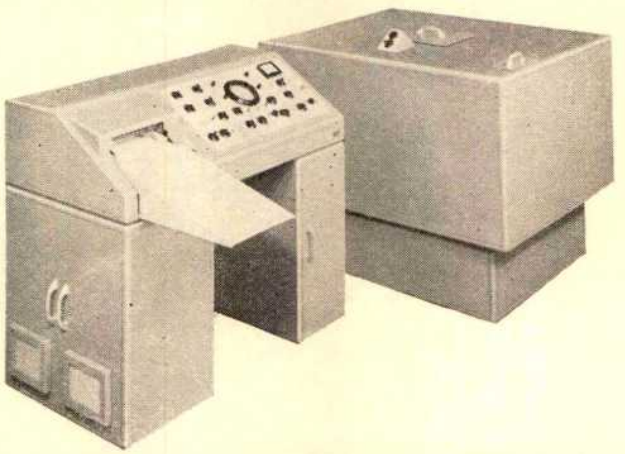
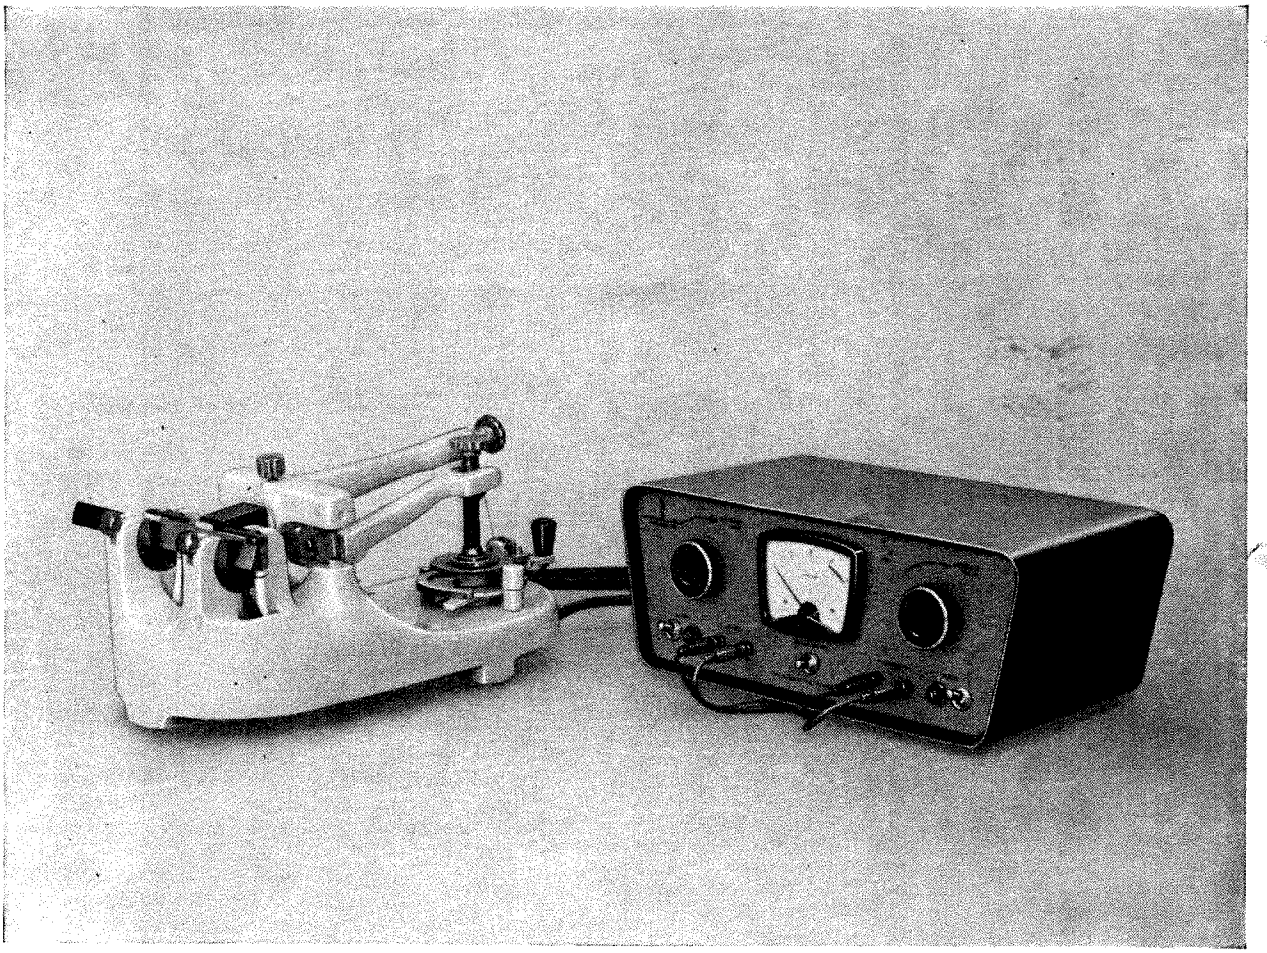
RADIOBIOLOGY



Exact Measurement of Gamma-ray Doses in the Ureter

WE have attempted to evolve a method for the accurate measurement of the radiation dose received by the ureter during radium therapy. Our radiation meter is a small rod-shaped piece of metaphosphate glass measuring 1 × 6 mm, which fits into a No. 6 ureteral catheter. In the course of a cystoscopy performed before the radiation therapy, one of us (O. W.) placed this measuring device in the tip of the ureteral catheter. A new hole was made in the catheter about 1·5 cm from its tip and the catheter as a whole inclusive of the glass was sterilized in formalin. The catheter was fixed to the thigh and the application of radium or cobalt was then carried out. The catheter or catheters were left *in situ* for about 30 min. The position

H F B P



NMR with almost unbelievable simplicity for H and for F, B and P as well

The Perkin-Elmer Model R10 makes Nuclear Magnetic Resonance available as a standard laboratory technique of almost unbelievable simplicity and versatility. The instrument is unique in employing a *permanent* magnet. This provides a magnetic field of unequalled stability, and leads to greater accuracy and to important operational features: the equipment is always ready for use; it employs pre-printed calibrated charts; data is provided for immediate interpretation. For Proton studies, the Model R10 provides the advantages of Proton-Proton spin-spin decoupling. In addition, it is equally suitable for studies on Fluorine, Boron and Phosphorus, extending this powerful method into entirely new fields of analysis in biology and chemistry. Please write or ring for detailed literature.

Operates at 60 Mc/s with Protons
Resolution better than 1 in 10^8
Field stability better than 4 c/s per hour
Chemical shift read directly from chart to 0.2 c/s
Only services required 750 watt electrical power, 10 p.s.i. air

CAMBRIDGE-FRIGISTOR* FREEZING MICROTOME

This new instrument has been developed from the established Cambridge rocking microtome by combining the latest advances in thermoelectric technology. Conventional cooling systems are replaced by FRIGISTOR cooling modules which cool both the microtome stage and the knife, separately.

An outstanding advantage is that fixed, unfixed and paraffin-embedded tissues can all be sectioned on the same instrument. The stage and knife temperatures can be varied independently, adjusted to the best sectioning temperatures, and so held indefinitely.

OTHER FEATURES

- Frigistor unit runs off normal A.C. mains and requires only a small flow of water.
- Only very low voltages (max. 3v.) are brought to the microtome itself.
- Freezing is rapid—stage, 90 seconds; knife, 3-4 minutes.
- Section thickness: 2-24 microns: cross section 20 x 20 mm.

Write for List A329N. For future publications, ask for Mailing Form N/6/66

Cambridge **CAMBRIDGE-FRIGISTOR FREEZING MICROTOME**

Cambridge Instrument Company Ltd, 13 Grosvenor Place, London, S.W.1

of the catheters was controlled using the routine radiograms taken for the isodose curves. The pieces of glass have a wide measuring range (50 mr.–10,000 r.) and a notable correlation with energy.

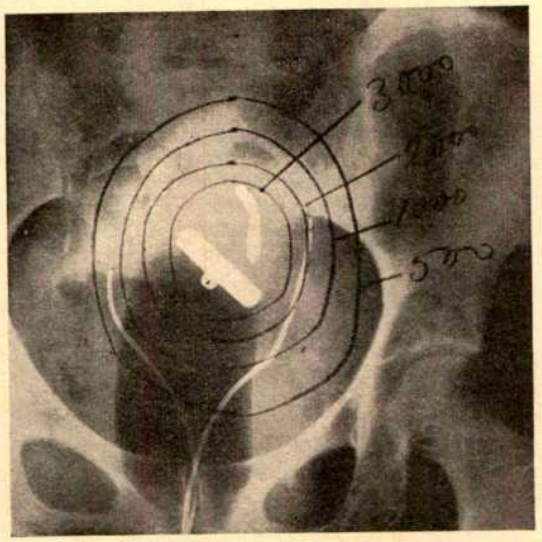

Fig. 1. X-ray picture showing catheters in the ureters and the applicators for γ-therapy. The isodose curves are drawn

Yokota *et al.*[1] investigated the energy-dependence of a corresponding glass on energy and found that the correlation with energies in excess of 110 keV was fairly small. We calibrated the glass for cobalt-60 radiation using doses of different magnitudes and the calibration was carried out with the glass in wax inside the catheter so that radiation scatter was also included. The correlation between the Toshiba readings and the radiation dose was linear. We used radium in addition to cobalt-60 in our radiotherapy. It has more than ten energies in the range 0·18–2·2 MeV, but the correlation with energy is smaller than 20 per cent. The glass was kept in the patient's ureters for about 30 min and ten patients were measured in this way. Comparison of the glass doses with those obtained by the isodose method showed a difference of under 20 per cent. The applicators in Fig. 1 were two cobalt tubes of 27 mgekV and a 100-mg radium plaque. The treatment time was 15 h. Using the glass method, the doses received by the ureters at the tips of the catheters during the whole period of treatment were 1,500 r. in the left ureter and 900 r. in the right. The corresponding doses according to the isodose curves were: left ureter, 1,800 r.; right, 800 r.

HISTOCHEMISTRY

Demonstration of Ribonuclease and Deoxyribonuclease Activities by Substrate Film Methods

In a recent paper[1], Dr. B. D. Lake states that an important proportion of the enzyme activity revealed by substrate film methods may be attributed to the non-specific action of proteolytic enzymes dissolving the gelatine constituent of the film. Such a statement leaves the impression that the substrate film methods for RNase and DNase are unreliable and that results obtained so far by these methods have been erroneously interpreted.

The facts are that the authors who have used these methods have carried out several control experiments, did actually use gelatine–nucleic acid films resistant to proteolytic activity and thus specifically demonstrated RNase and DNase activities of tissue sections.

The point raised by Dr. Lake had been discussed before[2,3]. It is known that some varieties of gelatine remain digestible by proteases after formaldehyde fixation and it has been stressed in previous articles that such varieties of gelatine are not suitable for preparing films of substrate.

SOIL SCIENCE

Contamination of Urban Garden Soils with Copper and Boron

Spectrochemical analyses of garden soils sampled in the Edinburgh and Dundee areas indicate that there is substantial contamination of urban soils with copper and boron.

This conclusion is based on the analysis of sixteen soil samples taken from gardens randomly selected in the Edinburgh area, and nine samples taken in the same way in the Dundee area. These soils were analysed spectrochemically with respect to total copper and water-extractable boron content with the view of comparing the levels obtained in urban areas with levels in arable soils in rural areas. The reference levels of copper and boron in arable soils were based on the analysis of one hundred soil samples representatively sampled from fields under cultivation in south-east Scotland. A modification of the method of Farmer[1], adapted for the analysis of soils, was used for the determination of total copper, and boron was determined by porous-cup spark excitation[2] following the hot-water extraction procedure of Truog[3]. 'Ultra' boron-free graphite preformed cups and counter electrodes were used in the sparking procedure.

The results (Table 1) indicate that urban garden soils tend to contain about four times as much copper and two to three times as much water-soluble boron as rural arable soils. The differences between the levels of copper and boron in the Edinburgh and Dundee soils were not statistically significant, but the levels in both urban areas were so much higher that statistical analysis of the results was almost superfluous ($P < 0{\cdot}01$). The existence of such a marked disparity between the levels of two potentially toxic elements in urban and rural areas is evidence of slow poisoning of the soil environment in built-up areas and is cause for concern.

Table 1. Mean Levels of Total Copper and Water-extractable Boron in Urban and Rural Soils

Sample	No.	Copper p.p.m.	*S.E.*	Boron p.p.m.	*S.E.*
Rural arable soils	100	15·5	± 1·5	0·70	± 0·03
Edinburgh garden soils	16	71·6	± 4·1	1·95	± 0·23
Dundee garden soils	9	56·2	± 7·6	1·56	± 0·21

All the copper levels encountered in the Edinburgh area (and, with two exceptions, in the Dundee area) were very high compared with levels generally encountered in arable soils, in which it is very unusual to find more than 50 p.p.m. total copper[4]. The boron levels in the urban soils were also abnormally high, not only in relation to

levels in arable soils in south-east Scotland but also in relation to levels reported by Lehr and Henkens[5] for arable soils in The Netherlands. It is likely that some of the levels of water-extractable boron encountered, for example, levels greater than 3 p.p.m., could be deleterious to plant growth.

While the major source of contamination of soils with copper and boron is still a matter for speculation, it is probable that the addition of soot to garden soils and the fall-out of sooty material in built-up areas where atmospheric pollution is a problem make a substantial contribution to the water-extractable boron content of urban soils. In this connexion, it is of interest that three samples of soot from domestic chimneys, obtained from independent sources, were found on analysis to contain 640, 650 and 555 p.p.m. water-extractable boron, and it is evident that the addition to soil of even small amounts of soot with a boron content of this order would have a marked effect on its water-extractable boron content.

Determination of Total Potassium in Soils using the Gamma Emission of Potassium-40

Dunavant and Christian[1] have described a large-volume 4 π liquid scintillation detector, and Harris, Kessler and Christian[2] have described its use to determine total potassium in solids and liquids by measuring the gamma activity of the natural radioactive isotope potassium-40. The instrument is similar to the Armac liquid scintillation counter produced by the Packard Instrument Company.

The use of a large-volume scintillation detector, similar to that described, for the determination of total potassium in soils was considered attractive to us for a number of reasons: the use of a large sample reduces sampling error; cumulative errors and contamination due to handling in chemical methods of determination are eliminated; the time required for handling samples and processing results is small.

To assess the suitability of the above technique, an Armac scintillation counter capable of handling samples of about 1,500 g of soil was used to determine the total potassium content of six New South Wales soils. The potash chemistry of these soils is currently receiving detailed investigation at our laboratory. Total potassium determinations were carried out according to the semi-micro-chemical method of Jackson[3].

The gamma radiation emitted by potassium-40 has an energy of 1·46 MeV, but with the equipment used, the peak appears at 1·24 MeV, and the pulse height analyser was set for a channel of 1·0–1·5 MeV. Potassium as potassium chloride mixed with the soils in varying quantities gave a figure of 17·0 ± 1·7 c.p.m./g potassium.

This figure provided the calibration to enable calculation of soil potassium figures. Compared with chemical figures for total potassium, the potassium-40 count figures were found to be high as shown in Table 1.

Table 1. COMPARISON OF PERCENTAGE TOTAL POTASSIUM IN SIX SOILS BY CHEMICAL AND LIQUID SCINTILLATION METHODS

	Chemical potassium	Potassium by potassium-40 count
Soil 1	1·35	1·90
Soil 2	0·20	0·99
Soil 3	0·04	0·78
Soil 4	1·49	2·44
Soil 5	0·06	0·37
Soil 6	0·10	0·38

It was apparent that the discrepancies between chemical and potassium-40 count figures were due to interference from radioactive elements other than potassium.

In order to learn more of this interference, the six soils were counted on a 5 in. diam. × 4 in. sodium iodide crystal using a multi-channel pulse height analyser to group the counts into channels of 10 keV width. The sample container fitted over the crystal so as to give a layer of soil 1 in. thick around the side and over the top of the crystal. Figs. 1 and 2 are typical curves of counts versus gamma energy. The potassium count is superimposed on a continuum of gamma counts which results from the scattering of higher energy gamma radiation emitted by the uranium and thorium series elements. A number of small photo-peaks from gamma rays of the uranium and thorium series of elements are also present within this range.

It is apparent that the liquid scintillation technique described by Harris, Kessler and Christian[2] is unsuitable for the determination of total potassium in soils because the continuum interferes and it is not possible to correct for it when using a liquid scintillation detector. The

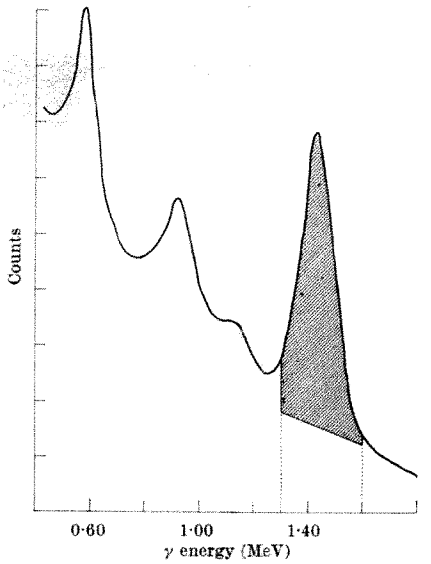

Fig. 1. Counts versus γ energy plot for a high potassium soil (Soil 1), using the sodium iodide crystal. The shaded area was taken to represent potassium counts. The remaining area on the plot represents the continuum and photo-peaks of the uranium and thorium series of elements

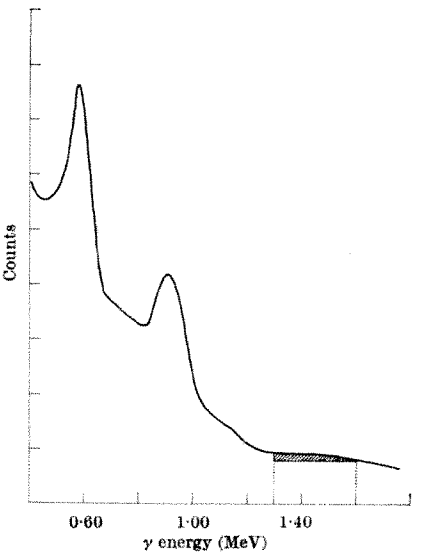

Fig. 2. Counts versus γ energy plot for a low potassium soil (Soil 3) using the sodium iodide crystal. The shaded area was taken to represent potassium counts. The remaining area on the plot represents the continuum and photo-peaks of the uranium and thorium series of elements

magnitude of the interference is not constant. It is about as great as the potassium count in high potassium soils, but many times as great in low potassium soils.

Estimates of total potassium obtained using the sodium iodide crystal in conjunction with the multi-channel pulse height analyser agreed well with the results of chemical analysis (Table 2).

Table 2. TOTAL POTASSIUM BY CHEMICAL METHOD AND POTASSIUM-40 COUNTING USING SODIUM IODIDE CRYSTAL

	Chemical potassium	Potassium by sodium iodide crystal
Soil 1	1·35	1·03
Soil 2	0·20	0·21
Soil 3	0·04	0 03
Soil 4	1·49	1·33
Soil 5	0·06	0·07
Soil 6	0·10	0·11

The determination of total soil potassium using the emissions from naturally occurring potassium-40 is possible using a sodium iodide crystal and multi-channel pulse analyser. The equipment is expensive and time spent counting samples of low potassium content is lengthy. On the other hand, the elimination of errors mentioned earlier is important and operator time using the equipment is short, so that where total potassium determinations on large numbers of samples are required the method may prove useful.

We thank the Prince Henry Hospital, Sydney, for making available the Armac liquid scintillation counter, Mr. Paix, Prince Henry Hospital, for his interest and assistance, and Dr. Duggleby and Mr. Parsons, Australian Atomic Energy Commission Research Establishment, Lucas Heights, for helpful discussions and for counting our samples on the sodium iodide crystal and multi-channel analyser.

VIROLOGY

Growth of Foot-and-Mouth Disease Virus in Monolayer Cultures of Calf Thyroid Cells

THE most successful laboratory systems for the growth and assay of foot-and-mouth disease virus (FMDV) have been suckling mice[1], cell cultures of calf and pig kidney[2,3], and the cell line derived from baby hamster kidney (*BHK* 21)[4]. All these systems vary in their relative sensitivity for various strains of virus and none appears to effect an absolute determination of the titre of infective virus. Recently it has been found that, in the assay of unmodified cattle virus, higher titres are obtained in primary monolayer cultures of calf thyroid cells than in the systems enumerated and in some instances these cultures are 100–1,000-fold more sensitive. Calf thyroid cultures have been used previously in the isolation and study of the virus of malignant catarrhal fever[5] and human thyroid cultures for the isolation of human enteroviruses and adenoviruses[6,7].

The proximal part of the trachea, and the larynx with the thyroids attached, were obtained from calves 2–14 days of age which were killed at abattoirs. The thyroids were removed, washed in phosphate buffered saline containing antibiotics, cleaned of connective tissue and fat, and minced with scissors. For the production of trypsin dispersed cells from calf thyroids a trypsin concentration of 0·45 per cent was used. This is higher than the 0·25 per cent generally used for mammalian tissues and follows the work of Plowright and Ferris[8], who used 0·4 per cent, and of French, Snowdon and Southern (unpublished), who used 0·45 per cent. The cells were collected at intervals of 45–60 min, and tubes, 15 mm × 150 mm, were seeded with 1 ml. of a cell suspension containing 1×10^5 clumps of cells (a clump comprised aggregates of three or more cells). The growth medium was one part of Hanks's saline, containing 0·5 per cent lactalbumin hydrolysate and 0·01 per cent yeast extract, 1 part of Eagle's basal medium, modified to contain twice the normal concentration of amino-acids and vitamins, and 10 per cent of unheated bovine serum. For maintenance of cultures, the 10 per cent of bovine serum was reduced to 3 per cent.

The growth and appearance of the thyroid cultures were similar to those described by Plowright and Ferris[8]. Aggregates of cells attached to the glass but remained rounded for 48 h. After this period, flattened epithelial type cells appeared at the base of the aggregates and after a further 3–5 days had grown out and joined up with neighbouring islets to form a confluent monolayer. Larger, elongated fibroblastic type cells separated many of the islets of epithelial cells and also proliferated extensively around the edges of the monolayer.

To infect cultures, the medium was removed and in some experiments the cell sheets were given one or two washes in phosphate buffered saline before they were inoculated with 0·2 ml. virus suspension. The inoculum was allowed to adsorb at 37° C for 1 h, after which 2 ml. of maintenance medium were added to each tube and the inoculated tubes incubated at 37° C in roller drums. Cultures were examined daily for cytopathic changes and the final readings of titrations were made 48 h after inoculation.

After inoculation of calf thyroid cultures with FMDV, the first cytopathic changes were observed in single cells or groups of cells, which contracted, became irregular in shape but remained attached to neighbouring cells by long thin processes. As incubation proceeded, these cells became rounded and eventually detached from the glass. The cytopathic changes did not involve all cells in the monolayer. The susceptible cells appeared to be of the epithelial type, whereas the elongated fibroblastic elements were insusceptible. After the susceptible cells were destroyed and became detached from the glass, the remaining cells proliferated and rapidly filled the gaps that had appeared in the monolayer. The final appearance of an infected culture was a complete sheet of elongated fibroblastic type cells with cell debris scattered over the surface.

The multiplication of two types of FMDV is shown in Table 1. Cultures were infected with $10^{5.2}$ $TCID_{50}$ of virus and the first evidence of cytopathic change in infected cells was seen at 8–10 h and was completed at 24 h. Peak infectivity was reached in 24 h and in both instances was $10^{8.4}$ $TCID_{50}$ per ml. So far, strains of FMDV of types *A*, *O*, *C*, *SAT* 3 and *Asia* 1 have been tested in thyroid cultures and all have grown equally well.

The sensitivity of four other assay systems was compared with calf thyroid cultures, and the results are shown in Table 2. Higher titres were always obtained in thyroid cultures.

The increased sensitivity of calf thyroid cultures has been used to demonstrate virus when other methods have failed. In work at this institute on the susceptibility of marsupials to infection with FMDV (to be published), nineteen blood samples collected from red kangaroos previously inoculated with type *Asia* 1 were assayed for virus in both suckling mice and calf thyroid cultures. The virus titres in calf thyroid cultures exceeded those obtained in mice by $10^{0.5}$ to $\geqslant 10^{2.5}$ $TCID_{50}$ per ml. and

five samples were positive for virus in thyroid cultures but negative when inoculated into mice.

We have also used calf thyroid cultures to recover virus from material in which it was present only in minimal amounts; for example, in specimens of oesophageal fluid from carrier cattle[10,11] and from specimens of cattle tongue epithelium collected from suspected clinical cases of the disease in the field. In both cases the infected tissue culture fluid was a satisfactory antigen in the complement-fixation test, and this technique is expected to be of great benefit in the rapid identification of virus in field samples. Another probable application is in the safety testing of inactivated vaccines, and preliminary work is in progress.

I thank Mr. P. B. Capstick, Mr. R. Burrows and Mr. R. H. Fagg for supplying some of the suspensions of unmodified cattle virus, and Mr. I. T. R. Barnett for carrying out the complement-fixation tests. The work described here was carried out when I was on secondment from the C.S.I.R.O. Division of Animal Health, Parkville, Victoria, Australia.

Electrophoretic Separation of Two Plaque-type Variants of Encephalomyocarditis Virus

THE surface properties of large (*r*) and small (r^+) (formerly designated *l* and *s* respectively (ref. 1)) plaque-forming encephalomyocarditis (EMC) virus[1] have been compared using a sucrose-gradient electrophoretic technique[2]. A difference was suspected because the relative plaque sizes changed on the addition of polyanions or polycations to the agar overlay of the plaque-assay[1,3]. Both variants produced 'small' plaques in the presence of excess polyanions (for example, sulphated polysaccharides), and 'large' plaques in the presence of excess polycations (such as diethylaminoethyl-dextran)[1].

Preparations of cloned large (*r*) and small (r^+) plaque-forming EMC virus were concentrated by centrifugation and purified by treatment with 0·02 per cent trypsin and chromatography on calcium phosphate columns[4]. The virus was re-sedimented from the peak column fractions, suspended in 0·02 M *tris*, *p*H 7·4, and stored at −70° C.

The electrophoresis was performed in an apparatus previously described[5]. A 1 : 1 mixture of large and small plaque-forming virus containing 2×10^7 P.F.U. in 0·5 ml., *p*H 8·8, 0·05 M barbitone-buffered-sucrose of appropriate density, was introduced near the top of a 5–20 per cent (w/v) sucrose gradient column (45 cm × 1 cm) buffered with *p*H 8·8, 0·05 M barbitone. Electrophoresis was carried out for 16 h at 150 V and 3·3 m.amp at 18° C. Fractions corresponding to 1 cm of tube length were collected from the bottom of the column and plaque-assayed for large and small plaque-forming virus. Two such experiments were carried out under the foregoing conditions with similar results. The results of the first experiment are shown in Fig. 1. The peaks of infectivity for the large and small plaque-forming variants differed about three-fold in electrophoretic mobility, the small plaque-type being the more negatively charged. In the absence of independent criteria of virus purity, it is possible that the electrophoretic properties of the variants may have been modified by interaction with contaminating cell components. This does not, of course, affect the basic conclusion that the variants have a surface property difference.

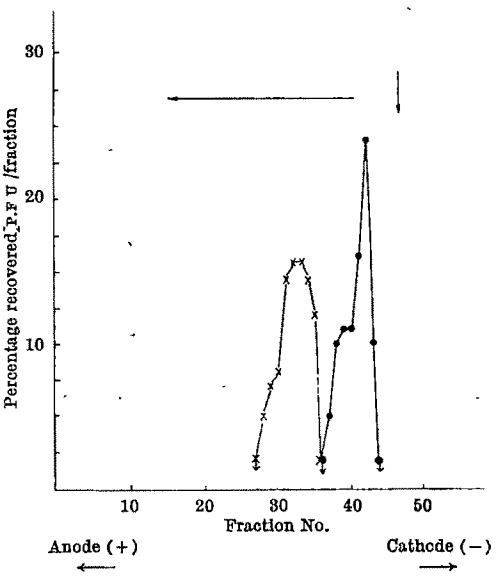

Fig. 1. Electrophoresis of small (×) and large (●) plaque EMC virus at *p*H 8·8. Horizontal arrow indicates direction of movement and vertical arrow the starting point

Following sucrose gradient electrophoresis in 0·02 M *tris* buffer at *p*H 7·4, the *p*H of the plaque assay, under conditions otherwise identical to the experiment first described, two separate bands of virus infectivity were not resolved. Nevertheless, a change in proportion of r^+ to *r* along the column, again demonstrating a higher negative charge for the small plaque virus, was clearly demonstrated (Fig. 2). For convenience the P.F.U./fraction as a percentage of the total recovered (about 20 per cent) is plotted on a log_{10} scale.

Although it cannot be concluded that the plaque-type difference is a consequence of differing charge-determined interactions of the two types of virion with polyanionic inhibitors in agar, much circumstantial evidence has accumulated in favour of this hypothesis[6–8]. Such

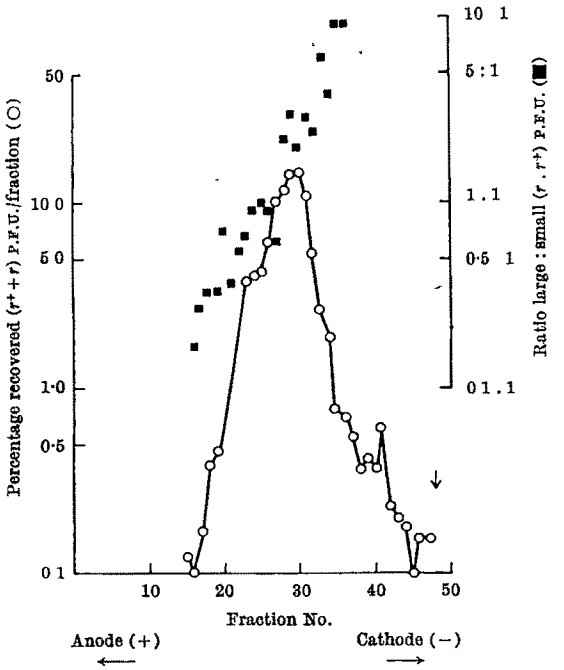

Fig. 2. Electrophoresis of small and large plaque EMC virus at *p*H 7·4. Vertical arrow indicates starting point

charge differences could occur following mutation and a consequent amino-acid substitution in the structural protein of the virus capsid.

We thank Miss Joyce Mason for technical assistance.

PSYCHOLOGY

A Local Sign for Depth

WHEN a human observer views a tridimensionally ordered scene, each of his eyes receives a slightly different perspective view of the scene. Differences in tridimensional location are coded on to the retinae as differences in bidimensional position, that is to say, as retinal disparities. As is well known[1], retinal disparity alone produces compelling perceived spatial separation. The way in which the nervous system decodes retinal disparity into perceived spatial separation is somewhat mysterious, since retinal disparity alone does not specify whether an object is nearer or farther than a fixated object, but merely that they are not in the same plane. (Disparities are geometrically ambiguous. For them to become unambiguous, additional information is required. Different authors have involved different sources of information, none of which is wholly satisfactory: see, for example, ref. 2).) The nervous system obviously can distinguish these two situations but the way in which it does this is not clear. Hering[3] solved the problem by giving each point on the two retinae a specific depth-value. On this model all points on the nasal hemiretinae of each eye have positive depth-values, so that any point imaged there will be seen as further than the fixation point, while points on the temporal hemiretinae have negative depth-values, so that points imaged there will be seen as nearer than the fixation point. This simple and elegant solution has never gained wide acceptance, largely because Hering never specified any mechanism which could add depth-values to inputs. The specification of a mechanism to do that is as great a problem as the specification of a mechanism to decode retinal disparity into perceived spatial separation. It is no wonder that the majority of investigators felt that Hering had solved one mystery by another mystery.

There have been a few attempts to explain depth-value. For example, Schön[4] suggested that we consider time of arrival at the cortex as the code mediating depth-value. It is well established that points on the retinae conduct at different speeds, and that points on the nasal hemiretinae transmit to the cortex much more quickly than corresponding points on the temporal hemiretinae[5]. Thus a depth-value would be given merely by the time of arrival of a signal relative to the time of arrival of other signals in the same 'message' in combination with its location in the bidimensional binocular field. This simple mechanism was tested and found to be valid in the following experiments.

The simplest test of the hypothesis seemed to be to vary the time of arrival of each eye's view of a tridimensionally ordered scene. (Such experiments are not new. However, previous authors have not been testing this hypothesis, and so have treated their data in ways which make them useless for this purpose, for example, by averaging near and far cases, by averaging, or not controlling for nasal and temporal hemiretinal position.) If Schön's hypothesis was correct, changing the time relations between signals should modify stereoscopic depth perception in a number of ways, depending on the stimulus situation in use. If the disparate images of an object fall, one on the temporal half of one eye and one on the nasal half of the other, presentation of the nasal image before the temporal image should not affect depth perception unless the delay is so long that the two signals cannot be seen as part of the same message. If, on the other hand, the temporal image is presented first, a number of phenomena should occur, dependent on the precise delay used. If the delay is such that both signals arrive at the cortex simultaneously, then zero depth should be perceived. If the delay is long enough for the temporal signal to arrive at the cortex before the nasal signal, then depth should be reversed, so long as the delay is short enough for both to be seen as parts of the same message.

Ten subjects with normal vision free from phoria served in the first experiment. Stimuli were presented at 1 m distance in a scientific prototype G.A. tachistoscope modified by the introduction of suitably crossed-'Polaroid' filters to serve as a stereoscope. In one field a continuous binocularly visible white fixation point was presented on a black ground. On test trials a white line was presented to each eye 2·5 cm to the right of the fixation point in one eye and 3·0 cm to the right in the other eye, so that the disparity was 18 min of arc. The lines were 10 cm long by 3 mm thick. The luminance of the white lines and fixation point was 31·8 equivalent lux, that of their black backgrounds 0·38 equivalent lux. By changing the orientation of the 'Polaroids', each line could be sent to either eye, thus reversing the direction of depth. The line going to the right eye always fell on the nasal hemiretina of that eye, that going to the left always on the temporal hemiretina of that eye. Stereo-lines were presented for 10 msec with the following delays between the onset of each: 0 msec, 0·50 msec, 1·00 msec, 1·5 msec, 2·5 msec, 3·5 msec, 5·0 msec, 7·5 msec, 10·0 msec, 15·0

msec. Each depth of direction was presented fifty times at each delay value, making a total of 1,000 presentations, given at a rate of one every 4 sec. Subjects were instructed to keep their eyes fixed on the fixation point and to report whether the white line was nearer or farther than the fixation point. Twenty-four hours later each subject was run through an identical experiment except that the lines were presented to the left of the fixation point. This was done in order to ensure that any effects were due to nasal-temporal differences, not right-eye left-eye differences.

Results are shown in Fig. 1. As can be seen there, there were no eye-specific effects, but there were strong nasal-temporal effects. The probabilities shown are uncorrected for guessing. They are the actual response probabilities obtained. With nasal preceding temporal the probability of a correct response falls to 0·5 monotonically and stays there. When temporal precedes nasal, probability of correct response falls to less than 0·5 ($P < 0{\cdot}01$), indicating a reversal of depth direction, and then climbs back to 0·5 with longer delays. These data obviously support Schön's hypothesis. From them we might infer that the difference in transmitting speed between temporal and nasal hemiretinae is about 1·5 msec, an estimate which is not at odds with the data cited here, and that the length of a visual message is probably not more than 7·5 msec.

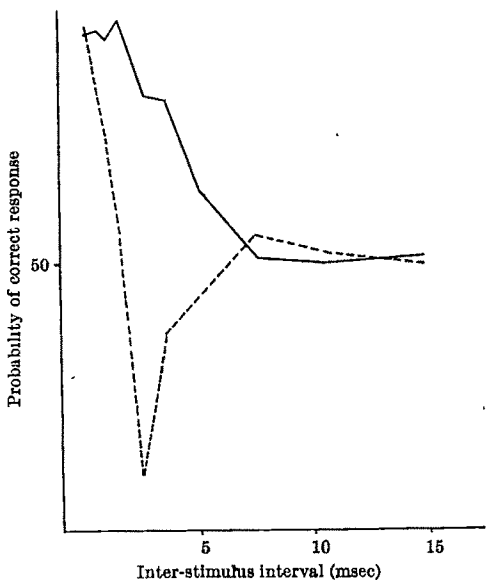

Fig. 1. Uncorrected probability of correct response at the inter-stimulus intervals. ——, Nasal→temporal, - - - -, temporal→nasal

Schon's hypothesis can thus provide a mechanism to explain Hering's depth-values. However, as it stands it is insufficient, since it does not explain the rigidity of stereoscopic depth. (Recent experiments have shown that the scale value of a given disparity may be rapidly modified; however, reversal of direction is not attained, even after some months of wearing right–left reversing prisms, which reverse disparity and thus lead to invalid stereo-depth judgments[6]. Were stereo-judgments the result of some kind of inferential process based on time of arrival only, one might expect that judgments would in time become valid once more.) If time coding was only a cue, stereodirection would be more reversible than it is. Hering thought that phenomenal depth-values were rigidly associated with retinal depth-values, and indeed carried out an experiment to test it[3]. He viewed a line the retinal representations of which were as disparate that both were seen; one fell on a nasal hemiretina, the other on a temporal hemiretina. He reported that the disparate images were seen at different distances. Stumpf[7] confirmed this, but Helmholtz[8] was unable to do so. Helmholtz suggested, as a critical experiment, that the nasal hemiretinae of each eye should be occluded. A flat wall viewed thus should then appear as a corner, with its two sides meeting at an angle. He reported that it did not. These experiments are obviously very poor tests of the hypothesis. In both cases there is too much supplementary information which contradicts the stereo-information, a fact which Hering noted. However, there are at least two experiments in the literature which indicate Hering's contention of fixed connexions as correct. Tschermak and Kiribuchi[9] required subjects to adjust a row of wires until it appeared to lie in their fronto-parallel plane. They used exposures so short that only information from the nasal hemiretinae could have been transmitted. In this case the apparent fronto-parallel plane was objectively a concave-semicircle, as Hering's theory would indicate. Katz and Schwarz[10] had subjects fixate a fixation point while attending to a light spot, moving in their fronto-parallel plane. 'Polaroid' filters were used to ensure that the light was seen only by one or other hemiretina of each eye. Vision was never binocular. The light spot was represented on only one retina at a time. When the light spot was seen by the temporal hemiretinae of the two eyes, the light spot was seen to move in a circular path in the third dimension, going from near to far to near as it went from periphery through fixation point to periphery. When the viewing conditions were reversed, so that only the nasal hemiretinae saw the spot, the direction of depth was reversed, the spot was seen to swing from far to near to far. These results are obviously just what Hering's theory would predict.

The experiment performed and the data reviewed here indicate that Hering's theory of stereopsis is probably correct, if time of arrival at the cortex of signals is introduced to provide a mechanism to account for depth-values. This modified version attributes phenomenal depth to a combination of bidimensional position and relative time of arrival. For this model to work, it is necessary to conceive of the visual system as sampling discrete, temporally defined messages from the available light. This conception is wholly plausible[11]. These data fill out the impressive array of evidence, assembled by von Békésy[12], which seems to show that spatial position is coded into the nervous system by way of differences in time of arrival of signals from paired receptor organs, the effectiveness of the code being independent of the sensory modality used. He has shown this for the auditory, olfactory and skin senses. Vision may now be added to the list.

This work was supported by the National Institutes of Health and the Milton Fund of Harvard University, and in part by the National Science Foundation through the Center for Cognitive Studies, Harvard University.

I thank Julian Hochberg and G. von Békésy for advice and criticism, and Miss A. Katz for invaluable library work.

T. G. R. BOWER

Department of Psychology,

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, June 6

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. Michael Sela (Rehovot) "Molecular Basis Antigenicity".*

Monday, June 6—Wednesday, June 8

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2). Conference on "Design and Construction of Large Steerable Aerials".

Tuesday, June 7

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Prof. R. King. "Chemical Change and Physical Change" (afternoon lecture for Fourth Form and Sixth Form Boys and Girls from Schools in London and the Home Counties. To be repeated on June 8, 14 and 15).

UNIVERSITY COLLEGE, LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Patrick Wall (Massachusetts Institute of Technology). "The Organization of the Dorsal Horn of the Spinal Cord".*

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5 30 p m —Prof. J. G. Clunie: "The Theory of Functions in Complex Analysis" (Inaugural Lecture).*

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5.30 p m.—Dr. Michael Sela (Rehovot): "Some Structural Aspects of Antibody Activity".*

Thursday, June 9

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (in Lecture Theatre No. 2, Physics Department, Imperial College of Science and Technology London, S.W.7), at 4.30 p m.—Annual General Meeting. 5 30 p.m.—Prof. W. G. Bickley: "Mathematics for the Blind".*

MINERALOGICAL SOCIETY (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Annual General Meeting.

CHEMICAL SOCIETY (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, South Kensington, London, S.W.7), at 6 p m —Prof. W. G. Dauben (University of California): "Strained Ring Compounds".

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 7.15 p.m.—Prof. Robley D Evans: "The Effects of Skeletally Deposited Alpha-Ray Emitters in Man" (Silvanus Thompson Memorial Lecture).

Thursday, June 9—Friday, June 10

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W 1), at 10.20 a.m. on Thursday and 10.30 a.m. on Friday—Discussion Meeting on "The Terrestrial Antarctic Ecosystem" organized by Dr. J. E. Smith, F.R.S.

Friday, June 10

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Manson Theatre, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Annual General Meeting.

Saturday, June 11

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C 1), at 5 15 p.m. —132nd Annual General Meeting. 6 p m.—Mr. L. H. C. Tippett. "Statistics in Manufacturing Industry" (Presidential Address).

Monday, June 13

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 3 p.m.—Annual General Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with good academic qualifications and the ability and desire to prosecute research) IN METALLURGY—The Principal, Lanchester College of Technology, Priory Street, Coventry (June 8).

JUNIOR LECTURER (graduate with medical qualifications) IN ANATOMY—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 10).

CHAIR OF STRUCTURAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (June 11).

LECTURER IN BIOCHEMISTRY—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 13).

LECTURER or ASSISTANT LECTURER (specialist in urban geography and planning) IN THE DEPARTMENT OF GEOGRAPHY—The Deputy Secretary, The University, Southampton (June 13).

LECTURER (with a good honours degree in mathematics) IN MATHEMATICS OR MATHEMATICAL STATISTICS; and an ASSISTANT LECTURER (with a good honours degree) IN MATHEMATICS—The Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W 3 (June 13).

RESEARCH ASSISTANT IN THE AGRICULTURAL CHEMISTRY SECTION OF THE DEPARTMENT OF AGRICULTURE—The Registrar, The University, Leeds, 2 (June 13).

ASSISTANT LECTURER (preferably with special qualifications in political geography) IN THE DEPARTMENT OF GEOGRAPHY—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (June 15).

RESEARCH WORKER IN THE DEPARTMENT OF BIOLOGY AS APPLIED TO MEDICINE, for the investigation of biochemical aspects of pattern formation in developing and regenerating systems—Prof. Lewis Wolpert, Middlesex Hospital Medical School, Mortimer Street, London, W.1 (June 15).

ASSISTANT LIBRARIAN in the Philosophical Library, to assist in co-ordinating library services in the scientific departmental libraries and eventually in the libraries of the Arts Faculties, with particular reference to the preparation of a union catalogue by computer—The Secretary, Philosophical Library Committee, University of Cambridge, Bene't Street, Cambridge (June 16).

ASSISTANT (Assistant Lecturer) (preferably graduate in veterinary medicine, pharmacology or physiology) IN VETERINARY PHARMACOLOGY—The Secretary of the University Court, The University, Glasgow (June 17).

LECTURER IN THEORETICAL PHYSICS—The Registrar, University of Kent at Canterbury, Canterbury, Kent (June 17).

LECTURER or ASSISTANT LECTURER (with a medical or scientific qualification) IN VIROLOGY IN THE DEPARTMENT OF BACTERIOLOGY—The Registrar, The University, Manchester, 13, quoting Ref 131/66 (June 17).

LECTURER IN MEDICAL BIOCHEMISTRY with responsibilities in the Rheumatism Research Centre—The Registrar, The University, Manchester, 13, quoting Ref. 132/66 (June 18).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, The University, Liverpool, quoting Ref. CV/76 (June 18).

RESEARCH ASSISTANT IN THE DEPARTMENT OF NATURAL HISTORY to work under the direction of Mr. Blaxter, on the physiology and development of vision in marine fish larvae—The Secretary, The University, Aberdeen (June 18).

M.R.C RESEARCH ASSISTANT (with a Ph.D. degree, or equivalent research experience, in organic chemistry) IN CHEMISTRY, to work under the direction of Prof. H. N. Rydon on the synthesis of peptides related to the active centres of esterases—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devon (June 20).

RESEARCH ASSISTANT for work under the direction of the Honorary Curator of the Geological Collections—The Secretary of the University Court, The University, Glasgow (June 20).

GEOLOGISTS (2) (with a good honours degree) IN THE DEPARTMENT OF GEOLOGY, one for studies in the Upper Carboniferous Rocks of the North Midlands, and the other for work on the Triassic rocks of Cheshire—Prof. F. W. Cope, The University, Keele, Staffordshire (June 22).

UNIVERSITY SENIOR ASSISTANT BIOCHEMIST TO ADDENBROOKE'S HOSPITAL —T. D. Kellaway, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge (June 23)

CHAIR OF OBSTETRICS AND GYNAECOLOGY at University College Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (June 24).

LECTURER IN PHYSICAL CHEMISTRY—Prof. R. M. Barrer, F.R.S., Imperial College of Science and Technology, London, S.W.7 (June 24).

LECTURER (medicine or science graduate) IN THE DEPARTMENT OF PHYSIOLOGY—The Assistant Registrar, The Medical School, University of Birmingham, Birmingham, 15 (June 24).

SCIENTIST (preferably with pathological or immunological training or experience in related chemical techniques) IN THE DEPARTMENT OF EXPERIMENTAL PATHOLOGY, to work with a group on immunological aspects of connective tissue reactions in repair and inflammatory processes in adults and embryos—The Secretary, Institute of Animal Physiology, Agricultural Research Council, Babraham, Cambridge (June 24).

LECTURER IN EXPERIMENTAL PSYCHOLOGY IN THE DEPARTMENT OF AUDIOLOGY AND EDUCATION OF THE DEAF—The Registrar, The University, Manchester, 13, quoting Ref. 134/66 (June 25)

LECTURER or SENIOR LECTURER IN CLINICAL EPIDEMIOLOGY IN THE DEPARTMENT OF INFECTIOUS DISEASES at Ruchill Hospital—The Secretary of the University Court, The University, Glasgow (June 25).

LECTURER (with special qualifications in the quantum theory of molecular electronic structure) IN THEORETICAL CHEMISTRY—The Registrar, The University, Sheffield (June 25).

READER IN MEDICINE at the Royal Free Hospital School of Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (June 27).

LECTURER or ASSISTANT LECTURER (qualified to lecture to honours degree standard and to supervise postgraduate research students) IN PHYSICAL CHEMISTRY—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3 (June 30).

POSTDOCTORAL FELLOW (with an interest in cell behaviour and function) IN THE DEPARTMENT OF ZOOLOGY, to work on the physiology and biochemistry of cell surfaces—The Deputy Secretary, The University, Southampton (June 30)

READER IN MATHEMATICAL STATISTICS at the University of Adelaide, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, June 30).

UNIVERSITY LECTURER to engage in research and teaching, with special reference to the agriculture of the developing countries—The Director, The Institute for Research in Agricultural Economics, The University, Parks Road, Oxford (June 30).

SENIOR LECTURER (with a doctorate or equivalent achievement in the field of industrial research or of process design and development) IN CHEMICAL ENGINEERING at the University of Newcastle, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 23).

LECTURER/SENIOR LECTURER (with a distinguished academic record and able to produce evidence of strong research interest and experience) IN THE DEPARTMENT OF STATISTICS, SCHOOL OF MATHEMATICS, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 29).

LECTURER/SENIOR LECTURER (with a degree in veterinary science which is registrable in Victoria, and preferably experience in a rural practice) IN VETERINARY MEDICINE (Large Animals) at the University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W 1 (Australia and London, September 1).

CHAIR OF PHYSIOLOGY at the Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

EXPERIMENTAL OFFICER or ASSISTANT EXPERIMENTAL OFFICER (with a degree or equivalent qualification and some experience of analytical chemistry) for research on air pollution and atmospheric diffusion—Dr. M. J. G Wilson, Chemical Engineering and Chemical Technology Department, Imperial College of Science and Technology, London, S.W.7.

LECTURER (capable of teaching at degree level) IN THE DEPARTMENT OF MATHEMATICS—The Registrar (R/S), Portsmouth College of Technology, Hampshire Terrace, Portsmouth, Hampshire

LECTURER IN PSYCHOLOGY (Experimental Psychology/General Psychology) —The Registrar, Goldsmiths' College (University of London), London, S.E.14.

RESEARCH ASSISTANT (preferably post-doctoral, with a Ph.D. or at least a good honours degree in chemistry, and research experience in the field of inorganic or physical chemistry) to undertake research on the preparation and properties of a range of metallic compounds of interest in developing new processes for producing metals—Dr. J. H. E. Jeffes, Metallurgy Department, Imperial College of Science and Technology, London, S.W.7

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (with, or expecting to obtain, a first- or second-class honours degree in biochemistry or chemistry or a related subject) IN THE DEPARTMENT OF NUTRITION, primarily to take part in investigations of the biochemical aspects of protein digestion and utilization—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 66/N/18.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Royal Observatory Bulletins. No. 106: Cape Catalogue of Circumpolar Stars for the Equinox 1950·0. Reduced by W. Gliese. Pp. A75–A94. 3*s.* 6*d.* net. No. 107: Discussion of Lunar Occultations Observed in 1958 and 1959 (including Treatment of Observations from 1943). By Flora McBain Sadley. Pp. A95–A102. 2*s.* net. (London: H.M. Stationery Office, 1966.) [253

Metropolitan Water Board. Forty-first Report on the Results of the Bacteriological, Chemical and Biological Examination of the London Waters for the years 1963–1964. By E. Windle Taylor. Pp. 152+9 plates. (London: Metropolitan Water Board, 1966.) 32*s.* 6*d.* [253

The Schools Council. Working Paper No. 4: Science in the Sixth Form. Pp. v+57. (London: H.M. Stationery Office, 1966.) 4*s.* 6*d.* net. [283

Association of Commonwealth Universities. Report of the Conference on Industry and the Universities—Aspects of Interdependence. Pp. 86. (London: Association of Commonwealth Universities, 1966.) 5*s* 6*d* [283

University of Leeds. Annual Report of the Librarian, Session 1964–65 (Leeds: The Brotherton Library, The University, 1965.) [283

Report of the Rugby School Natural History Society for the year 1965. Pp. 23+1 plate. (Rugby: Rugby School Natural History Society, 1966.) [283

Wool Industries Research Association. Report of the Director of Research for 1965. Pp. 43. (Publication No. 226.) (Leeds: Wool Industries Research Association, 1966.) [283

Ministry of Agriculture, Fisheries and Food. Annual Report of the Director of Fishery Research 1965. Pp. iv+90. (Lowestoft: Fisheries Laboratory, Ministry of Agriculture, Fisheries and Food, 1966.) [283

Shipbuilding Inquiry Committee 1965–1966: Report. Pp. 209. (Cmnd. 2937.) (London: H.M. Stationery Office, 1966.) 13*s.* net. [303

ONE WHITE ELEPHANT

THE decision of the British Government to withdraw from the current programme of the European Launcher Development Organization is at best a calculated indiscretion. Evidently it is intended that a sufficient show of intransigence shall leave no doubt that the British Government is washing its hands of ELDO. In diplomatic circles behaviour of this kind, though rare, is not unknown. General de Gaulle's rejection of the British case for joining the European Economic Community in January 1963 was in the same tradition. By making an unreasonably ferocious statement he erased, no doubt deliberately, all possibility of compromise. The British Government cannot be surprised if the position it has now taken on ELDO is reminiscent of that earlier intra-European squabble. It will have ensured that there can be no confusion about its intentions only by acquiring something of a reputation as a querulous and unreliable party to international agreements. It has done much harm and scarcely any good.

The unreasonableness of the British repudiation of ELDO is particularly regrettable because the case against the current programmes based on the *Blue Streak* rocket is even stronger now than it was in 1962, when the convention of ELDO was opened for signature by European countries. The truth is that the organization has from the start been an attempt to put a cart before a horse. Once it had become apparent that *Blue Streak* had no great future as a military weapon, chiefly because of its vulnerability to pre-emptive attack but also because of the inconvenience of liquid fuels in military rockets, it was natural that the British Government should seek other uses for it. After all, nobody likes to be left with a white elephant on his hands. And when the British Government was anxious to explore ways of making closer links with Europe, it was only natural that *Blue Streak* should seem potentially a makeweight in that exercise. The trouble, which has been apparent from the start, is that a rocket system developed as a military weapon of intermediate range is unlikely also to be the most effective means of launching scientific satellites and of exploring the potential usefulness of such things as communications satellites as well. To say this is not to suggest that *Blue Streak* is a bad rocket, but merely that one rocket cannot be as versatile as a dozen. The ELDO programmes based on *Blue Streak* have never made much sense to technical people. The British scientists most directly concerned have often been resentful that so much money has been spent on a white elephant when comparable projects have been short of funds. The first thing to be said about ELDO is that it was wrongly begotten.

ELDO has also been badly organized. The first estimates of cost were hopelessly optimistic. To have supposed that it would be possible to sustain a five-year programme of advanced research and development, involving tests of rockets in places as far apart as the north of England and the Australian desert, and the engagement of laboratories in a dozen European countries, was wishful thinking of an ostentatious kind. The surprise is not that the most recent estimate of the cost is twice the original, but that it is still thought feasible to design a complicated satellite launching system on what is, by all experience elsewhere, a shoestring.

Then ELDO has been overtaken by events. If the organization had started work soon after it was first mooted, five years ago, it might by now have accomplished something useful. In the event, however, diplomacy has been the thief of time. Only in 1964 did things begin to move, and only now has it really become apparent what technical difficulties lie ahead. In the meantime, the United States and the U.S.S.R. have made unexpectedly rapid progress towards the exploitation of communications satellites. The advantages of stationary satellites, which are for practical purposes beyond the scope of ELDO, have been made plain. And there is no reasonable basis for hoping that an independent European development can yield such prowess in rocketry that Europe will be able to act, or think of acting, independently of the United States and the U.S.S.R. in the design of communications systems. It is therefore pertinent to ask the question that ELDO itself has consistently run away from—what is ELDO really for?

These arguments are now so strong that it is hard to see why the British Government has not set out to persuade its ELDO partners of their force. For if those who conceived of ELDO five years ago are now convinced that it has no future, should it not be possible for them to persuade the others that it is time for a re-appraisal? This is what reasonable men elsewhere will ask. And it would have been entirely proper for the British Government to have insisted that other nations should form a realistic view of what they hope that launching *Blue Streak* rockets from the Australian desert will accomplish for the future prosperity of Europe. If the British Government had asked that its European partners should learn a few of the elementary lessons of cost-effectiveness, that would have been admirable, for there is still evidence that skill in rocketry is sometimes confused with national prestige. In other words, the circumstances required that the British Government should have used its influence to bring about a realistic reappraisal of the purposes of ELDO. If it had failed to do so, withdrawal might have been permissible.

Whether ELDO survives these troubles is in itself comparatively unimportant. To the extent that the British assessment of the situation has been accurate, it may be better for Europe if the whole thing comes to an end. Certainly the defects apparent with British membership will not now vanish if Britain becomes a sleeping partner until the ELDO convention comes to an end in 1969. It is, however, important to know how these events will affect the institutions for technical collaboration in Europe, and it is important to know what future there will be for rocket technology in Europe.

The first thing to be said is that a sudden shock of this kind unsettles confidence. Though the British decision on ELDO may be legally valid, and though it may have been heralded by all kinds of warnings within the working parties and committees, the members of other international organizations are likely to look out for early warning of possible withdrawal. ELDO is likely to have

a nervous time ahead. Future developments at CERN will be closely watched. Will there be a British contribution for the 300 GeV accelerator that the planners would like to contract? That is what people will be asking. If the British Government wishes to show that its behaviour over ELDO is not pure pique, it could not do better than make some clear promise about the future of CERN.

The future of rocket technology in Europe is more difficult to foresee, but some things are plain. The problems of ELDO have sprung from trying to accomplish in five years, and with small resources, developments which have taken three times as long, and which have cost enormous efforts elsewhere. There is a case for supporting modest programmes of rocket development in Europe in the decades ahead, but it is inevitable that European countries will have to look to the United States and the U.S.S.R. for such practical applications of rocket technology as may be feasible in the decades immediately ahead. But in the short run, a capacity to launch rockets is less important than fair access to whatever the benefits of rocket technology may be. In other words, what has happened in ELDO should be a spur to the negotiations of a lasting and equitable agreement on the operation of the international system of communications satellites now being established. The existing agreement with the United States COMSAT Corporation, like the ELDO convention, will have to be renewed in 1969, and it is not too soon to begin making plans for what comes next.

NO MORE MANDARINS

THE departure of Sir Solly Zuckerman from the post of chief scientific adviser to the British Minister of Defence is something of an occasion. For one thing, he has been there so long that he will be missed, to say the least of it. For most of the past decade his influence has been pervasive, and on the side of realism. He has helped to broaden the thinking of the defence people, and in particular has done much to expose them to the influence of academics of all kinds. He has been enlivening and stimulating. It is therefore good to know that he will not promptly disappear from Whitehall. The suggestion that Sir Solly will now concern himself with research and development on the civil side of government is particularly welcome, partly because the recommendations of the Committee on the Management and Control of Research and Development, of which he was chairman and which reported in 1961, are still only partially digested, but also because the British Government has not yet paid as much attention to the management of its own research and development as to the scrutiny of what is done elsewhere with public money.

The days are long since gone when ministries were dependent for scientific advice on such a small number of people that each adviser became a kind of mandarin, possessed, in the eyes of politicians and soldiers, of magic such as the differential calculus, and set apart from academic colleagues by having access to classified information. Instead, quite properly, there are now arrangements for making sure that scientific advice and criticism are an integral part of planning for defence and not an afterthought. At the same time, there has been a shift of interest from technology to economics. Cost effectiveness is the order of the day, in defence ministries everywhere. That, too, is as it should be.

MATHEMATICAL METEOROLOGY IN THE U.S.S.R.

Investigation of the Bottom 300-Meter Layer of the Atmosphere

Edited by N. L. Byzova. Translated from the Russian by A. Moscona. Pp. v+112. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 27*s*.

Long-Range Hydrodynamic Weather Forecasting

Edited by E. N. Blinova. Translated from the Russian. Pp. iv+124. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 27*s*.

Objective Analysis of Meteorological Fields

By L. S. Gandin. Translated from the Russian by IPST Staff. Edited by R. Hardin. Pp. vi+242. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 81*s*.

AFTER 20 years of comparative stagnation, relieved by only a few isolated bright spots, dynamical meteorology began to move forward soon after the end of the Second World War to become, what it can now claim to be, a coherent branch of quantitative fluid mechanics. For a number of years progress was much stimulated by close relations between American and European workers, while the work going on in Russia was unknown and ignored in the West, and it is only in quite recent years that representative literature has become available and readily accessible in translation. With still many gaps to be filled, the initiative of the Israel Program for Scientific Translation in publishing the three meteorological texts under review will be widely welcomed.

Investigation of the Bottom 300-Meter Layer of the Atmosphere is a collection of thirteen short research papers concerned with the data from a 300-m meteorological mast. The study of the planetary boundary layer is one in which the basic theoretical contributions from the Soviet Union have been of the greatest importance, and it suffices to draw attention to this translation to ensure that all workers in the subject will give it their attention.

Long-Range Hydrodynamic Weather Forecasting is also a compilation of research papers, seven in all, providing further examples of mathematical techniques and physical concepts which, in spite of the title, were largely anticipated by Kibel's[1] text-book which appeared in translation some years ago. Again, the mere notice of the work will ensure that it will be scrutinized carefully by the relatively few specialists engaged in mathematical studies of problems of meteorology on the largest scale. Special attention may, however, be drawn to a paper by M. B. Galin which attempts to set up a closed set of equations to determine certain correlation functions which emerge when the basic dynamical equations are averaged to produce relations between climatological or other time-mean values. The treatment of these functions, effectively of synoptic-scale turbulence, is perhaps the most fundamental problem of fluid mechanics for which no basic solution applicable to world-scale problems is yet in sight. It is doubtful whether purely mathematical manipulation will really overcome the physical difficulty, but the attempt will be studied with interest.
